Peripheral Resistance. The peripheral resistance depends upon the caliber of the small vessels, mainly of the arterioles and, to a less extent, of capillaries, and upon viscosity of the blood It has also been demonstrated by Haddy et al (1957) that the macroscopic vessels (smaller arteries and veins) contribute significantly to resistance across systemic vascular beds By far, the greater part of the peripheral resistance of the circulatory system is constituted by the minute vessels of the muscles and of the abdominal structures In this connection the importance of the latter—the so-called splanchnic area—can be demonstrated by tying off all branches of the aortic arch, except the carotids, and the abdominal aorta below the inferior mesenteric branch, when little change in peripheral resistance results, on the contrary, an increase in the latter at once occurs when the blood supply to the splanchnic area is reduced by ligating the superior mesenteric artery Stimulation of the great splanchnic nerve, which innervates the rings of muscle fibers in the walls of these vessels, causes their constriction, and consequently a reduction in the outflow from the arterial system The pressure will continue to rise until inflow and outflow are again balanced. In the absence of compensatory changes in the other factors concerned in the maintenance of the pressure, this remains at the higher level so long as the constriction per-

sists Dilation of the vessels, i e , reduction in peripheral resistance, will of course be followed by the opposite effect When the vessels of the splanchnic area are fully dilated they are capable of accommodating almost all the blood in the body, in such an event the blood pressure would fall to zero The peripheral resistance might be compared to a dam in a river If the dam is raised or lowered, and no change occurs in the supply of water flowing down the river to the dam, the water continues to rise or fall, respectively (and its pressure in consequence increases or diminishes), until it reaches the new level From then on the quantity of water which overflows in a given time is the same as it was at the original level

The total peripheral resistance in animals or in man can be calculated from the mean blood pressure gradient (M) and the cardiac output (F), since all blood entering the aorta must, of course, pass through the peripheral vessels This can be derived for the whole body from the simultaneously measured arterial pressure and cardiac output, and for an organ or region from the local arterial pressure and flow There is a curvilinear relationship between pressure and flow in the aorta (Fig 3 154) This is also true in separate vascular beds where pressure and flow have been measured but the shape of the curves may be quite different

Various terminologies have been used to define peripheral resistance A *peripheral resistance unit* (PRU) has been defined as the flow in ml /sec /1 0 mm Hg pressure gradient

$$\text{PRU} = \frac{\text{mm Hg}}{\text{ml /sec}}$$

For a resting human with a cardiac output of 6 liters/min and mean blood pressure gradient from systemic arteries to veins of 100 mm Hg, the resistance would be

$$\text{PRU} = \frac{100 \text{ mm Hg}}{100 \text{ ml /sec}} = 1\ 0$$

Values range from 0 25 PRU with marked vasodilation to 4 0 PRU with intense vasoconstriction in man

In the pulmonary circuit with a mean pulmonary arterial pressure of 14 mm Hg and mean left atrial pressure of 4 mm Hg the gradient would be 10 mm Hg At the same cardiac output of 6 liters/min , the total peripheral resistance would be

$$\text{PRU} = \frac{10 \text{ mm Hg}}{100 \text{ ml /sec}} = 0\ 1$$

Values range from 0 03 PRU with exercise to 1 0 PRU in pulmonary hypertension

Many authors take such a ratio and by expressing M in dynes per square centimeter and F as milliliters per second, the peripheral resistance can be given in absolute units of force Thus,

$$\text{Peripheral resistance } (R) = \frac{M(\text{mm Hg}) \times 1332}{F(\text{ml /sec})}$$

$$R = \frac{\text{dynes/cm}^2}{\text{cm}^3\text{/sec}}$$

$$R = \frac{\text{dyne sec}}{\text{cm}^5}$$

1332 is a figure for the conversion of pressure to dynes

The peripheral resistance so calculated is found to vary inversely with the size of the animal, i e , directly with the surface area It amounts normally to from about 600 to 2000 absolute units in man, but may be over 5000 in arterial hypertension in which F shows little change The values for the dog and rabbit range from 2000 to 9000 and from 11,500 to

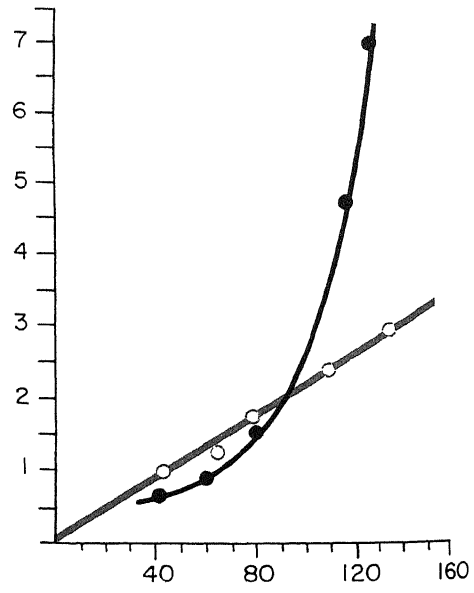

Fig 3 154 Relationship between mean arterial pressure in millimeters of mercury (abscissa) and cardiac output in liters per minute (ordinate) in a typical experiment Solid circles represent values observed with buffer nerves intact open circles values obtained after bilateral vagotomy and while a constant pressure of 210 mm Hg was exerted upon the isolated innervated carotid sinuses (From Levy et al 1954)

12,000, respectively This means that the minute vessels in a large animal offer less resistance than do the fewer number in a smaller animal, even though the vessels of both are constricted to the same degree This is due to the fact that the rate of flow in the smaller animal is greater in relation to the size of its vascular bed (cardiac output bearing a constant relationship to surface area which varies inversely with body weight)

Quantity of Blood in the Arterial System In any closed system of rigid tubes fluid must fill it to capacity in order that a pressure can be developed within it The arterial walls are distensible and elastic, and a certain degree of stretching of these must occur before any considerable pressure is created The arterial system must be actually over-filled, and the greater the extent of the over-filling, the greater will be the blood pressure Loss of blood, either of all its elements, as in hemorrhage, or of the fluid portion alone, if not compensated for sufficiently by readjustment of the other factors concerned in blood pressure maintenance, must inevitably result in a fall of pressure Increasing the total amount of circulating fluid artificially, as by the transfusion of blood or blood substitute, will elevate the pressure again

Viscosity of the Blood The greater the viscosity or "thickness" of any liquid the greater is the pressure required to force it along a length of narrow tube in a given time, or if the pressure remains constant the longer will be the time required for the liquid to traverse the tube The frictional resistance which is developed between the parts of the liquid itself, that is, the internal friction is greater when the viscosity is high than when it is low Viscosity depends upon the degree to which the molecules or particles of a fluid cohere Blood is some five times more viscous than water [1] With regard to the influence of viscosity upon the blood pressure, it is again a matter of outflow through the arterioles If the driving force remains constant and the caliber of the vessels is unchanged, then the greater the viscosity, the greater will be the frictional resistance developed in this region, and the less will be the quantity of fluid that will pass through in a unit of time The blood owes its viscosity to its colloids (plasma proteins) and to an even greater extent its suspended corpuscles, friction is developed between the surfaces of the latter and the surrounding fluid Changes in the concentration of the blood as a result of changes in its protein content or in the number of its corpuscles will therefore alter its viscosity

Elasticity of the Vessel Walls. This is concerned mainly with the origin and maintenance of the diastolic pressure and with sustaining the mean pressure at a higher level than would be possible in a rigid system under otherwise identical conditions The conversion of the pulsatile flow to a uniform one depends also upon the existence of a diastolic pressure

The physical principles involved in the maintenance of the diastolic pressure and the disappearance of the pulse beyond the arterioles may be best illustrated by a simple artificial model similar in principle to one devised by Borelli for the same purpose some 300 or more years ago In Figure 3 155 is represented a bulb syringe, *S*, valved at *V*, and having a short tube, *T*, which dips into a basin of water Leading from the opposite pole of the bulb is a longer tube When the bulb is alternately compressed and released, fluid is drawn from the basin and discharged from the mouth of the tube If the walls of the latter are composed of some rigid material (Fig 3 155*A*), it will be found that when the pump is worked the fluid issues from the tube in spurts or jets synchronous with each stroke, but no flow occurs between the strokes An increase in the frequency or force of the strokes does not alter the intermittent character of the flow nor does lengthening the tubing If the peripheral resistance of the vascular system be imitated by attaching a nipple of small bore

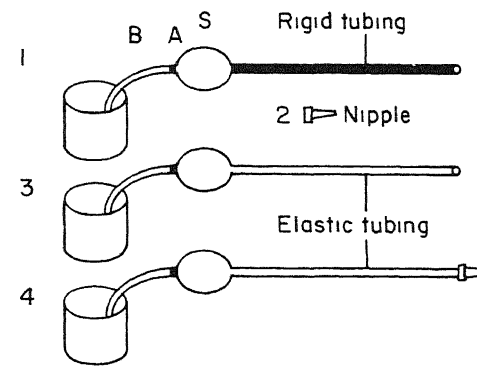

Fig 3 155 Demonstration of pulsatile and continuous flow

[1] This is an average figure Values obtained by different observers for the viscosity of blood, taking distilled water as unity, vary considerably but the majority range between 4 5 and 5 5

to the mouth of the delivery tube so as to increase the resistance to the outflow of fluid, the issuing stream is finer and its velocity is increased, but it still remains intermittent Let the elasticity of the arterial wall now be imitated by replacing the rigid tube by one of rubber, yet let the mouth of the tube be left free and not constricted in any way (Fig 3 155*B*) The intermittent character of the stream is unaffected However, if the small-bored nipple representing the peripheral resistance be fixed into the mouth of the elastic tubing the stream will be found to have lost its pulsatile character and to have become continuous (Fig 3 155*C*) Two factors are therefore necessary to produce this result, *a*) *resistance to the outflow*, and *b*) *elastic tubing* The reasons for this are clear If the fluid has free egress from the tube, most of that which enters it from the pump is discharged from the open end before the next beat occurs, the pressure, in consequence, does not rise to a sufficient height to distend the rubber wall, i e , elasticity is not called into play, overfilling of the tube does not occur, and in consequence the latter acts simply as though it were composed of rigid material

The foregoing facts apply directly to the arterial system The elasticity of the vascular walls and the peripheral resistance are both essential for the maintenance of the diastolic pressure As the contents of the ventricle are thrown into the already over-filled system during systole the added pressure which is then exerted upon the vascular walls causes their further distension After the completion of systole, the elastic walls rebound and, pressing upon the blood within their embrace, force it onward through the peripheral vessels In other words, the arterial lumen returns to its previous diameter and the energy that had been stored up during the stretching of the elastic tissue is in this way gradually expended during diastole

The elastic recoil of the arterial wall thus acts in a sense as a subsidiary pump to drive the blood onward in a continuous stream between the heart beats Otherwise, the pressure would fall to zero after each systole

It is clear then that any increase in the elasticity of the arteries, other factors remaining unchanged, will tend toward a lowering of the diastolic pressure If the aorta and its larger branches are stiffened (as a result of sclerotic changes), they cannot expand to the same degree as can healthy, resilient vessels, and therefore do not so readily accommodate the blood (60 to 100 ml) ejected from the heart during systole Such a state will lead to a rise in the systolic pressure Normally, however, the cross sectional area of the aorta increases considerably with age, so that it needs to expand much less to accommodate the systolic discharge

CRITICAL CLOSING PRESSURE

The finite intravascular pressure at which a vessel will close has been termed critical closing pressure It is measured by progressively lowering perfusion pressure and determining the level at which flow ceases This has been considered an index of vasomotor tone, although the subject remains controversial There is ample experimental proof that perfused peripheral vascular beds behave as though there exists a finite level of pressure at which resistance vessels simultaneously collapse, since flow ceases before driving pressure is reduced to zero Controversy exists over whether this mechanism plays a role physiologically In some situations, e g , the isolated rabbit ear perfused at low vascular tone, critical closure can be shown not to occur As L E Bayliss has suggested (Daly and Hebb, 1966), large numbers of resistance vessels often lie in parallel in tissues, and it seems unlikely they would all have identical critical closing pressures Thus, they would tend to close one after another and resistance should rise gradually, rather than becoming suddenly infinite, just as if the vessels were becoming gradually smaller In any case, the concept is quite generally used to explain cessation of flow through a perfused tissue when this occurs at perfusion pressures greater than zero

The idea of critical closing pressure has been evoked to explain, for example, renal failure in hypotensive shock Renal arteries are capable of high vasomotor tone which would increase reflexly with drop in arterial pressure, thus accounting for shutdown of kidney function when mean arterial pressures fall below 60 mm Hg or so

THE ARTERIAL PRESSURE PULSE

Velocity. The pressure change created by the ejection of blood into the aorta from the left ventricle is propagated throughout the arterial tree with a velocity considerably greater than the forward movement of the blood itself Were the vascular walls rigid, the impact of ventric-

ular ejection would be transmitted almost instantly, since liquids are incompressible However, the arterial walls are elastic and transmission velocity of the pulse wave is determined largely by vascular distensibility (i e , with the change in volume for a given change in pressure, $\Delta V/\Delta P$) The relationship may be expressed as follows $v = K(V\Delta P/\Delta V)^{1/2}$ where v is pulse wave velocity, V is initial volume, ΔV is increment in vessel volume, ΔP is increment in pressure and K is a constant (Bramwell and Hill, 1922) As vessel wall stiffness increases (decreased compliance), ΔV decreases and pulse wave velocity increases With increased blood pressure the arterial walls are more strongly stretched and pulse wave velocity increases (Fig 3 156) Similarly, the velocity is increased in old age when arterial walls are stiffened by arteriosclerosis The velocity in the young adult aorta is 3 to 4 m /sec and increases to 10 m /sec in the elderly In the stiffer peripheral arteries pulse wave velocity is 7 to 14 m /sec

Contour. The shape of the pulse curve changes as it travels peripherally (Fig 3 153) The high frequency components, such as the incisura, are damped out and disappear The systolic portion of the pressure wave becomes more narrow and its peak exceeds that of the central curve (i e , systolic pressure is higher peripherally) The diastolic limit of the pressure

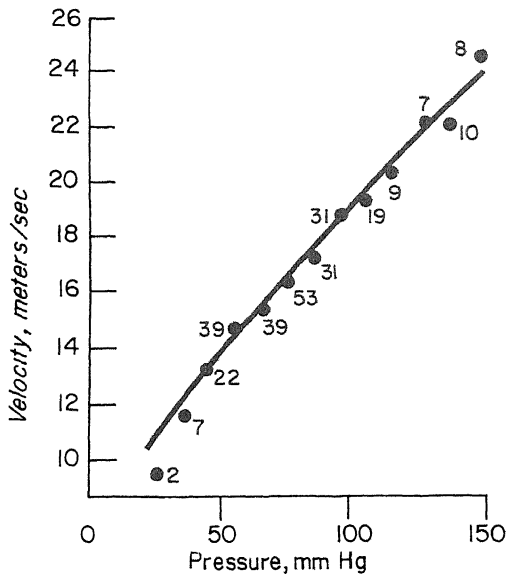

Fig 3 156 Curve showing the relation between arterial blood pressure (abscissa) and pulse wave velocity (ordinate) (From Landowne 1958)

pulse becomes lower, so that a mean pressure gradient accounting for blood flow prevails A hump appears in the diastolic part of the pulse wave The pressure wave passing along the arterial tree rebounds from areas of greater resistance, and travels retrogradely The magnitude of such a reflected wave can be roughly determined by subtraction of the peripheral pulse pattern from the central aortic pattern (Fig 3 153) Different parts of the pulse wave travel at different velocities, thus, contributing to the alteration in pattern from aorta to periphery The high pressure portion travels faster than the low pressure portion because arterial distensibility is less at higher pressure The result is crowding together of high pressure components at the periphery and peaking of the pressure pulse at the periphery (Fig 3 153*F*)

Determinants of Aortic Pulse Pressure Pattern. The aorta and its larger branches can be regarded as a large elastically distensible compression chamber with cardiac ejection entering at one end and drainage occurring at the other end The chamber possesses varying degrees of distensibility, conforming to those existing in various portions of the aorta and its branches The generated pulse pressure is caused by an imbalance between the ventricular outflow entering the aorta, and the peripheral run-off leaving the aorta with each systole The systolic portion largely expresses input into the aorta, the diastolic portion expresses decompression of the aorta or peripheral run-off, since, at this time, it is disconnected functionally from the ventricle Four factors are of major importance in determining the pressure and increments of pressure from moment to moment the elasticity or distensibility of the vessel walls, the volume of contained blood, the volume increment from cardiac ejection, and the decrement in volume caused by peripheral drainage These relations are expressed by the equation

$$E = (\Delta P/\Delta v)\ V$$

in which E = volume-elasticity coefficient, ΔP = change in pressure, Δv = change in volume, and V = capacity of aorta in diastole If the aorta and arteries constituted a simple elastic chamber, the pressure-volume relations (P/V) should be predictable from the preceding, and if P is known, V should become available It would be helpful if such a relation could be used to indicate what is happening to the blood

and whether the effect is centrally or peripherally induced However, difficulties in such an approach are *1*) there is no way to quantitate *V*, *2*) the pressure-volume relation of any part of the aorta is linear over only a limited pressure range, *3*) distensibility is different in various regions of the arterial tree, and *4*) changes have been revealed in the distensibility characteristics of the aorta by reflex stimulation and adrenalin injection

Usefulness of Aortic or Central Artery Pulse Patterns. Despite the difficulties in elucidating the pressure volume relations in the aorta, pressure pulses from the large arteries, depicting fairly well the pattern of the central aortic pulse pressure, have been found useful in predicting hemodynamic changes Such interpretation and extrapolation is based on experiments in dogs in which changes in peripheral resistance and cardiac activity have been deliberately induced and their effects on the pressure pulses separately determined Figure 3 157 shows the human subclavian pulse obtained indirectly The duration of systole and diastole can be determined In the presence of a high peripheral resistance and in a normal vessel, the pulse shows a much steeper rise throughout systole In the presence of a low aortic resistance but with good vascular volume, the curve has an initial early spike followed by a lower systolic tip, a rapid decline and a greatly reduced slope during diastole When the stroke volume is low, as in hemorrhage, the systolic part is small, smooth, and rounded, and diastole is almost flat Decreased distensibility of the aorta is revealed by a rapid, sustained, and large elevation of the pulse, a high incisura and a gradual decline during diastole Distinctive pulse patterns caused by lesions of the aortic valves are also shown Attempts to use central arterial pressure pulses to estimate stroke volume have been numerous but none has been successful

Arterial Blood Flow

With contraction of the human ventricle, a stroke volume or systolic discharge of 60 to 70 ml is ejected into the distensible aorta within less than 0 25 sec Of this, at least 45 ml is pushed into the aorta within the first 0 1 sec Space for this volume in the aortic arch is made by distending it and by removing some of its blood The resulting pressure change travels as a wave throughout the length of the aorta and its branches to the capillaries (and sometimes through them), and expands the entire arterial tree radially and longitudinally This enlargement results in a forward movement of blood from aortic valves to capillaries before the end of ventricular systole

PHASIC AORTIC FLOW

The phasic flow in the ascending aorta of the dog is roughly triangular in shape Fig 3 158*A* Acceleration reaches a peak ejection rate early

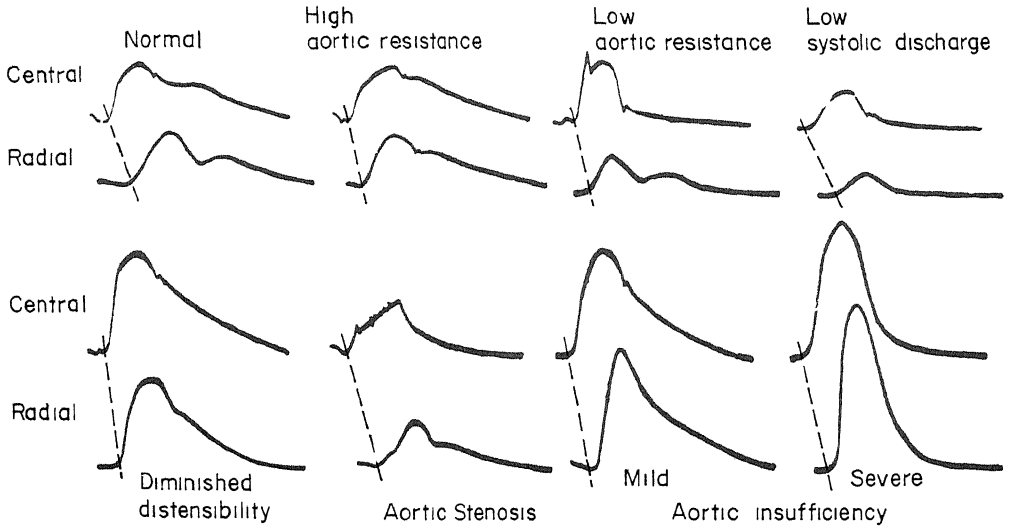

Fig 3 157 Illustration of changes in contour and amplitude of subclavian and radial pulses under abnormal cardiovascular conditions Discussion in text Note changes in transmission rates (Wiggers 1952)

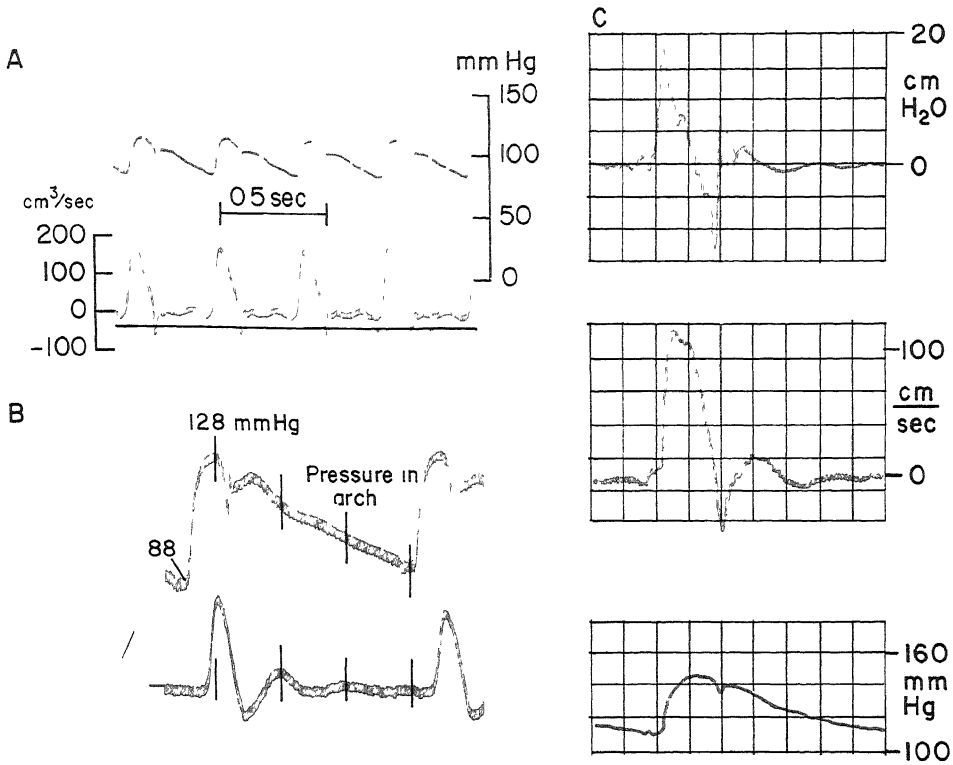

Fig 3 158 *A* Tracings from bottom to top flow in the ascending aorta pressure in the aorta (from Wetterer Minnesota Med 1954 37 79) *B* Tracing from top to bottom pressure in aortic arch flow in terminal aorta (from Spencer Circulation Res 1958 **6**, 492) *C* Simultaneous recording of *1*) aortic axial pressure drop between two points 6 cm apart at level of subclavian artery *2*) computed blood velocity at this level and *3*) aortic blood pressure at subclavian artery junction (From Fry et al 1957)

in systole following which there is a rapid deceleration ending in a momentary, small, high frequency backflow at the time of closure of the aortic valves The flow curve is flat with almost zero velocity during most of diastole The considerable modifying effect of the aorta upon the left ventricular ejection pulse is seen in Figure 3 158*B*, taken near the terminus of the aorta The flow pulse is now a series of smooth, highly damped oscillations of a frequency of 3 to 4 cycles/sec which continue to extinction, but which are renewed with each heart beat There is quite a large backflow in very early diastole Flow pulses in the isthmal area of the aorta (proximal portion of descending aorta) are intermediate in pattern between the central and abdominal patterns In Figure 3 158*C* are the calculated blood velocity curve and the aortic differential pressure curve, the latter taken by a double lumen catheter with pressure pick up holes 6 cm apart This shows the positive and negative acceleration waves which act on the aortic blood column to produce the flow pulsations The effects of inertia are seen throughout the cardiac cycle The beginning upstrokes of both pressure and flow curves coincide quite well, but when the first positive wave of the ΔP reaches its peak, flow acceleration is maximal, and when ΔP is maximally negative, flow deceleration is maximal This represents about a 90° phase lag

PHASIC FLOW IN PERIPHERAL ARTERIES

Flow patterns and simultaneous intra-arterial pressure curves characteristic of several peripheral arteries are illustrated in Figure 3 159 There are certain distinguishing characteristics A flow pattern is made up of waves whose directional changes have a qualitative correspondence with gradient changes in the simultaneously recorded intravascular pressure pulse and which may be characteristically distinctive for that artery and vascular bed Since the flow

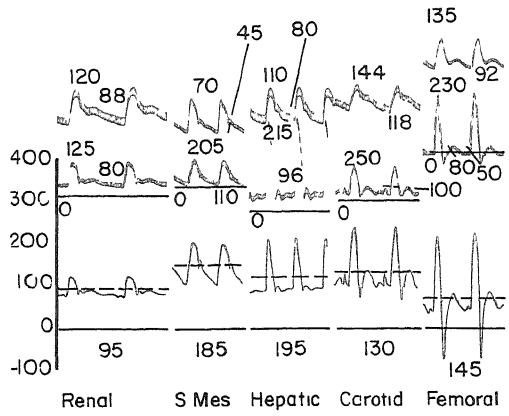

Fig 3 159 Phasic flow in peripheral arteries obtained by orifice meter (Shipley and associates 1943)

velocity varies with the differential pressure existing at the site of the flow meter, similarity in contour of the flow and applied pressure pulse is one criterion for the comparison of flow curves from different arteries Certain patterns, especially those of the superior mesenteric and renal arteries, have a well-rounded and sustained systolic portion in relative conformity to that of the pressure pulse Those of the hepatic and common carotid arteries are less well-rounded, those of the brachial and femoral arteries have a sharp systolic peak The flow pulse pressure is generally small in the renal and axillary patterns, and somewhat larger in the superior mesenteric and hepatic, while the femoral may be quite large Backflow components are consistently found in the femoral and axillary patterns and, on occasion, in the common carotid, while the renal, hepatic, and superior mesenteric flow curves exhibit only forward flow However, the main feature which permits a separation of the flow curves is the variable relation of the early diastolic to presystolic flow rates Comparison of this relation with similar early diastolic and presystolic points on the corresponding pressure curve, shows that the superior mesenteric, renal, hepatic, common carotid, and femoral patterns have, on this basis, a progressively graded dissimilarity to their respective pressure curves

ARTERY TO VEIN PRESSURE AND FLOW

In the quite small vessels (0 2 mm diameter) of the dog forepaw, while constant blood flow is maintained by a pump (Fig 3 160), it can be seen that with the environmental temperature at 20° C , the pressure drop from small artery to small vein approximates 40 mm Hg, and, from small vein to large vein, 6 mm Hg (Fig 3 161) Upon exposure to 0° C , the increase in pressure gradient is almost entirely through the small vessels with little gradient change between the small and large veins Since the blood flow was maintained constant, the increase in pressure gradient represents directly active vasomotor resistance changes

Venous Pressure

The superficial veins, which can be observed and whose pressure values and pulse pressure contours can be easily measured, serve as indicators of the functional status of the less accessible and deeper lying portions of the systemic venous system

THE VENOUS PRESSURE PULSE

The venous pressure pulse is best determined with the subject in the recumbent position Venous pressure is measured directly with an indwelling needle or catheter, or indirectly (without pressure values) by applying a cup over a vein external to the chest, such as the jugular, and connected to a manometer or a microphone receiver The venous pulse waves are usually timed against an electrocardiogram, arteriogram, or phonocardiogram (see chap 4) Two distinct types of pulsations, respiratory and cardiac, are seen in the peripheral and central veins With inspiration, blood is aspirated into the chest and the external veins tend to collapse while internal veins expand, with expiration, venous inflow is impeded and the external veins become distended while the chest veins tend to become smaller These

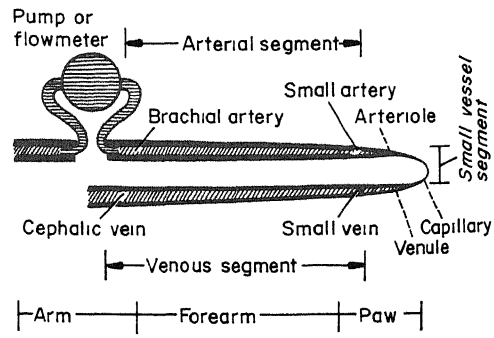

Fig 3 160 Schema showing means of measuring pressure gradient and resistance across small peripheral vessels (Haddy, 1958)

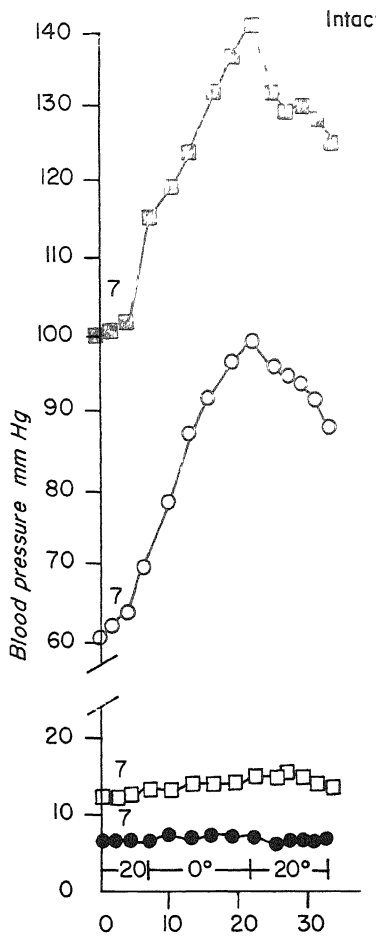

Fig 3 161 Effect of temperature change upon vascular pressures with flow rate constant in the foreleg of the dog *Ordinate* blood pressure *Abscissa* time in minutes and temperatues in ° C Numbers at each curve indicate number of animals in each series ● Cephalic vein □ small vein ○ small artery ■ brachial artery

changes make up the respiratory venous pulse The cardiac venous pressure pulse represents a retrograde reflection of a somewhat distorted version of the right atrial pulse pattern (see chap 4) These *a*, *c*, *v*, waves are clearly seen in the record obtained from a peripheral vein in Figure 3 162

NORMAL VENOUS BLOOD PRESSURE AND ITS VARIATIONS

Using the techniques previously described, mean blood pressure in the large, superficial veins of unanesthetized man at rest and in the supine position is found to be a function of distance from the right atrium The average value decreases from 13 8 mm Hg (188 mm H_2O) in the dorsal venous arch of the foot to about 5 2 mm Hg (70 mm H_2O) in the jugular vein The average pressure of 7 1 mm Hg (97 mm H_2O) in the antecubital vein drops to about 4 6 mm Hg (63 mm H_2O) in the vena cava opposite the right atrium (Fig 3 163) Thus, the overall venous pressure gradient approximates 9 2 mm Hg (125 mm H_2O) with a pressure difference of only a few mm H_2O occurring between the upper thoracic veins and the right atrium Although venous pressure measurements in the same subject are quite constant, considerable variation (up to 100 mm H_2O) may occur in the venous pressure from the same area in different persons

Peripheral and central venous pressures are altered in the same direction under many circumstances They do not appear to be related to age, sex, or hypertension, but they are decreased in severe hemorrhage and surgical shock They are increased by positive pressure breathing, the Valsalva maneuver, tilting, the excitement stage of anesthesia, the apneic

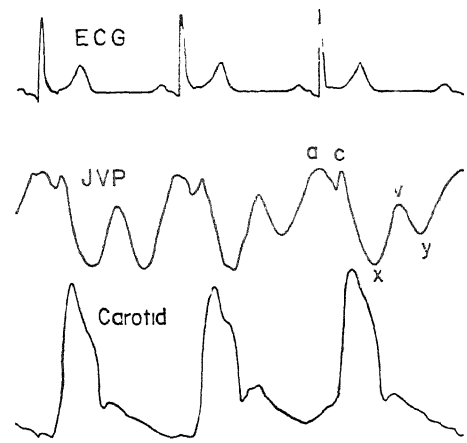

Fig 3 162 The jugular venous pulse pattern (*JVP*) of a normal subject An electrocardiogram (*ECG*) and carotid pulse tracing were simultaneously recorded The presystolic *a* wave is caused by atrial contraction The *c* peak is secondary to closure of the tricuspid valve although it may also represent transmission of the arterial pulse to the vein The descending limb of the pulse tracing after the *c* wave is secondary to emptying of the vein into the right atrium The negative *x* wave occurs during lowering of the atrioventricular septum and tricuspid valve during ventricular systole Then the pressure rises as the right atrium fills to form the *v* wave The second negative depression the *y* wave represents the fall in jugular venous pressure as the tricuspid valve opens and the right atrium empties (From Wood 1968)

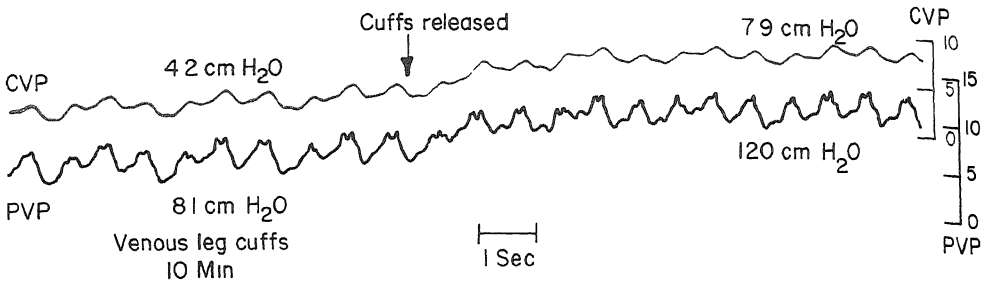

Fig 3 163 Comparison of central venous pressure (*CVP*) and the peripheral venous pressure (*PVP*) After release of occluding cuffs at the thighs the pressures return to control levels without a change in the pressure gradient (From Gauer et al 1956)

phase of asthmatic attacks, and in Cheynes-Stokes breathing The main pathological condition in which central and peripheral venous pressures are elevated, sometimes as high as 22 mm Hg (300 mm H_2O) in the antecubital vein, is congestive heart failure

DETERMINANTS OF VENOUS PRESSURE

The interplay of factors which determine systemic venous pressure and venous flow can be briefly stated The veins are placed between the capillaries or the AV anastomoses, and the right heart The blood enters the venules with an appreciable pressure residuum (vis a tergo) from the arterial side, after it has passed through the capillaries This pressure is met by the resistance to flow from the veins themselves and from the heart itself (the vis a fronte) The venous pressure is affected by internal factors which control the relation between the contained venous volume and the state of distensibility of its vessel walls Finally, there are various external or extramural factors (vis a latere), such as the actions of respiration, muscle, and gravity, which together represent the pressure effect of the surrounding tissues These factors act to insure that the pressure in the veins can never be less than the right atrial pressure, and whenever right atrial pressure increases, the peripheral venous pressure increases This excess of pressure (10 to 12 mm Hg or 125 mm H_2O) in the various veins, over that in the right atrium, is an expression of the pressure gradient (P_1–P_2 in Poiseuille's formula) This, together with a reasonable venous cross-section, causes blood to flow from vein to atrium

The Contraction of the Left Ventricle (the "Vis a Tergo"). *Vis a tergo* means "force from behind," and represents the pressure gradient from any point in the systemic circulation to the right atrium *Vis a fronte* means "force from the front," and has been used to represent any factor which affects the flow of blood into the right atrium Since both positive and negative pressure influences operate, usage of the term has become confusing It has been employed to designate *1*) the "back" pressure from the right atrium which impedes blood flow into the heart, *2*) the controversial suction effect of ventricular dilatation, *3*) the effect ("respiratory pump") of negative intrathoracic pressure which draws blood into intrathoracic veins, and *4*) the impediment to venous return imposed by positive intrathoracic pressure (e g , the Valsalva maneuver) (Guyton, 1963)

The energy of the ventricular contraction (the "vis a tergo") is expended in driving blood through the arterioles and onward through the capillaries and veins to the right atrium By the time the blood reaches the venules, the remaining pressure may approximate 7 to 8 mm Hg When it reaches the right atrium, the energy has been almost entirely dissipated in overcoming the frictional resistance offered by the vascular channels, at this point, the pressure may be less than 1 mm Hg

Quantity of Blood Flowing through the Arterioles in Relation to Capacity of the Veins. With dilated arterioles, the difference between the arterial pressure on the one hand and venous pressure on the other, tends to be reduced, with constricted vessels the pressure difference will be increased Rough estimates based on the volume-elasticity of the various compartments of the vascular system indicate that if a liter of blood is transfused into the circulation of man at rest, only 10 to 20 ml would be found in the arterial tree and about 980 ml in the extra-arterial system (systemic venous and pulmonary circuits), and that the pressure

elevation in the whole system would be only 4 or 5 mm Hg In bleeding and transfusion experiments in man, the circulation behaves like an elastic container, with pooling of blood in the extremities by occlusive cuffs, the central venous pressure falls without any apparent sign of counter-venomotor control This emphasizes the view that normal stresses to which the circulation is exposed, if they are not too abrupt or excessive, lead to only passive change in the resistance vessels and systemic venous system, and do not cause relaxation or strong contraction of the peripheral capacitance vessels

The veins are capable of adjusting their capacity to the quantity of blood received from the arterial system by reflex vasomotor activity The participation of venomotor tone in the control of the venous pressure and venous blood flow can be shown in animal experiments in which oxygen want, high CO_2, stimulation of the carotid sinus, and excessive hemorrhage are effective in reducing the size of the capacitance vessels In man, using strong stimuli such as the Valsalva maneuver, asphyxia, high G, or large blood losses, the veins constrict in what may be called an emergency reaction In the latter case, the central venous pressure may be normal or even increased

Central and peripheral venous pressures do not necessarily shift in the same direction The pressure gradient from very small veins (0 5 mm diameter or less) to large central veins, is not necessarily constant and can be markedly affected by various states With cold, hyperventilation, and moderate exercise, only the peripheral venous pressure may rise significantly This often independent action of local venous pressure and central venous pressure indicates that reflex venomotor activity of the capacitance vessels in normal persons is highly selective and regional in operation and that local small vein or venule pressure is not necessarily an index of happenings in the central venous system Hence, the state of distensibility of the arterioles, venules, and small veins, and large central veins, are not necessarily related, and net effects are unpredictable

The Action of the Right Side of the Heart upon the Blood Flow in the Veins. Obviously, if the blood is not passed on again by the right heart as quickly as it is carried to it by the great veins, the venous pressure will rise If the heart fails, the venous pressure rises and back pressure effects ensue

There is experimental proof that the activity of the right ventricle itself actually increases greatly vena caval flow into the right atrium This is illustrated in the vena caval flow curves of Figure 3 164, in which it can be seen that there is a larger forward flow of blood during right ventricular systole than during diastole During contraction, the descent of the atrioventricular junction enlarges the great venous reservoir which comprises the atria and venae cavae Obviously, this could be a very useful mechanism for maintaining venous return during tachycardia In slow hearts most of atrial inflow occurs during the long ventricular diastole, but during a rapid heart rate the proportion of atrial inflow due to active systolic "injection" of blood from the veins into the right atrium is greatly increased

The influence of cardiac action upon the movement of blood in veins and atria does not necessarily imply that the ventricles exert an aspirating action during diastole This problem has been debated many years and is considered on page 3-103 In general, it can be said that under strictly controlled experimental conditions, there is some positive evidence for this

Sometimes when vigorous respiratory efforts are made, slight fluctuations of the venous pressure can be detected in the peripheral veins of the human subject These variations rarely amount to more than 10 mm of H_2O, but may be considerably higher than this when dyspnea resulting from obstruction to the free entrance and egress of air from the lungs exists Owing to the inertia of the blood column, the aspirating effect is less evident, the nearer to the

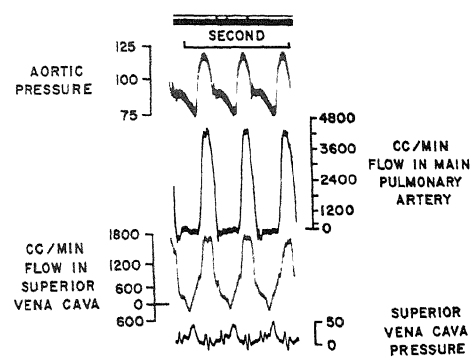

Fig 3 164 Simultaneous recording in open-chest dog of aortic pressure superior vena cava pressure and pulmonary artery pressure and superior vena cava flow with bristle flowmeter Note acceleration of venous return during systolic ejection (From Brecher 1956)

periphery at which the pressure measurements are made

If a forced expiration is made with the glottis closed (Valsalva's maneuver), the negative intrathoracic pressure can be abolished and a positive pressure of several millimeters of mercury substituted The veins of the neck, face, and limbs become distended with blood as a result of the impediment to the flow into the right atrium The peripheral venous pressure under these circumstances may rise to 400 mm H_2O or more In the converse maneuver of Mueller in which a forced inspiration is made with the glottis closed, the powerful suction effect may cause a fall of 50 mm H_2O or so in the venous pressure of a peripheral vein

Youmans et al (1963), have described an abdominal compression reaction in anesthetized dogs, thought to influence cardiac filling Tonic contraction of abdominal muscles is suspended during inspiration and restored upon its cessation Procedures which decrease blood volume in cardiac chambers lead to increased activity of the abdominal muscles without causing corresponding changes in amplitude of inspiration It is speculated that this reaction may serve to compress abdominal vessels and thus favor venous return

External Forces Natural and artificial respiration have a very large effect on central venous pressure and flow Direct measurements of flow with the bristle flowmeter in the closed-chest dog have shown flow to increase in both the superior and inferior vena cava during inspiration, and in turn, this effect is transmitted to the outlying veins (Fig 3 165) In the closed-chest dog, intermittent, positive-atmospheric-pressure artificial respiration (expiration occurring passively against atmospheric pressure) reduces significantly venous return to the right heart over that occurring with natural respiration Intermittent positive-negative pressure respiration (use of mild suction during expiration) augments vena caval flow over that occurring during positive-atmospheric pressure respiration In unanesthetized, normal humans, continuous negative pressure breathing increases cardiac output and stroke volume, while continuous positive pressure breathing has the opposite effect The untoward effects of artificial respiration arise when there is positive pressure applied during artificial inspiration, the intrapleural pressure, instead of decreasing, actually increases, and may even become positive This decreases vena caval flow secondary to an induced increase in pulmonary vascular resistance and, in part, to the mechanical compression or "tamponade" of the heart and lungs caused by the expanding lungs The mechanical aspects of respiration, however, are apparently not essential to maintenance of venous return or cardiac output, for in the presence of apneic oxygenation in dogs (a condition of induced ventilatory arrest with the trachea connected to a reservoir of oxygen), life continues and the cardiac output may even increase

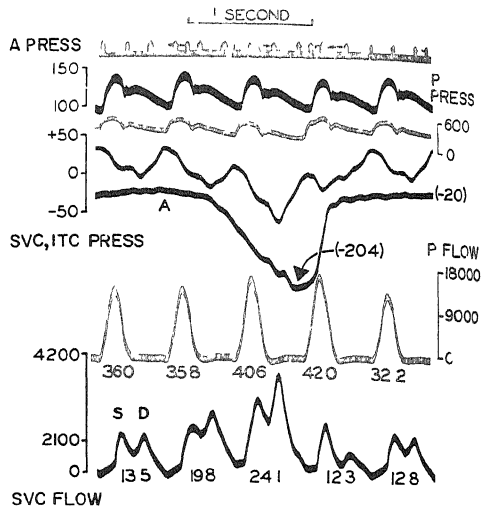

Fig 3 165 Effect of spontaneous respiration on venous return and cardiac output (closed-chest) Tracings from top to bottom time and base line aortic pressure in millimeters of mercury pulmonary artery superior vena caval (*SVC*) and intrathoracic pressure (*ITC*) in millimeters of water pulmonary arterial and superior vena caval flows in cubic centimeters per minute *A* beginning of inspiration *S* acceleration of superior vena caval flow during ventricular systole *D* acceleration of superior vena caval during ventricular diastole Stroke volume (in cubic centimeters) under pulmonary arterial flow curve Flow (in cubic centimeters) through superior vena cava during each cardiac cycle at bottom of record Electrical frequency response of both flowmeters reduced from 400 to 40 cycles/sec Superior vena caval pressure curve damped (Brecher 1956)

Posture and Exercise. The venous pressure varies, of course, as a result of the gravity effect, i e , with the position of the vein in relation to the right atrium, at which level, venous pressure is assumed to approximate zero (Fig 3 166) If man assumes the upright position and is motionless and relaxed, the measured pressure in an ankle vein approximates 85 to 90 mm Hg Similarly, the arterial blood pressure measured at the ankle will be increased over that at the heart level by an amount equal to

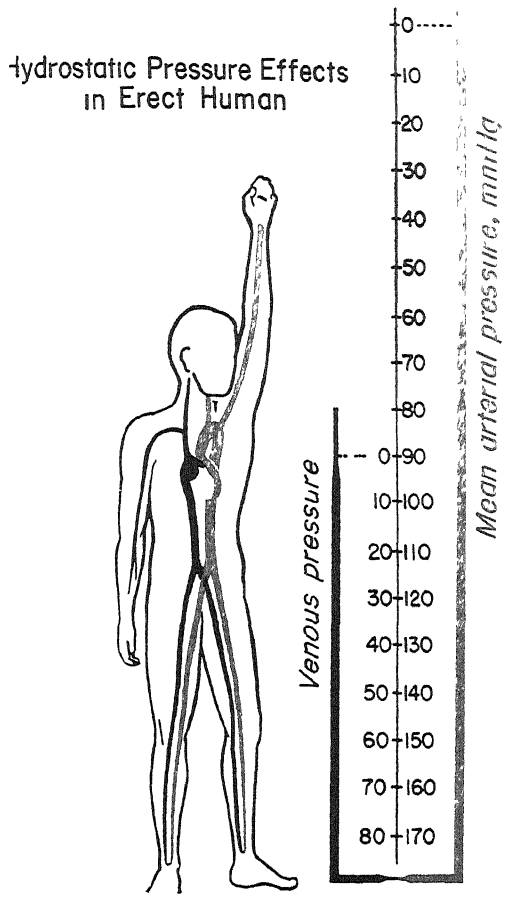

Fig 3 166 In erect position arterial and venous pressures are both increased by about 85 mm Hg at the ankle With the arm elevated over the head the arterial pressure at the wrist is about 40 mm Hg and the effective venous pressure is zero down to a level just above the heart (From Rushmer 1970)

the hydrostatic level Thus, the arterial and venous pressures at the ankle are increased by the same amount, and the pressure difference between vein and artery is the same at ankle and heart level This means that a favorable pressure gradient exists for venous flow Below heart level, the veins increase in fullness and the venous pressure gradient responsible for venous return from periphery to the heart is the measured venous pressure minus the hydrostatic column This is a small gradient but, since the veins are distended, resistance is quite low In the upright position, veins from the upper part of the body empty towards the heart These upper veins partially collapse and their intravascular pressure may approximate zero Above heart level, the pressure gradient along the venous channels is the height of the hydrostatic column above heart level This gradient is large but since the veins are partially collapsed, resistance is high

There is, however a special feature of the venous system which distinguishes it from the arterial system This is the tendency of the veins to collapse In the low pressure system, even in the recumbent position, the veins are not usually round but may be partially or fully, and intermittently collapsed For surface veins, collapse arises from increase in atmospheric pressure, in the deeper veins, it is caused by the surrounding tissue pressure acting on the venous walls This occurs during normal respiration in the neck veins, and in the inferior vena cava below the diaphragm where this process is aided by the increased intra-abdominal pressure With deep and prolonged inspiration, these veins may completely collapse Such a collapse tendency may be greatly augmented by an increased gravitational stress In the upright position, the pressure in the neck veins falls to 0 mm Hg, and the atmospheric pressure on the outside of the neck causes these veins to collapse all the way up to the skull This causes the pressure in these veins to remain at zero along their course It is this tendency for collapse that causes resistance in the large veins, for when distended, resistance is minimal However, not all veins are collapsible, especially the venous sinuses in the skull, vertebral column, bones, liver, and spleen, which are held open by firm-walled surrounding tissues For example, the veins in the skull are in a noncollapsible chamber, and in the standing position a negative venous pressure of about 10 mm Hg exists in the sagittal sinus because of the hydrostatic pressure difference between the top and base of the skull

In man, tilting into the feet-down position produces an immediate decrease of inferior vena caval flow which is more or less proportional to the degree of tilt The decreased venous return under such conditions is of short duration because of a number of compensatory vasomotor mechanisms which operate very quickly However, even with these compensations, the venous return is somewhat less than in the supine man In tilting the human subject into an upright posture, the blood pressure at the carotid sinus decreases mildly and the heart becomes smaller (Fig 3 167) About 400 ml of blood leaves the thoracic compartment to accu-

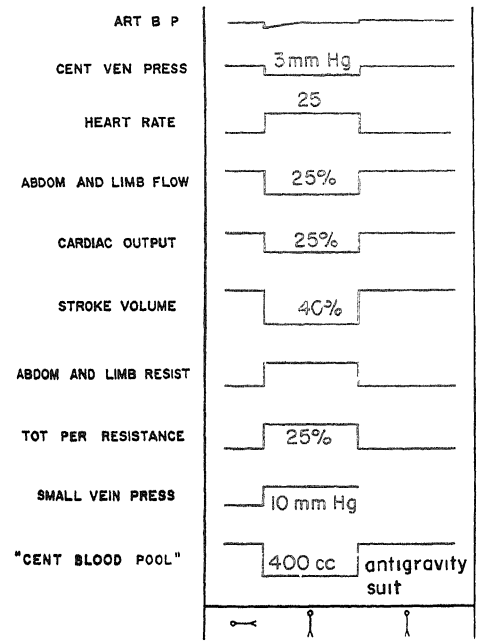

Fig 3 167 Effect on various cardiovascular parameters in man of changing from supine to the upright position

mulate mainly in the veins of the extremities (determined by leg plethysmographs) The pressure in them increases and the filling pressure of the heart drops Cardiac output drops mildly, stroke volume decreases considerably, the heart rate rises There is also a decrease in blood flow through skin, skeletal muscle, liver, and kidney These changes are at least partially explainable on a mechanical basis, i e , tipping into the erect posture might be regarded as a functional hemorrhage into the lower portions of the body Since the pressure in a superficial arm vein maintained at heart level rises considerably (about 10 mm Hg), peripheral venous constriction has taken place to shift blood centrally to make more blood available to the heart for maintaining cardiac output, although its effect is not enough to maintain central venous pressure That this limitation of peripheral blood flow and pooling are reflex phenomena is shown by its absence in a sympathectomized extremity The fact that application of a G suit before or after the subject has assumed the upright position, either prevents these changes, or re-establishes the original state of the circulation, mitigates against the role of the arterial baroreceptors and favors the stimulation of low pressure receptors While their precise stimulus and accurate location are not known, they presumably belong to the many receptors demonstrated anatomically in the thoracic vascular bed

The circulation of animals such as the domestic rabbit, eel, and snake, which have not acquired a compensatory mechanism, are placed at great disadvantage when the vertical position is assumed The eel and snake can be killed by immobilization in the vertical head-up position They literally bleed to death into their veins Thus, in the human subject if, upon assuming the erect posture after a protracted confinement to bed, the muscles of the abdomen and limbs are weak and the tone of the nervous mechanism governing the peripheral vessels lowered, the hydrostatic effect is overcome with difficulty The blood subsides into the capacious abdominal veins and capillaries, and the right heart is no longer adequately supplied with blood The arterial pressure falls and the cerebral blood flow becomes inadequate The subject turns pale, sweats freely, and feels giddy or perhaps nauseated, and in a complete faint loses consciousness (syncope)

In exercise, a much greater volume of blood enters the central veins from the arterial side The various mechanical assists already mentioned, that increase the venous pressure gradient and venous blood flow toward the heart and decrease the venous reservoir, now operate even more effectively In addition, the act of muscle shortening propels blood toward the heart

PULMONARY CIRCULATION

Regulation of Pulmonary Pressure and Flow

Uniquely interposed between the right and left heart and entirely enclosed within the negative pressure confines of the thorax, the pulmonary circulation exhibits certain pecularities uncommon to the other organ-perfused systems For instance, *1)* it is the only circuit in the body to receive the total cardiac output, *2)* it operates at a perfusion pressure one-seventh to one-eighth that of the systemic circuit, *3)* its mean transit time is equal to the systemic, albeit across a much reduced linear distance, reflecting the enormous surface area of the pulmonary capillary bed, *4)* it is predominantly controlled by the beat to beat pressure differential between the pulmonary artery (right ventri-

cle) and the left atrium upon which phasic, intrathoracic respiratory variations are superimposed, and 5) it is the only arterial circuit which carries desaturated hemoglobin and which, by virtue of the alveolar-capillary pressure difference, the desaturated hemoglobin and the huge surface area participates in large instantaneous gas exchanges Normal data for dog and man are given in Table 3 21

GENERAL CONSIDERATIONS

Bronchial Circulation. The blood supply to the bronchial connective tissue of the lung is part of the systemic circulation There is free communication between the capillaries of the pulmonary and bronchial systems, and these capillary beds may drain into either the systemic venous system through the azygos vein or through the pulmonary veins into the left atrium Thus, oxygenated pulmonary venous blood is diluted to a small extent (perhaps 1 to 2%) by unoxygenated bronchial venous blood The intermingling of the two circulations at the capillary level provides a potential shunt, which can serve to prevent elevation of capillary hydrostatic pressure should increase in either right or left atrial pressure occur unilaterally Under such circumstances, capillary blood can drain through the venous system with the lower pressure

The bronchial vessels can also provide collateral circulation to the lungs when the pulmonary arterial supply is inadequate Thus, in pulmonary artery atresia the bronchial arteries enlarge anastomoses with pulmonary arteries develop and poorly oxygenated blood reaches alveolar capillaries from the aorta

Pulmonary Resistance. To determine the mechanisms controlling pulmonary flow, it is necessary to know the resistance to flow Classically, this should be simply the ratio of the difference of pressure across any portion of a vascular bed to the blood flow that develops, it is a convenient factor by which the pressure drop can be divided to give the flow Such resistance gives information regarding the two factors upon which it depends, the viscosity and geometry of the vascular bed Since, however, the relation of pressure and flow is not a straight line and when plotted does not pass through the origin, the mechanisms involved are not determinable from a single point relationship To make the results interpretable, a vascular bed must be perfused in the control state and in the presence of a variable at the same pressure while flow is measured, or at the same flow while pressure is measured In no other way can it be even roughly determined that a calculated change in resistance (pressure divided by flow) reflects vasomotor activity produced by the stimulus, or reflects only the passive change in resistance caused by altera-

tion in left atrial pressure or in pulmonary flow There is also an additional difficulty in measuring changing resistance in the pulmonary circulation, for here the relationship between pressure and flow is quantitatively quite different from that in the systemic circulation The difference is that with the same volume perfusing both circuits, the pressure drop from the pulmonary artery to the left atrium is only about one-fifth that from the aorta to the right atrium This is illustrated in Figure 3 168 where the differential pressure between the pulmonary artery and the pulmonary veins is only about 15 to 20 mm Hg This means that while the systemic resistance at the arterioles is high and these vessels have relatively thick muscle cuffs, the resistance vessels at the outlet of the small pulmonary artery branches have quite thin muscular coats with relatively large luminae The tone of the terminal pulmonary vessels is thereby relatively low so that a rise in pulmonary venous pressure is readily transmitted to the arterial side, or so that a rise in blood volume injected into the arterial side will increase greatly the volume in the lungs As a result of the high degree of distensibility of the pulmonary vascular bed, secondary to the opening up of fresh capillaries or further opening of those being used, the blood contained within the lungs shows wide variations under different conditions and on a passive basis

Pulmonary Artery "Wedge" Pressure. If a small catheter is advanced along the pulmonary arterial tree until it wedges in a small branch artery, blood flow behind the catheter is blocked, and fluid in the catheter perfuses the capillary bed beyond Then, the mean pressure in the catheter reflects that in the capillaries, and the synonym "*pulmonary capillary pressure*" has been applied to such "wedge" pressures Since the level of left atrial pressure influences that in the capillaries, arterial "wedge" pressure has been used as an indirect measure of the mean pressure in the left atrium However, large discrepancies between the two may prevail, so that pulmonary arterial "wedge" pressure may not give sufficiently accurate representation of the left atrial pressure for hemodynamic studies (Daly and Hebb, 1966)

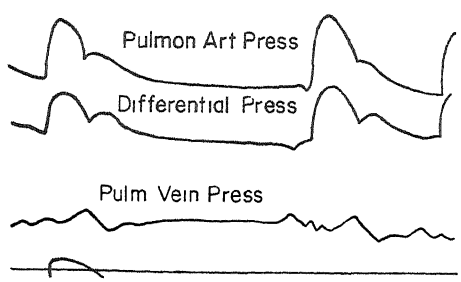

Fig 3 168 Record from the unanesthetized dog showing the pressure pulse contours in the pulmonary artery upper curve pulmonary vein lower and the differential pressure between the two middle curve Pulmonary artery pressure 28/10 mm Hg mean pulmonary vein pressure 10 mm Hg differential pressure 5 to 10 mm Hg (From Hamilton et al 1939)

Pressure Pulse in the Pulmonary Circuit. Pulmonary circuit pressures are much lower than those in the systemic arterial circuit In the unanesthetized dog the pulmonary artery pressure may be, for example, 40/10 mm Hg and the pulmonary vein pressure, 2 to 12 mm Hg (Fig 3 168) The pattern of the pulmonary arterial pressure is distinctive showing a marked incisura low on the dicrotic limb In late diastole, the pressure descent almost ceases and becomes horizontal

Pulse contours of the peripheral and central portions of the pulmonary artery display differences somewhat like those of the systemic circuit The pulse wave velocity in the pulmonary artery in man, studies during thoracic surgical procedures, is about 2 m /sec at normal pulmonary arterial pressure levels In patients with pulmonary hypertension, pulse velocity is increased to about 4 m /sec , indicating reduced distensibility of the pulmonary artery, since the pulse velocity is inversely related to distensibility The contour of the pulmonary vein pressure curve clearly shows a, c, and v waves, and closely resembles pressure pulses taken from the left atrium In open-chest dogs a 4 to 5 mm Hg pressure gradient was found between mean pulmonary venular (small pulmonary venous) and mean left atrial pressures

PULMONARY BLOOD FLOW

Phasic flow. In the pulmonary artery the flow of blood rises and falls more slowly than in the aorta (Fig 3 158A, 3.165) A small back flow occurs at the end of systole, as in the aorta (Fig 3 164) Flow remains pulsatile throughout arteries and capillaries (Fig 3 169), and small oscillations persist into the left atrium The dis-

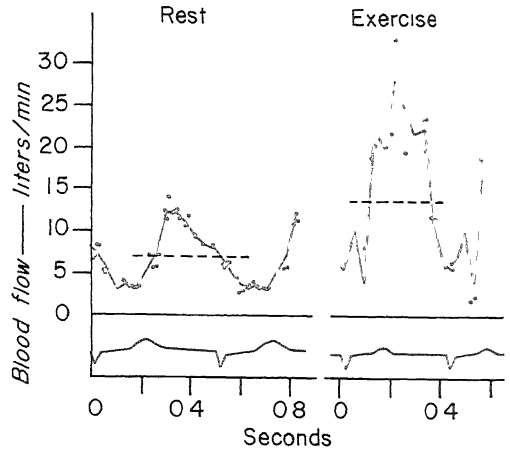

Fig 3 169 Simultaneous pulmonary capillary blood flow curves at rest and during exercise (DuBois and Marshall 1957)

tribution of flow within the lungs is affected by gravitational hydrostatic forces Thus, in the erect posture the lower lobes are perfused better The capillaries in the lung apices are about 15 cm above the heart base and are nearly or completely closed, those at the bases are distended and regional blood flow is greater here Thus, the normally low pulmonary artery pressure is barely adequate to perfuse the upper areas of the lungs The net effect of low capillary pressure combined with normal plasma oncotic pressure is to favor fluid reabsorption from the lung interstitial tissue Pulmonary edema appears first in the lower lobes, as would be expected because this is where hydrostatic pressure is highest

Sheet-Flow Concept. It has been suggested (Sobin et al, 1970) on morphological grounds, that the alveolar microcirculation is organized into a vascular sheet That is, an arrangement in which two walls of endothelium, held apart by connective tissue and cellular posts, enclose a sheetlike space, rather than the conventional model of a network of cylindrical tubes The interalveolar capillary bed would thus be visualized as an endothelium-lined, flat vascular sinus, with variable reservoir capacity through which blood advances as a moving sheet The validity of this concept as a better basis for understanding microcirculatory flow and gas exchanges across the capillary alveolar barrier has not yet been realized

Vascular Waterfall Concept. Some of the pressure-flow relationships in the pulmonary circulation suggest that under certain conditions arteriolar resistance alone is relevant, and the resistance of capillaries and veins is not In a waterfall, the flow is not influenced by the height of the fall, i e, the pressure drop, and vice versa, the pressure drop does not influence flow over the precipice In lung circulation perfused at constant pressure, flow maximizes when pulmonary venous pressure is slightly higher than alveolar pressure Changes in venous pressure much less than alveolar pressure fail to influence flow Since capillary pressure must exceed alveolar pressure for flow to occur at all through collapsible capillaries, lowering venous pressure must create a larger pressure drop between end-capillaries and pulmonary veins, while flow remains constant Thus a "waterfall" can exist between capillaries and veins (Permutt and Riley, 1963) Physiologically, this mechanism would operate only where arterial pressure is greater than and venous pressure less than alveolar pressure (Fig 3 170)

The influence of pulsatile arterial pressure on flow distribution in the lung appears to be frequency dependent (Maloney et al, 1968) Effective pulsatile pressure transmission to capillaries falls with increasing frequency of the arterial pressure pulse Thus, in the vertical lung, the height above the heart level at which blood flow will be detected decreases with increasing pulse frequency

In Figure 3 170, factors acting to influence distribution of blood flow in vertical lungs are diagrammed

CRITICAL CLOSING PRESSURE IN PULMONARY VESSELS

There is experimental evidence (Lopez-Muniz et al, 1968) that in the pulmonary circulation, critical closing pressure exceeding intra-alveolar pressure can be caused in both alveolar and extra-alveolar vessels by low pH or high CO_2 levels

EFFECTS OF RESPIRATION UPON PULMONARY AND SYSTEMIC BLOOD PRESSURES AND FLOWS

The effects of natural respiration on the hemodynamics of the pulmonary circulation are illustrated in Figure 3 165 The pulmonary arterial pressure falls during inspiration and rises during expiration One should expect that, as a result of the increased flow of blood into the right ventricle during inspiration (see superior

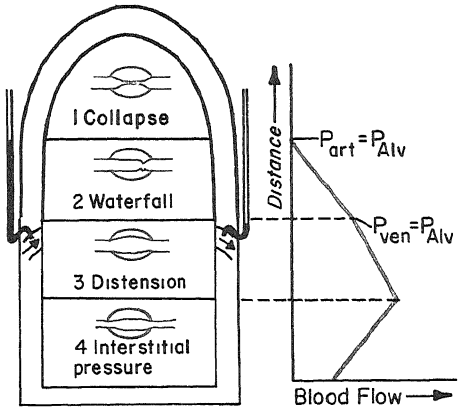

Fig 3 170 The resistance of vessels in different parts of the lung *1)* In this region the lung capillaries are collapsed if alveolar pressure exceeds arterial pressure and no flow occurs *2)* In this zone arterial pressure exceeds alveolar pressure and alveolar pressure is greater than venous pressure Flow is determined by the arterial - alveolar pressure difference (vascular waterfall) *3)* Both arterial and venous pressure exceed alveolar pressure and flow depends on arterial venous pressure difference Flow increases down this zone owing to vessel distension by gravity and to recruitment of vessels *4)* In the deepest zone flow decreases as the base is approached probably owing to interstitial pressure narrowing the diameter of extra-alveolar pulmonary vessels (Redrawn from Hughes et al 1968)

caval flow) and the greater systolic discharge, both the pulmonary pressure and pulmonary flow would rise during this phase of respiration However, only the pulmonary flow rises Because of the traction exerted upon the circumference of the pulmonary vessels by the surrounding lung tissue, their capacity is increased This more than compensates for the lack of change in the pressure gradient and for the greater amount of blood entering the pulmonary circuit during the inspiratory phase During expiration these effects are reversed The right systolic discharge is less but the capacity of the vascular bed of the lungs is at the same time reduced, an upward swing in pulmonary arterial pressure occurs With maximal expansion of the lungs, or during a forced expiration with the glottis closed (Valsalva's experiment), the vessels are strongly compressed by the surrounding lung tissue, and the pulmonary arterial pressure rises sharply

The increased capacity of the pulmonary vessels during inspiration reduces, momentarily, the flow of blood into the left atrium, the consequent reduction in the systolic discharge of the left ventricle causes a fall in aortic pressure (Fig 3 165) After a few beats of the right ventricle, the greater capacity of the pulmonary vessels again becomes filled and the flow of blood into the left chambers of the heart increases, the aortic pressure rises The succeeding expiration, by reducing the capacity of the pulmonary vessels, drives blood to the left side and further increases the discharge into the aorta, the systemic pressure, in consequence, continues its rise until near the end of the expiratory phase If the respiratory movements and the systemic blood pressure are recorded simultaneously, it is found that the blood pressure commences to fall at the commencement of inspiration and reaches its lowest point in the latter half of this phase, the blood pressure tracing then commences to rise and reaches its maximum toward the latter part of expiration In addition to these mechanical effects of respiration on systemic flow and pressure, irradiation of impulses to the vasomotor center from the respiratory center during inspiration can increase arterial pressure These are correctly called *Traube-Hering* waves after their discoverers (Schweitzer, 1945) Also, reflex pressoreceptor and chemoreceptor influences accompanying fluctuations in pressure and blood oxygenation with the respiratory cycle can contribute to the net effect

Distinguished from the respiratory waves in systemic arterial blood pressure are slower fluctuations called *Mayer* (sometimes erroneously referred to as Traube-Hering waves) waves, occurring at rates of from 1 to 3/min These represent oscillations in pressoreceptor and chemoreceptor reflex control systems, which are exaggerated under conditions of hypotension and tissue hypoxia Elevation of cerebrospinal fluid pressure elicits an increase in arterial blood pressure, the *medullary ischemic response of Cushing* (pp 3-179 and 3-211) When the blood pressure becomes high enough, ischemia is relieved and the pressure falls again until tissue hypoxia builds up once more, and the cycle is repeated Similar oscillations from cyclic carotid and aortic body chemoreceptor stimulation are seen especially in hypotension following hemorrhage The sinoaortic baroreceptors likewise participate in generating these waves, and may be the primary reflex influence under certain circumstances

EFFECTS OF EXERCISE ON THE PULMONARY CIRCULATION

The general form of the curve relating pulmonary artery pressure and pulmonary blood

flow in man and the intact dog at rest and exercise is shown in Figure 3 171 The curve indicates that pulmonary artery pressure is maintained below the upper limit of normal until the flow exceeds at least three times the base level, whereupon it increases progressively This absence of pressure rise with increased flow implies an expansion of the vascular bed from opening of new channels, widening of those already perfused, or a combination of both Thus, the resistance decreases It is believed (without proof) that this is on the basis of passive distension of the lung vasculature, especially since the same relation holds when attempts are made to denervate the lungs, when isolated lung lobes are perfused, or when variations in the quantity of blood in the lungs is induced by different procedures

As pointed out earlier, to understand what is happening hemodynamically in the pulmonary circulation, it is more important here than in any other vascular bed to know both the pulmonary artery pressure and pulmonary vein (or left atrial pressure) This is because the pressure gradient is only a few millimeters of mercury, and a 5 mm Hg-change in the pulmonary venous pressure could be transmitted back as a 5-mm Hg rise on the pulmonary artery side without any active change in peripheral resistance in the lung vessels So, unless it is known what is happening in the pulmonary veins, one

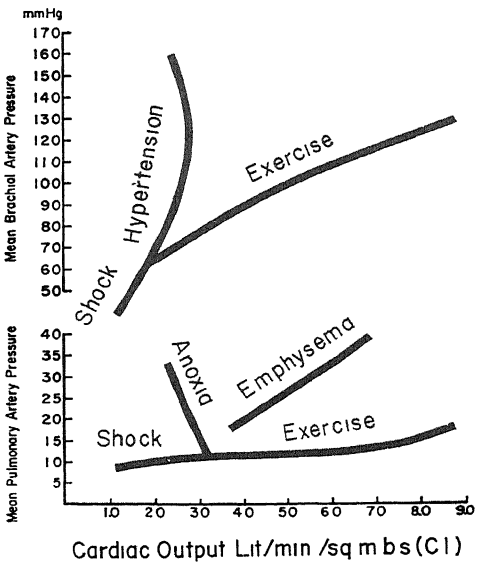

Fig 3 171 The relationship of pressure to flow in the systemic circulation and pulmonary circulation in normal and abnormal states Note the difference in response of the two circulations to exercise

is at a loss to ascribe the cause of a change in pulmonary artery pressure

Factors which passively affect pulmonary vascular pressure volume and flow include *1)* cardiac output, *2)* systemic arterial pressure, *3)* bronchial blood flow, *4)* ventilation, *5)* bronchomotor activity, and *6)* release of hormones (e g , catecholamines) into the circulation Active pulmonary vasomotion can be demonstrated by causing hypoxia, which produces vasoconstriction, or infusing acetylcholine, which causes vasodilatation and alterations in vascular tone are increasingly being recognized as important in the pulmonary circulation However, pulmonary blood volume changes are primarily passive in response to alterations in vascular distending pressure Thus, pulmonary blood volume increases in exercise, systemic vasoconstriction, impaired left ventricular function, and infusion of fluid It decreases with fall in systemic arterial pressure (vasodepressor reactions), improved left ventricular function, or decrease in total blood volume (hemorrhage)

Evidence for and against Vasomotor Control of the Pulmonary Circulation

The pressure in the pulmonary artery may increase as the result of back pressure from the left heart, an increase in pulmonary blood flow and vasoconstriction in the pulmonary vascular bed Also, pressure changes follow alteration of intrathoracic pressure

The pulmonary vasculature could respond to active vasoconstriction and contribute to an increase of pulmonary artery pressure The small pulmonary vessels possess muscular coats and are equipped with dual nerve supply—sympathetic and parasympathetic, stimulation of the pulmonary nerves increases the pulmonary vascular resistance, stimulation of the baroreceptors gives increased pulmonary flow and decreased pulmonary arterial pressure, casts of the two sides of a lung are markedly different if one side is perfused with noradrenaline up to the time of plastic injection (the latter showing marked constriction in the vessels of less than 25 μ in diameter Narrowing and gnarling of the small, muscular pulmonary arteries can be demonstrated angiographically in response to hypoxia and to the intrapulmonary arterial injection of catecholamines and serotonin in the closed-chest dog There is little doubt that wide variations in vascular resistance can normally occur in a purely passive way However, active changes in sympathetic

tone causing alterations in stiffness of large pulmonary arteries have been implicated in rapid circulatory adjustments (see pp 3-22 and 3-125)

In normal subjects, hypoxia, induced by breathing 12% oxygen in nitrogen, considerably increases pulmonary arterial pressure, mildly increases cardiac output, and is without effect on left atrial pressure or central blood volume This suggests that the vasoconstriction induced is on an active basis Although generalized, such vasoconstriction of the pulmonary bed would seem to serve no useful purpose, local hypoxia, however, could be helpful in regulating the distribution of blood by causing vasoconstriction which, in turn, diverts blood from the affected region to vessels in better aerated parts of the lung In experiments in man and animals in which one lung was respired with an hypoxic mixture, the lung probably developed vasoconstriction, since the arterial saturation returned to normal This would be the case if the vessels in the hypoxic lung constricted and forced the blood normally flowing through them into well-oxygenated channels Final proof, however, that hypoxia induces active vasoconstriction in man is contained in the experiments in which acetylcholine (a drug with strong vasodilating effects on the systemic circulation) was infused into the right atrium, but in such quantities that no systemic effects were produced In the presence of hypoxia induced by breathing a low oxygen mixture, infusion of acetylcholine decreased the elevated pulmonary arterial pressure but did not change the left atrial pressure, cardiac output, systemic blood pressure, or heart rate This seems to indicate that an active vasoconstriction caused by hypoxia is relieved by the drug This view is further substantiated by the observation that in emphysematous patients who represent a chronic and more limited form of hypoxia with some degree of arterial unsaturation, acetylcholine infusion lowers still further the arterial oxygen saturation The site and mechanism of action are unknown but they could be many—a local reflex from alveoli or pulmonary veins, chemoreceptor stimulation of the sinus or aortic body, direct local action on pulmonary bed, and shift of systemic blood into the pulmonary circuit, etc Presumably, the action is not related to sympathetic nervous control since the vasoconstrictor effect of hypoxia can be observed in man with a total sympathectomy Serotonin (5-hydroxytryptamine) infused into the intact dog produces a considerable rise in pulmonary arterial pressure with only a modest increase of cardiac output and no change in pulmonary venous or left atrial pressures, indicating active vasoconstriction

Summary

In summary, the pulmonary vessels are capable of considerable passive dilatation as part of their function as a blood reservoir Pulmonary blood volume and vascular resistance, thus are adjusted so as to minimize pressure changes as, for example, in exercise when blood flow can increase several fold with little increase in pulmonary arterial pressure Factors which increase systemic arterial pressure often have little effect on pulmonary arterial pressure (e g, pressor reflexes and pressor drugs), and pulmonary hypertension ordinarily does not accompany essential hypertension However, there is evidence suggesting that sympathetic tone variations alter vascular compliance in the lungs, thus affecting pulsatile flow and pressure transmission between the two ventricles In this sense, the pulmonary vascular bed probably serves as more than a passive conduit, but rather participates directly in maintaining equality of right and left ventricular output (see pp 3-124 and 3-21) The local vasoconstrictor effect of hypoxia serves to shunt blood away from poorly ventilated lung areas to those where oxygenation can take place In the vertical position, gravitational effects govern blood flow distribution in accordance with hydrostatic principles Thus, flow is minimal in the apices, increases at heart level and below until the most dependent areas are reached, where vascular resistance is elevated owing to increased interstitial fluid pressure (Fig 3 170)

CIRCULATION THROUGH BRAIN, SKIN, AND SKELETAL MUSCLE

Cerebral Circulation

Cerebral blood flow is determined by two opposing sets of forces the effective perfusion pressure and cerebral vascular resistance (see Fig 3 172) Effective perfusion pressure is the gradient between arterial blood pressure and internal jugular venous pressure, cerebral vascular resistance is defined here as the sum of all factors opposing the flow of blood through the brain, such as intracranial pressure, blood viscosity and vascular diameter

Internal jugular venous pressure for all practical purposes is negligible as compared to arterial pressure Even the obstruction of the vein by means of a tourniquet placed on the neck, producing pressures up to 300 mm of water, has no effect on cerebral blood flow (Moyer et al , 1954) Thus, arterial blood pressure is the sole important determinant of the driving force of blood flow across the brain

In man the cerebral blood flow may be determined by the nitrous oxide method (Kety and Schmidt, 1948) which is based on the Fick principle (see sect 3, chap 7) The subject breathes a gas mixture containing 15% N_2O, while blood samples are obtained from a peripheral artery and from the internal jugular vein (representing mixed cerebral venous blood) Cerebral blood flow per unit weight of brain may be calculated from the arterial and venous gas concentrations and the partition coefficient for nitrous oxide between brain and blood Results are usually expressed as milliliters of blood per 100 g of brain per minute, in resting, normal young men the mean value is 54 ml Assuming a weight of 1400 g for the brain, total cerebral blood flow is about 750 ml./ min

The relation of arterial blood pressure to cerebral blood flow is determined by the level of the blood pressure itself A lowering of the mean arterial pressure to a level of about 60 to 70 mm Hg by means of high spinal anesthesia, paralyzing most of the sympathetic vasoconstrictor nerves has no effect on cerebral blood flow which remains constant (Kleinerman et al , 1958) This indicates a compensatory lowering of vascular resistance in the brain (see below) Similarly, an elevation of blood pressure is without effect on blood flow due to a secondary increase in resistance (Moyer et al , 1954) This autoregulation of the cerebral circulation becomes ineffective, however, when mean blood pressure falls below 60 mm Hg In this hypotensive range, a lowering of blood pressure results in a reduction of blood flow Initially, this is compensated for by increased oxygen extraction by the tissues, but at mean pressure levels of about 30 mm Hg when cerebral blood flow is reduced to about 30 ml / 100 g of tissue/min , signs of cerebral ischemia appear (Finnerty et al , 1954) Conversely, raising the blood pressure under these conditions increases blood flow, unlike in the normotensive range

As seen in Figure 3 172, several extravascular factors contribute to "cerebral vascular resistance" Intracranial pressure, exerted upon the freely collapsible capillaries of the brain is a force opposing the flow of blood Any increase in this pressure, resulting from an expansion of the contents of the rigid cranial box (such as a brain tumor) elevates cerebral vascular resistance in a direct, linear manner (Kety et al , 1948) In spite of this, cerebral blood flow does not diminish until intracranial pressure reaches very high levels (about 450 mm of water) The maintenance of normal flow is due to an increase of systemic blood pressure brought about by peripheral vasoconstriction (see pp 3-208 and 3-179) It has been suggested that the stimulus for the latter is ischemia of the medullary vasomotor center

Viscosity of the blood increases resistance to flow in polycythemia cerebral blood flow is considerably reduced, it is restored to normal levels after correcting the increased viscosity by phlebotomies (Nelson and Fazekas, 1956).

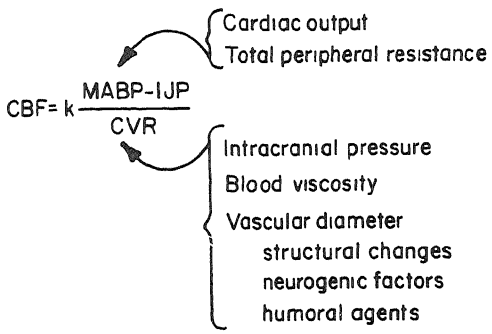

Fig 3 172 Factors determining the cerebral blood flow CBF cerebral blood flow MABP mean arterial blood pressure IJP internal jugular venous pressure CVR cerebral vascular resistance (From Kety 1958)

In anemia, on the other hand, cerebral blood flow is increased in proportion to the decreased red cell mass, transfusion produces a return to normal flow (Robin and Gardner, 1953)

The most important component of cerebral vascular resistance is the diameter of the cerebral blood vessels Their adjustment is responsible for the remarkable constancy of blood flow over a wide range of perfusion pressures, discussed above The exact mechanism of vasomotor regulation in the brain is not known Although the cerebral vessels are supplied by sympathetic fibers and norepinephrine is a powerful cerebral vasoconstrictor (King et al, 1952), there is no evidence to show that they are physiologically active in man Bilateral blocking of the stellate ganglia fails to produce any change in cerebral vascular resistance or blood flow, contrary to what might be expected if these nerves were normally contributing to the maintenance of cerebral vascular tone

RESPONSE TO HIGH CO_2

In contrast to this is the marked sensitivity exhibited by the cerebral vasculature to changes in arterial concentration of carbon dioxide and oxygen Carbon dioxide is the most powerful cerebral vasodilator known Inhalation of a gas mixture containing 5 or 7% CO_2, which raises arterial P_{CO_2} by 9 mm Hg, causes a 75% increase in cerebral blood flow Systemic blood pressure rises without any change in cardiac output, indicating a peripheral vasoconstrictor effect, but cerebral vascular resistance falls, showing the specific vasodilator action of carbon dioxide on the cerebral vessels (Kety and Schmidt, 1948) Hyperventilation, which lowers arterial P_{CO_2}, reduces cerebral blood flow

These effects of carbon dioxide are not related to associated changes in hydrogen ion concentration Intravenous infusion of sodium bicarbonate, which produces an increase of the total carbon dioxide content of the blood and a systemic alkalosis, has the same qualitative effect on cerebral vascular resistance as inhalation of 5% CO_2, which also raises total blood carbon dioxide but results in acidosis Conversely, an infusion of NH_4Cl duplicates the cerebral effects of hyperventilation both procedures reduce the total carbon dioxide content of the blood, but the accompanying pH changes are in the opposite directions (Schieve and Wilson, 1953)

The vasodilator effect of carbon dioxide is a threshold phenomenon No change in cerebral vascular resistance is detectable for arterial P_{CO_2} increases of up to 4 5 mm Hg, beyond this point there is progressive vasodilation with further arterial P_{CO_2} increments (Patterson et al, 1955) Decreasing the arterial CO_2 tension below normal produces cerebral vasconstriction, but the reduction in cerebral blood flow is proportionately less than the increase resulting from hypercapnia (Wasserman and Patterson, 1961)

In view of the pronounced cerebral vasomotor activity of carbon dioxide on the one hand, and the absence of any demonstrable neurogenic control on the other, it is logical to postulate that cerebral blood flow is regulated, at least in part, by local carbon dioxide concentrations It was calculated that a reduction in blood flow of about 30% would be required for capillary carbon dioxide tension to reach the average vasodilator threshold level of 4 5 In all likelihood, however, a reduction of this magnitude is not necessary, since under physiological conditions any increase in carbon dioxide concentration would be accompanied by hypoxia (see below)

RESPONSE TO LOW O_2

The cerebral vasomotor action of oxygen is qualitatively the direct opposite of that produced by carbon dioxide Inhalation of a gas mixture containing 10% oxygen, which reduces arterial oxygen content by about one-third, causes a 35% increase in cerebral blood flow, despite a fall in systemic blood pressure and a

decreased arterial Pco_2 and pH (due to increased pulmonary ventilation) (Kety and Schmidt, 1948) The net effect of this degree of hypoxia on cerebral vascular resistance equals that produced by the inhalation of 5 to 7% CO_2 Inhalation of high concentrations of oxygen which increase arterial Po_2, causes a reduction of cerebral blood flow, but this does not occur if care is taken to prevent concomitant hypocapnia (Turner et al , 1957)

If, as it may seem plausible, hypercapnia and hypoxia act synergistically on cerebral vascular resistance, possibly in combination with other metabolic products resulting from a diminished blood supply, this could well explain the mechanism of autoregulation exhibited by the cerebral circulation Any impairment of blood supply resulting from a drop in perfusion pressure would automatically lead to an accumulation of metabolic products which, when present in sufficient concentrations, would act to restore blood flow by producing vasodilation At the present time, however, this is still an unproved hypothesis

REGULATION OF CEREBRAL BLOOD FLOW

Whatever is the exact mechanism of cerebral vasomotor regulation, cerebral blood flow shows a remarkable constancy under a variety of physiological conditions studied so far In spite of the increased cardiac output and arterial blood pressure associated with physical exercise, cerebral blood flow remains unchanged (Hedlund et al , 1962), there may be a slight increase in cerebral vascular resistance, probably due to the concomitant drop in arterial Pco_2 secondary to hyperventilation (Kleinerman and Sancetta, 1955) Intellectual efforts, such as mental arithmetics, have no effect on cerebral blood flow (Sokoloff et al , 1955) Anxiety also seems to be devoid of influences on cerebral hemodynamics (Scheinberg and Stead, 1949) Natural sleep induces cerebral vasodilation and a small increase in blood flow without changes in arterial oxygen or carbon dioxide tensions (Mangold et al , 1955). Eating does not affect cerebral blood flow (Rowe et al , 1959) The effects of tilting from the supine to the upright position depend on the degree of tilting Moderate elevations (20° from horizontal) have no effect on cerebral blood flow (Shenkin et al , 1948), but more near-vertical positions which lower the mean arterial pressure at head level below 60 mm Hg cause, as it might be expected, a reduction in blood flow despite a decrease in cerebral vascular resistance (Scheinberg and Stead, 1949)

Cutaneous Circulation

ANATOMY

In the skin the arterioles, upon approaching the bases of the papillae (the layer of the corium immediately underlying the epidermis), turn horizontally, and give rise to metaterioles from which originate, in turn, hairpin-shaped endothelial tubes—the *capillary loops* The proximal or arterial limb of the capillary loop ascends in the papilla and then turns upon itself to form the venous limb The latter on reaching the base of the papilla joins with the venous limbs of neighboring loops to form a *collecting venule* The collecting venules anastomose with one another to form a rich plexus—the *subpapillary venous* plexus—which runs horizontally beneath the bases of the papillae and drains into deeper veins The capillary loops can be seen readily in the living skin under the low power of the microscope The vessels at the base of the human fingernail are shown diagramatically in Fig 3 173

The *color* of the skin is dependent upon the capillary loops and the subpapillary venous plexus The vessels of the plexus, though more deeply placed, present a greater area parallel to the skin, whereas the capillary loops are disposed chiefly at right angles to the skin surface When little blood is contained in the

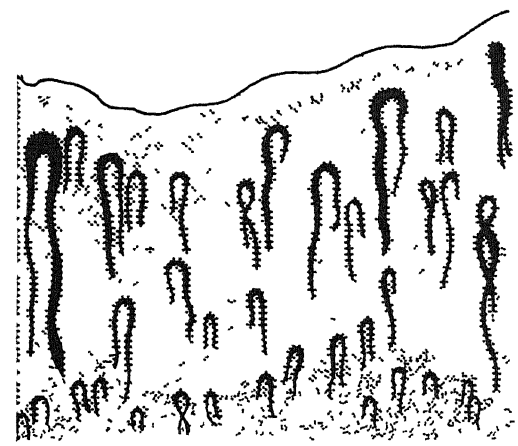

Fig 3 173 The bed of the finger nail in a healthy subject showing the capillary loops and the summits of the skin papillae (After Lewis T 1927)

superficial vessels, the skin is unusually pale and more transparent, and the deeper venous plexuses then contribute largely to the color of the skin, often adding a leaden tint to the pallor When the overlying vessels are open and the skin is well supplied with blood, these deeper vessels are hidden from view

The *hue* of the skin, i e , the dominance of the reddish or of the bluish hue, depends upon the extent to which the oxyhemoglobin becomes reduced during the passage of the blood through the cutaneous vessels The degree of reduction will depend, as a rule, upon the rate of blood flow With rapid flow, the blood is more arterial in character, with slow flow, more venous, and the color of the skin varies accordingly

CUTANEOUS BLOOD FLOW IN THE HAND AND FOOT

Only a vasoconstrictor nerve supply with adrenergic sympathetic fibers has been identified in the hand or foot, its contribution to the regulation of body temperature has been shown to be of importance The demonstration of specific cholinesterases by histochemical methods in the digital arteriovenous anastomoses suggests they may be cholinergically controlled It has also been postulated that the sympathetic nerve supply to human fingers exerts a tonic dilator influence on vessels through the release of acetylcholine The indirect evidence for this theory includes the dilation of vessels by extracts of human digital arteries, prevention of digital vessel dilation by atropine, and the presence in digital vessels of pseudocholinesterase activity

The vasodilator nonapeptide, *bradykinin*, was suggested as a mediator of cutaneous vasodilator effects associated with sweat gland activity, but the importance of this mechanism is now considered doubtful (Kellermeyer and Graham, 1968)

Body warming elicits a reflex vasodilation in the hand or foot which has been shown to correlate with a release of vasoconstrictor tone (a decreased number of impulses traveling over the sympathetic nerve fibers) The reflex may originate either in cutaneous receptors or by central nervous system stimulation The vessels themselves are also sensitive to warm temperature for the dilation following vasomotor nervous inhibition (by blocking agents) can be augmented by local heating of the hand

Arteriovenous (AV) anastomoses are communications between smaller arteries and arterioles and the corresponding venous channels, through which the blood may be shunted and capillary areas short circuited (Fig 3 174) These AV anastomoses do not appear to be under metabolic control but, rather, governed chiefly by reflex influences from temperature receptors and from central nervous system centers

CUTANEOUS VEINS

In dogs and cats, it has been shown that the superficial large and small veins of the skin have a nerve supply, undergo rhythmic changes in diameter, and respond to pharmacological agents The small veins may contract separately and independently from the large veins or arterial vessels during sympathetic nerve stimulation When the veins constrict, an increase in pressure results Thus, a reduced blood flow may occur through the vascular bed without an obstruction or constriction of the arterial tree being present In humans, forearm cutaneous vein segments, which were isolated in situ by pressure, have been demonstrated to constrict following a variety of normal and noxious stimuli The venoconstriction was blocked by chemical or surgical sympathectomy or infiltration of an anesthetic solution around the vein Venous tone was decreased during vasovagal syncope and by stroking the skin over the vein The fact that cutaneous veins constrict by cooling and are not affected by warming is evidence for the existence of only a vasoconstrictor nervous supply

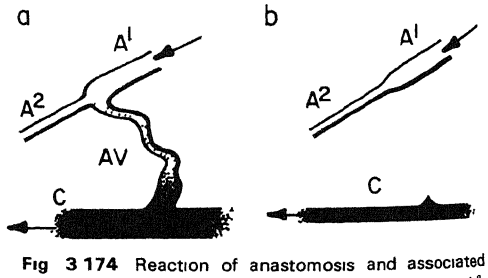

Fig 3 174 Reaction of anastomosis and associated vessels to lowering of body temperature A^1 artery, A^2 arteriole AV, arteriovenous anastomosis C vein Left figure (*a*) anastomosis open right figure (*b*) anastomosis closed (After Grant 1930)

Although active capillary constriction and dilatation has been denied, some obscure change in endothelial cells resulting in capillary dilatation has not been entirely ruled out Because skin color is thought to be governed largely by the amount of blood in venules, skin color responses are probably attributable chiefly to venular responses, but capillary dilatation is also described Therefore, in the following descriptions the term venular dilatation will be employed for changes not known to be passive effects of arteriolar or precapillary sphincter relaxation, but which may be accompanied by capillary dilatation

VASCULAR RESPONSES OF SKIN TO STIMULATION BY MECHANICAL AND OTHER AGENCIES

The White Reaction If the surface of the skin is stroked lightly with a blunt "pointed" instrument, a line of pallor appears in 15 to 20 sec which traces the path taken by the instrument The line attains its maximal intensity in ½ to 1 min , and then gradually fades to disappear in 3 to 5 min The white reaction proper is due to direct stimulation of vessel walls and has no nervous basis It has been shown to be due to the tension exerted upon the walls of the minute vessels—collecting venules and especially of the subpapillary venous plexus—which respond to the stimulus by contraction The sharply delineated character of the white line, and the fact that it can be obtained after the circulation through the region has been occluded by compression of the larger vessels, show that it is an active venular response, and not the result of arteriolar constriction

The Triple Response. This comprises *a) the red reaction, b) the flare*, and *c) the wheal*

The Red Reaction If the pointed instrument is drawn more firmly across the skin, especially of the forearm or back, a red instead of a white band appears after a somewhat shorter latent period (3 to 15 sec.), reaches its maximum in ½ to 1 min , and then gradually fades Like the white reaction it is strictly localized to the line of stroke, it is due to *dilation* of the venular vessels The red reaction can be induced in its full intensity in the skin from which the circulation has been occluded, so it is due to active dilation of the venular vessels and not merely a passive result of arteriolar dilation The red reaction is not dependent upon nervous mechanisms since it occurs after section and degeneration of the cutaneous nerves

The Spreading Flush or Flare If the stimulus is unusually strong, or is repeated often enough, the reddening of the skin is not confined to the line of stroke but surrounds it for a variable distance (1 to 10 cm) according to the intensity of the injury inflicted The temperature in the suffused area is definitely raised This flare reaction appears a few seconds (15 to 30) after the local red line, and fades sooner It is due to dilation of the arterioles and venules since it does not appear after the circulation of the part has been occluded by means of a tourniquet, also, unlike the red reaction, the flare is dependent upon local nervous mechanisms (axon reflex) It occurs after the nerves are divided but not after they have degenerated

Local Edema or Wheal When the stimulus is still more intense, the skin along the line of the injury becomes blanched and raised above the surrounding area to a height of 1 or 2 mm or even more Such a wheal or welt can be produced in a normal person by the lash of a whip and other types of strong localized stimulation In susceptible individuals, even light stimulation, such as drawing a pencil with moderate pressure over the skin of the back, will produce linear wheals surrounded by a diffuse red halo along the pencil's track In this way letters or other designs may be embossed upon the skin (Fig 3 175) This phenomenon is spoken of as *dermographism or factitious urticaria* The wheal is preceded by, but then completely replaces, the usual red reaction It makes its appearance in 1 to 3 min from the time of injury and is at its maximum height in

Fig 3 175 Dermographism (Ormsby and Montgomery 1954)

3 to 5 min It is surrounded by the flare described above The raised patch at first is clearly demarcated, but as time passes it increases in width and decreases in height, loses its sharpness and finally, although perhaps not for some hours, disappears The wheal is due to the transudation of fluid from the minute vessels involved previously in the red reaction, it is, therefore, a localized edema Increased permeability of the capillary wall is judged to be the immediate cause Wheal production does not depend upon a nervous mechanism

The triple response has been attributed to the release of some diffusible substance by the injured cells Injection of histamine produces a similar reaction, but whether histamine or some other vasoactive substance (e g , ATP, bradykinin, etc) is involved is not known

DORSAL ROOT VASODILATOR FIBERS

The dorsal root of the spinal cord contains vasodilatory fibers supplying mostly the cutaneous vessels They do not convey impulses to or from the higher central nervous system centers for control of the cutaneous circulation No true cutaneous vasomotor reflexes are seen after sympathectomy Experiments have shown that the dorsal root vasodilator fibers do not engage in the baro- or chemoreceptor control of vascular tone, nor in the regulation of heat loss from the skin The transmitter substance of these fibers is unknown but they probably act in an axon reflex arrangement to affect regional blood vessels These are probably the fibers that, upon damage to the superficial tissues, are involved in the vasodilator (flare) reaction of the triple response Any stimulus causing damage to the skin, such as severe cooling and heating, activates these fibers

CENTRAL NEURAL CONTROL OF CUTANEOUS AND MUSCLE BLOOD FLOW

The central neural control of blood flow is through the sympathetic fibers

A variety of stimuli affecting peripheral receptors elicit spinal vasomotor reflexes, the efferent limbs are the cutaneous sympathetic vasoconstrictor fibers These reflexes are usually segmentally or regionally arranged Also, in certain animal preparations, the preganglionic sympathetic neurons in the lateral horns of the spinal medulla may exhibit spontaneous activity independent of afferent stimuli

The vasomotor center located in the oblongate medulla is believed to be the primary controlling factor of cutaneous and muscle vessel vasoconstrictor tone Experiments on dogs and cats have shown that stimulation of the midline of the oblongate medulla leads to vasodilation in both skin and muscle This vasodilatory response is not blocked by atropine and, therefore, is secondary to a release of vasoconstrictor tone Stimulation lateral to this vasodilator area elicits vasoconstriction in the same regions Both these responses are absent in sympathectomized animals The vasodilator and vasoconstrictor areas may act as an integrated unit and, evidently, are primarily involved in vascular reflexes arising from the baroreceptors in the carotid sinus and aorta A decrease in blood pressure causes reflex vasoconstriction in the dog hindlimb via the carotid sinus baroreceptors while stimulation of the carotid sinus nerve induces vasodilation in skin and muscle

The vasomotor center possesses automaticity for it continues discharging impulses without apparent afferent stimuli from the periphery or higher autonomic centers The marked fluctuations from moment to moment that occur in the digital and forearm arteries and veins, and that disappear following sympathectomy, are thought to be secondary to the activity of the vasomotor center The pat

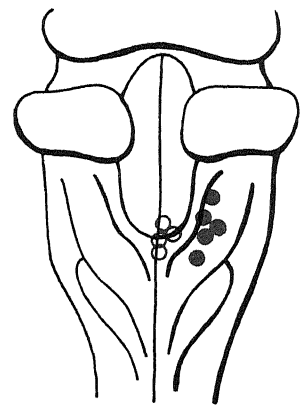

Fig 3 176 Schematic drawing of the oblongate medulla showing the situation of points yielding skeletal muscle vasodilation secondary to inhibition of vasoconstrictor tone (*open circles*) and points yielding sympathetic vasodilator discharges (*black dots*) (From Lindgren and Uvnas 1955)

terns of these continuous variations in pulse volume of the fingers, toes and ears, appear to correlate with the personality types (emotional stability or lability) of the humans studied

Stimulation of a more lateral area to the vasomotor center invokes a vasodilation in skeletal muscle through the activity of the cholinergic (blocked by atropine) sympathetic fibers (Fig 3 176) The vasodilatory area of the vasomotor center has no anatomical or apparent functional connection with these cholinergic fibers which pass through, but do not synapse in, the oblongate medulla

The anterior hypothalamus is often referred to as the "heat loss center for it controls the vasoconstrictor fibers in association with the vasomotor center Local heat applied to this area inhibits vasoconstrictor fiber discharge (vasodilation) while electrical stimulation excites the fibers (vasoconstriction) This center is thought to predominantly regulate the cutaneous vessels and, perhaps, the arteriovenous anastomoses Sympathectomy also abolishes these effects of the hypothalamus Stimulation of certain areas in the hypothalamus may elicit a vasodilation in muscle via the cholinergic fibers which synapse in this area This muscle vasodilation is often associated with a vasoconstriction of the skin

Many areas of the cerebral cortex have been found that influence, by excitation or inhibition, vasoconstrictor fiber discharge For example, stimulation of the motor or premotor cortical areas results in cutaneous vasoconstriction A muscle vasodilation also occurs but is evidently secondary to a baroreceptor reflex from a rise in blood pressure The cholinergic vasodilator fibers to skeletal muscle are also represented near the motor cortex These fibers, which probably are distributed only to muscle, synapse in the hypothalamus and mesencephalon and pass through the oblongate medulla as described above Their function in man is not completely understood, but they appear to be involved in the control of the blood flow needs of muscle and not in the regulation of blood pressure It is probable that the sympathetic vasodilator innervation of muscle is activated by emotional reactions and prepares for vigorous muscular effort

Skeletal Muscle Circulation

Resting forearm skeletal muscle blood flow has been estimated to range normally from 1 8 to 9 6 ml per 100 ml of muscle per min The blood flow in skeletal muscle is affected and controlled by a multitude of factors Many of these factors are poorly understood and their relative importance in the normal functioning of skeletal muscle is not known Investigation of skeletal muscle blood flow is performed in man by techniques similar to those outlined under skin blood flow The plethysmograph measures both the skin and muscle blood flow, the forearm is considered representative of muscle and the hand or foot, of skin because of the relative amounts of each tissue in these regions However, it has been shown that 60% of the total forearm flow may be in the skin under certain conditions The skin may be iontophoresed with epinephrine to limit or abolish its blood flow in order to obtain forearm muscle flow determinations However the depth of penetration of the epinephrine is a problem and may alter the muscle blood flow In animals blood flow may be measured by more direct methods and the results of central nervous system manipulations may be studied

NEURAL CONTROL OF SKELETAL MUSCLE BLOOD FLOW

Vasoconstrictor fibers have been shown to supply skeletal muscle by the demonstration of an increased blood flow in human forearms following nerve blocks, and by other indirect procedures The transmitter substance for these constrictor fibers is presumably norepinephrine Intra-arterial epinephrine has both a vasodilator and vasoconstrictor effect (see α, β, and γ receptors, p 3-171) on human skeletal muscle vessels, while norepinephrine has only a vasoconstrictor action Vasodilator cholinergic sympathetic fibers also supply skeletal muscle as demonstrated by a responsiveness of the bed to acetylcholine, blocking of the vasodilator response with atropine, and the results of studies performed during vasovagal syncope Despite a fall in blood pressure in vasovagal syncope, the forearm blood flow increases (and hand flow decreases) If the patient has had a sympathectomy, the forearm blood flow does not increase demonstrating that an active vasodilation via sympathetic nerve fibers had presumably occurred in the intact extremity These vasodilator fibers appear to be activated by higher brain centers as described previously and do not participate in reflex blood pressure adjustments

At present, the vasoconstrictor fibers are believed to be primarily concerned in postural and other homeostatic blood pressure adjustments When the legs of a subject are raised, an increased blood flow occurs in the forearm but not the hand This reflex has been shown to be secondary to an increased volume of blood in the thorax and an elevated central venous pressure which probably stimulates receptors in the low pressure vascular bed of the thorax Since atropine does not abolish the forearm vasodilation, it is considered to be a result of a release of vasoconstrictor tone

BLOOD GASES, pH AND IONS IN SKELETAL MUSCLE BLOOD FLOW

The effect of blood gases and pH on skeletal muscle blood flow has been referred to in Chapter 8 Studies in the dog forelimb show that many factors affect the vascular bed Arteriolar dilation is elicited by increased blood levels of potassium, magnesium, acetate, citrate, pyruvate, AMP, ADP, ATP, hydrogen ions, increased plasma tonicity and decreased calcium blood levels A decrease in hydrogen ions causes arteriolar constriction, elevated calcium concentrations or decreased plasma tonicity act similarly Combinations of low potassium, increased calcium, low magnesium, and alkalosis produce more vasoconstriction than the ions alone Changes in blood oxygen content induce only small changes in forelimb resistance Studies on isolated vessels and in denervated, adrenergically blocked limbs demonstrate that the ions act directly on vascular smooth muscle The importance of these studies is apparent when the many disease states with electrolyte abnormalities are considered

Studies in man have shown that the increase in forearm blood flow during hyperventilation (increased pH, decreased arterial P_{CO_2}) is *1)* prevented by breathing air mixtures containing 5% CO_2, 2) occurs only in muscle and not in skin, and *3)* is not abolished by blocking the nerve supply to the limb This evidence points to a humoral mechanism which causes the increased forearm blood flow by a direct action on peripheral vessels It is interesting that a similar increase in forearm blood flow is found when 5 to 10% oxygen is breathed If CO_2 is added to the latter mixture, the blood flow response is greatly attenuated Therefore the decreased peripheral resistance present in hypoxia may be secondary to hypocapnia

Inhalation of 5 to 10% CO_2 (or intravenous sodium bicarbonate) does not increase skeletal muscle blood flow unless sympathetic blockade is present Thirty percent CO_2 inhalation decreases forearm blood flow, nerve block or general anesthesia abolishes or even reverses the vasoconstriction Intra-arterial sodium bicarbonate also increases forearm blood flow Thus hypercapnia produces an *indirect* muscle vasoconstriction and a *direct* vasodilation The vasoconstriction is believed to be elicited by the effect of increased CO_2 (or decreased pH) on the carotid or aortic body chemoreceptors

A decreased pH of the blood by 0 08 units (intravenous lactic acid or ammonium chloride) or an increased pH (intravenous sodium bicarbonate) induces no change in forearm blood flow If the sympathetic nerves are blocked, an increased or decreased pH leads to an increase in blood flow, therefore a sympathetic vasoconstriction was concealing a direct vasodilation due to the local pH (or CO_2) effect

In the above studies, the separation of the effects of arterial P_{CO_2} and pH on the peripheral blood vessels is difficult In humans, local increase in P_{CO_2} or pH changes in either direction from normal produce vasodilation Systemic increases in P_{CO_2} or changes in pH in either direction induce sympathetic vasoconstriction, systemic hypocapnia causes vasodilation Data obtained in the dog hind limb does not entirely agree with these findings, the local effect of an increased hydrogen ion concentration is arteriolar dilation but a lowered pH caused by an increased P_{CO_2} has little effect Before it can be decided whether pH or P_{CO_2} is the important variable, further study is necessary It must be remembered that changing the pH of blood also affects P_{CO_2}

MECHANICAL EFFECTS ON SKELETAL MUSCLE BLOOD FLOW

When perfusion pressure is plotted against skeletal muscle blood flow (as determined in isolated muscle beds of the hindlimb of a dog), a parabolic-shaped curve is found in the upper and lower ranges (Fig 3 177), as in the skin vascular bed These two normal relationships of pressure to flow are joined in the intermediate range by a sigmoid curve (a large drop in

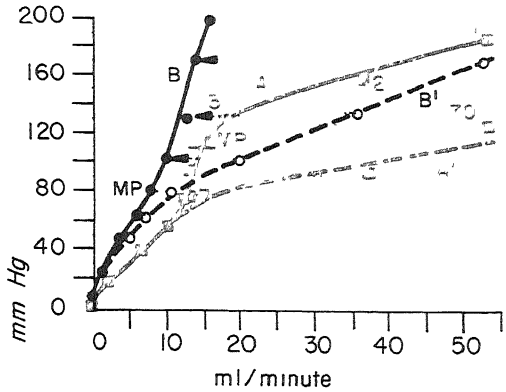

Fig 3 177 Plots of relationship between perfusion pressure and blood flow in the portion of the canine quadriceps muscle supplied by the branches of the femoral artery between the inferior epigastric and saphenous branches Plots *A* and *B* were obtained 6 hr apart in the same animal A^1 and B^1 (*dashed lines*) flow during first 2 sec of perfusion at each pressure *A* and *B* (*solid lines*) stabilized flows after maintenance of perfusion pressure for 10 to 20 sec Arrows indicate change of flow with time at each perfusion pressure MP represents the level of mean arterial pressure Ordinate scale represents the perfusion pressure in mm Hg expressed as the difference between arterial and venous pressures abscissal scale blood flow in milliliters per minute (from Green et al 1944)

perfusion pressure changes blood flow little) It is postulated that the reason for the sigmoid curve is a reactive dilation at perfusion pressures below mean normal aortic pressure to maintain blood flow to the muscular bed The two parabolic areas on the curve would represent perfusion pressures during two states of vasomotor activity of the vessels Because of the shape of the curve, changes in vasomotor activity, secondary to a variable being tested, cannot always be predicted from the perfusion pressure and blood flow

METABOLITES AND SKELETAL MUSCLE BLOOD FLOW

The skeletal muscle vascular bed is subjected to very active and widely ranging fluctuations in blood flow The idea has often been expressed that the formation of metabolites by the muscle cells is the main factor in controlling the bed Since direct stimulation of an animal's curarized muscle still elicits an increased blood flow, while motor nerve excitation does not, it is felt that the hyperemia of contracting muscle is secondary to a local physicochemical change. Also, humans with sympathectomized extremities can perform as well as those with an intact innervation Local or reflex warming or cooling has little effect on this intrinsic vasomotor tone of muscles It has been suggested that the metabolites, accumulated from the muscle cell metabolism, may act directly on the smooth muscle cells of vessels or indirectly via a local nervous mechanism, such as peripheral ganglion cells or an axon reflex The existence of ganglion cells among the muscle fibers has not been proven

In the dog muscular activity induces a dilation of the femoral artery which is mediated by an axon reflex (elicitable by acetylcholine) This mechanism, if it was shown to be present in the smaller arterial branches, could account for the vasodilation of exercise In the cat limb, post exercise muscle hyperemia is blocked by substances (cocaine, botulinum toxin) which are likely to abolish such axon reflexes The vascular reactivity is not paralyzed by these agents for the vessels continue to respond to epinephrine and acetylcholine Since botulinum toxin specifically paralyzes cholinergic nerve endings, the fibers in the axon reflex may be cholinergic However, a strong argument against this theory is that the vasodilation of exercise hyperemia is not blocked by atropine (although atropine does not block cholinergic fibers in all areas)

The role that local metabolites play in stimulating such axon reflexes is not known Anoxia, increased CO_2 tension, lactic acid, hydrogen ions, bradykinin, histamine, acetylcholine, adenosine triphosphate, adenylic acid, and potassium ions have been suggested as the local determinant eliciting exercise vasodilation Most of the metabolites have been studied by infusion into the musuclar vascular bed or by examination of venous blood leaving the muscle following exercise hyperemia Each one has received little support as the dilator agent, but a combination of two or more of these factors may provide the answer

Bradykinin has been shown to be a very potent vasodilator in skeletal muscle by plethysmography and radioisotope disappearance rates No change in oxygen consumption occurs despite the large increase in human calf blood flow However there is no evidence for the presence of bradykinin activity in skeletal muscle, the venous blood draining exercising muscle does not contain increased bradykinin

activity These results do not rule out bradykinin as an agent affecting skeletal muscle blood flow, since the half-life of bradykinin in the blood is extremely short and only biological assay methods are available for its detection

The circulation in human skeletal muscle has been studied by indirect methods during sustained muscular contraction It was found that below a certain critical strength of sustained contraction of the calf muscle, blood flow was not decreased, but, above this critical point, the vessels were evidently compressed, for hyperemia followed release of the contraction

With rhythmic contraction of calf or forearm muscles, blood flow was increased during and immediately following exercise It was felt that increased flow (vasodilator metabolite mediated) alternating with decreased flow (mechanical compression of vessels) paralleled the relaxation and contraction of the muscle Mechanical obstruction, metabolite formation, and the action of muscles on the venous flow are probably all intricately involved in the muscular blood flow of exercise It has been shown that an increase in venous pressure may alter arterial inflow to muscle The sympathetic nervous system probably does not have a significant effect on the circulatory changes during exercise, for vasodilation is similar during the after exercise in normal and sympathectomized limbs Also, the vascular bed of the exercising hindlimb of the dog becomes less responsive to sympathetic stimulation as the strength of contraction and oxygen uptake increases

The blood flow of exercising skeletal muscle in the dog, except during maximal exercise, is reduced by sympathetic nerve stimulation intra-arterial norepinephrine or epinephrine infusions, and carotid sinus stimulation However the hypothalamic vasodilator sympathetic pathway does not affect exercising muscle Both resting and active skeletal muscle show autoregulation in the dog An increased resistance occurs with a rise in perfusion pressure and vice versa, i e despite changes in blood pressure, the blood flow tends to remain stable Theories to explain autoregulation involve a myogenic responses of the vessel walls, release of vasodilator metabolites, or decreased oxygen The level of metabolic activity does not affect autoregulation, the phenomenon also occurs in denervated muscles

CIRCULATORY ADJUSTMENTS WITH EXERCISE

The changes in regional blood flow with exercise are summarized in Fig 3 178 As expected, the increased cardiac output supplies an enormously elevated skeletal muscular blood flow Skin flow increases at first, until 50 to 60% of the maximal work load is reached, then declines This increase favors body cooling But further increase in work load causes a progressive decrease in skin flow as sympathetic vasoconstrictor tone continues to rise, apparently overcoming thermoregulatory skin vasodilator responses Visceral flow (splanchnic, hepatic, and renal) decreases, cerebral flow remains unchanged, and coronary flow increases in proportion to cardiac work These findings are, in general, based on indirect determinations of blood flow applied one at a time to various vascular beds, e g , renal clearance (sect 5, chap 1) hepatic bromsulphalein (BSP) excretion, skin temperature changes, etc (see also p 3-142) However, in dogs with implanted flowmeters, renal artery flow remain unchanged while hepatic artery flow to liver and stomach and through hepatic vein decreased with short term treadmill exercise (Rushmer, 1970) Such responses appear

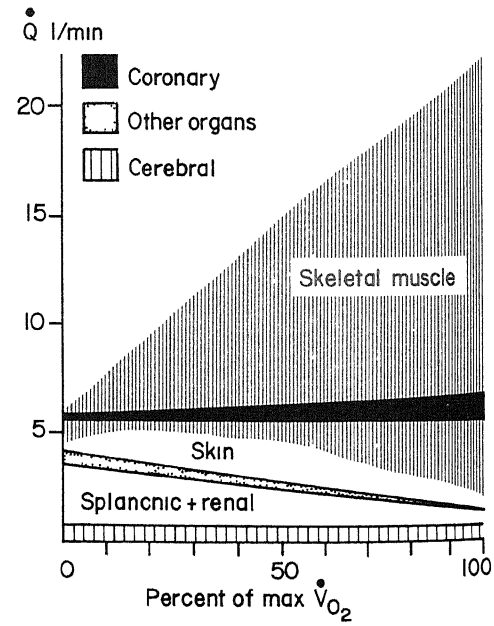

Fig 3 178 The changes of regional distribution of cardiac output as work load is increased Q̇ blood flow V̇O2 oxygen consumption as a measure of work load (Redrawn from Clausen 1969)

characteristic of short term work and brief bouts of exhausting exercise In prolonged moderate work or sustained strenous exercise, blood flow distribution to kidney, liver, gastrointestinal tract, and skin must be maintained at levels adequate for continued functions of these organs Telemetered flowmeter data (mesenteric artery, renal artery) from sledge dogs indicate no decrease in splanchnic and renal flow with prolonged strenuous exercise (Van Citters and Franklin 1969b) More work is required to reconcile various results based on findings from studies employing different methods and species At present, the consensus remains that with short term exercise abdominal visceral and renal flow decrease, cerebral flow is unchanged, skin flow increases with moderate, decreases with severe work, coronary flow increases with cardiac output, and flow to skeletal muscle increases During prolonged exercise, the elevated flow to skeletal muscle is not produced at the expense of adequate flow to abdominal viscera

Physical conditioning or training affects the cardiopulmonary and skeletal muscular systems in a variety of ways which improve work performance (Clausen, 1969) Stroke volume, blood volume, total hemoglobin, muscle capillary bed, and mitochondrial content of muscle are all increased Thus, all oxygen delivery and utilization systems involved in exercise are enlarged The capacity to increase cardiac output is elevated by the increase in stroke volume, which is reflected in lower heart rates at rest and for given work levels Muscle blood flow at a given work load is actually reduced (Clausen, 1969) This occurs because there is an increased oxygen extraction in trained muscle, made possible by an increase in oxidative mitochondrial enzymes and in the number and size of mitochondria Thus, "white" muscle fibers come to resemble "red" muscle fibers in histological appearance and enzymatically, an adaptation favoring aerobic metabolism and endurance (see p 3–35 and Tables 3 7 and 3 9) This change appears to be mediated by motor neuronal activity, i e , muscle composition is perhaps governed by the average rate of stimulation or migration of a specific trophic substance from the central nervous system, a hypothesis supported by cross innervation experiments which can cause transformation of white fibers to red and vice versa (Guth, 1968, Buller et al , 1969)

The net effect of these changes is that following physical training at a given work load myocardial and skeletal muscle blood flow can actually be reduced and less reduction in splanchnic blood flow is required for adequate muscle perfusion (Clausen, 1969) This may explain the failure to record reduction in mesenteric and renal blood flow in racing sledge dogs, as contrasted with reported decreases in splanchnic flow in exercising men not trained for endurance performances On the other hand, the microcirculatory bed to muscle is enlarged, so that greater peak flows can be attained

Thus, physical conditioning is a complex affair in which cardiac performance is improved through increase in stroke volume, reduction in heart rate, and decrease in peripheral resistance, peak muscle blood flow can be increased by enlargement of the microcirculatory bed, but the demand for muscle blood flow is relatively decreased by elevation of oxygen extraction from blood

REACTIVE HYPEREMIA

Following a period of complete occlusion of the arterial supply to a limb, the blood flow increases markedly and then returns to the control level This phenomenon has been named "reactive hyperemia " For measurement of reactive hyperemia, the blood flow in excess of that expected (the control blood flow) is usually calculated The response occurs both in skin and muscle and can be decreased in the skin by cooling, epinephrine, or tobacco smoking The amount and duration of reactive hyperemia correlate with the previous length of arterial occlusion This has been shown to be true for occlusion periods up to 10 min

The blood flow and oxygen debt incurred during the period of occlusion are calculated by multiplying the control blood flow or oxygen usage before circulatory arrest by the duration of occlusion This assumes that the blood flow and oxygen usage of the muscle would have remained at the previous control rates if the blood flow had not been occluded and that the metabolic rate of the muscle is not affected by the circulatory arrest In the isolated gracilis muscle of the dog and in the human forearm, the oxygen debt is approximately repaid for different periods of occlusion, while the blood flow debt repayment ranges from 50 to 200% of that expected

The phenomenon of reactive hyperemia has also been demonstrated in the exercising dog

hindlimb Flow debts are underpaid or barely repaid Oxygen debts are entirely or partially repaid depending upon the level of muscle performance and the duration of the ischemic period In resting muscle and during light exercise, both increased blood flow and oxygen extraction are involved in repayment of the oxygen debts but during medium and strong exercise, the increased blood flow is most important Since oxygen debts are often not repaid during strong exercise in the presence of a *decreased* arteriovenous oxygen difference, oxygen extraction is the limiting factor

The metabolites incriminated as the cause of exercise hyperemia have also been postulated as eliciting reactive hyperemia Since reactive hyperemia occurs in sympathectomized and denervated limbs, nervous system control is not considered as important The mechanical effect of the lack of pressure in the vessels during the period of occlusion has been demonstrated to play a role in the dilation If the forearm is "packed" with venous blood before the circulatory arrest, the ensuing reactive hyperemia is decreased However, the peak flow of the reactive hyperemia is not altered so that intravascular pressure cannot be the entire cause of the dilation Lewis and Grant (1925) postulated that H-substance was involved in the production of reactive hyperemia, some observers have found an increased histamine concentration in venous blood after circulatory arrest but others have not However, antihistamines do not decrease nor abolish reactive hyperemia As in exercise hyperemia the vasodilator metabolites and effects of pH cannot be ruled out by studying only the venous blood, tissue studies would probably be more informative Failure to discover the causative agent of vasodilation in muscular exercise and following arterial occlusion has been a major obstacle to the understanding of muscle physiology and the diseases involving a decreased blood supply to human limbs It seems likely that the study of aerobic and anaerobic tissue metabolism of skeletal muscle would be more profitable than blood flow studies, which evidently do not correlate with oxygen usage

ARTERIOVENOUS ANASTOMOSES IN SKELETAL MUSCLE

The question of whether arteriovenous shunts actually exist as functional units in skeletal muscle is still unsettled to most physiologists Microscopic studies on the circulation of rat skeletal muscle reveal many communications between small arteries and veins which do not enter the muscle proper During inactivity, most of the flow is through these anastomoses and not to the muscle fibers When the rats are bled in small amounts, the muscular arterioles close and flow in the capillaries ceases while it persists in the anastomotic channels However, that such communications actually function in man and possess a means of shunt regulation has not been demonstrated Indirect evidence for the existence of functional anastomoses is the decreased oxygen consumption and increased lactic acid production during vasodilation, such findings would occur if capillary flow were reduced As mentioned previously, the disappearance rate of a radioisotope from a depot in skeletal muscle is thought to represent only capillary blood flow and not shunt flow For example, during emotional stress, total forearm blood flow increases (plethysmograph) but radioisotope clearance from forearm muscle does not change Such studies have led to the concept of a dual circulation in *resting* muscle, one circulatory pathway has been referred to as "nutritional" and the other, "nonnutritional "

COLLATERAL BLOOD FLOW

When the major artery to a vascular bed is occluded, smaller vessels arising from arteries above the occlusion supply the area with blood This collateral flow may prove adequate for all functions Some patients withstand an embolic femoral artery occlusion with no adverse effects to the limb In dogs, ligation of the femoral artery rarely produces signs of ischemia Since collateral arteries function within seconds of arterial occlusion, it is thought that these vessels pre-exist, however they increase in size following arterial occlusion In patients with aortic bifurcation thromboses, aortography often reveals vessels as large as the femoral artery arising from the mesenteric arteries and supplying the limbs

In normal young subjects, plethysmographic studies of calf blood flow show that mechanical compression of the femoral artery decreases flow to one-sixth of the previous resting level with recovery to normal flow within 6 min despite continued compression The flow is non-, or only slightly, pulsatile Reflex warming of the body and ganglionic blockade

increase the collateral blood flow demonstrating that it is affected by the sympathetic nervous system Exercise of the leg usually increases the collateral flow but the increase may be due to a rise in systemic blood pressure

When the external iliac or femoral artery is acutely occluded in dogs or cats, the flow drops to one-third of the previous resting level and then gradually rises to 50 to 100% of normal In dogs with acute or chronic arterial occlusions, the blood pressure below the obstruction initially falls to low levels, but approaches normal in a few weeks

11 / SPLANCHNIC, RENAL, AND FETAL CIRCULATIONS

Splanchnic Circulation

The splanchnic circulation may be represented as consisting of three parts *1*) the mesenteric bed, supplying the gastrointestinal tract, *2*) the splenic bed, and *3*) the hepatic bed

A unique feature of this circulatory system is that the combined outflow from two of the components (mesenteric and splenic) constitutes the major portion of the inflow of the third one (hepatic), through the portal vein In its hemodynamic implications, this anatomical arrangement has been compared to the Wheatstone bridge in an electrical circuit (Bradley, 1958), because of the placement of the resistance vessels (Fig 3 179) This serves mainly to emphasize the large number of variables that influence blood pressure and flow in any one point of the system, and the potential fallacy of conclusions based upon measurements of a single variable, such as portal venous pressure

As in other regions of the circulation, it is the measurement of blood flow that presents the greatest source of difficulties Direct methods to this date can only be applied at the cost of considerable surgical and anesthetic trauma, and with various degrees of interference to flow (particularly venous flow) due to cannulation procedures This latter obstacle has been eliminated by the application of noncannulating electromagnetic flow meters (Green et al , 1959) Indirect methods, based on the Fick principle and the ability of the liver to clear certain dyes, such as bromsulphalein (Bradley et al , 1945) or colloidal substances from the blood stream, do not have these disadvantages, but—aside from their failure to meet strictly the criteria of the Fick principle—can be used only for measurement of total splanchnic outflow (i e , hepatic venous flow), not for that of its various components

MESENTERIC CIRCULATION

The nature of pressure-flow relationships in the intestinal vascular bed is controversial at the present time According to one group of investigators, the mesenteric bed behaves in a passive manner, similar to other areas such as the skin There exists a "critical closure" pressure of the order of 15 mm Hg below which flow ceases, above this point, progressive increments of pressure result in greater and greater increments of flow in other words, vascular resistance decreases with increasing perfusion pressure (Selkurt and Johnson, 1958, Hinshaw, 1962) The reasons for this deviation from Poiseuille's law are dilatation of blood vessels with increased intraluminal pressure and the opening up of "*dormant*" capillaries This view is opposed by others who find evidence for mesenteric vascular auto-regulation, such as is seen in the brain and kidney—i e , a tendency to maintain blood flow (or possibly another variant, such as capillary pressure) constant in the face of a varying perfusion pressure This implies an increase in vascular resistance as perfusion pressure is increased (Johnson, 1960, Texter et al , 1962, Folkow et al , 1963) In all likelihood, differences in experimental methods, particularly in perfusion techniques, are responsible for the conflicting results

Certain hemodynamic characteristics peculiar to the mesenteric circuit derive from the location of these vessels in the walls of viscera capable of actively or passively changing their intramural tension Isolated, perfused intestinal loops exhibit two sorts of spontaneous contractile activity rhythmic segmental contractions, and alterations of the muscular tone Each of these has a definite influence on blood flow within the loop (Sidky and Bean, 1958) During segmental contractions, there is an increase in venous outflow and decrease in arteriolar inflow, porportional to the strength of the contraction, reverse changes occur during relaxation In addition to these phasic changes associated with individual contractions, there is close relationship between mean blood flow per unit time and the frequency of rhythmic segmental activity All other things being equal, the minute volume flow increases with

increasing frequency of contractions Changes in the gut's muscular tone are of longer duration and involve greater lengths of intestine than segmental contractions An increase of tonus results in reduction of both arterial inflow and venous outflow Following cessation of tonic contraction, blood flow temporarily increases above precontraction levels, in a manner analogous to the reactive hyperemia observed in skin, skeletal muscle and myocardium (see Chap 10) Since segmental and tonic contractions occur independently from one another and may be more or less superimposed, their effect on intestinal blood flow can be quite complex If these processes observed in the isolated loop also operate in the intact animal or man, the musculature of the intestine may emerge as a factor in the regulation of splanchnic and systemic blood flow

Passive changes in intramural pressure, such as those occurring in acute distension, also influence intestinal circulation (Noer et al , 1951) It was shown in serosal vessels of rabbit's intestine, that at intraluminal pressures of 15 to 20 mm Hg, segmental contractions cease, accompanied by slowing of blood flow in the venules With progressive rising of the pressure, circulation slows, then ceases, first on the venous, then on the arterial side While such levels of intraintestinal pressures are clearly outside the physiological range, these circulatory changes are the basis of the massive trapping of blood and leakage of plasma into the wall and lumen of the gut observed during acute intestinal obstructions

In the maintenance of normal mesenteric circulation, the hemodynamic characteristics of the local vascular bed and the possible influence thereon of the intestinal smooth musculature are supplemented by a rich network of vasomotor nerves These nerves belong to the sympathetic nervous system, their preganglionic fibers are contained in the splanchnic nerves, the postganglionic fibers form large plexuses around the abdominal aorta and accompany its branches to all the viscera The function of vasomotor nerves has been discussed in detail in Chapter 8 Electrical stimulation of the splanchnic nerves in anesthetized dogs produces sharp decline in blood flow in the mesenteric artery, along with increasing the arterial (and portal vein) pressures, indicating that vasoconstriction has occurred There is no evidence for the existence of vasodilator fibers in the splanchnic nerves (Deal and Green 1956) Intra-arterially injected norepinephrine reproduces the effect of splanchnic nerve stimulation (see chap 8), while section of the nerves or administration of ganglionic blocking agents increases mesenteric flow

Vasomotor reactions in the mesenteric circuit are of considerable importance in various circulatory adjustments (see pp 3-173 and 3-174) Not all vasomotor activity, however, is necessarily mediated by the nervous system In the dog, experimental elevation of the portal venous pressure results in a reduction of mesenteric blood flow greater than the decrease in mesenteric artery-portal vein pressure gradient, indicating that mesenteric vascular resistance had increased (Selkurt and Johnson, 1958) This change in resistance is shown to be independent from nervous activity and due to "myogenic" response of the arterioles to the pressure increase transmitted through the capillaries (Johnson, 1959) It is not known what role, if any, this venous-arteriolar response plays in the intact animal

SPLENIC CIRCULATION

The nature of the intrasplenic circulation is a long-standing, unsettled controversy Lack of agreement is centered around the manner of connection between arterial and venous capillaries whether their lumina are continuous with one another ("closed circulation") or is arterial blood discharged directly into the meshwork of the splenic pulp from which it seeps back into the venous capillaries ("open circulation") The basis for suspecting a discontinuity of the circulatory bed (unparalleled elsewhere in the body) is the presence of blood cells and intra-arterially injected foreign material in the splenic pulp, seen on histological examination, this is attributed to experimental artifacts by adherents of the "closed circulation" theory Microscopic transillumination studies in the living animal (Whipple et al , 1954) suggest that both open and closed circulatory patterns function simulatenously ("combined circulation"), but it is debatable whether these observations on mouse spleen are applicable to the human organ in view of the demonstrated structural differences between the two (Snook, 1950) Pressure-flow relationships in the perfused dog spleen show a continuous drop in vascular resistance, without any plateauing, even at high pressure and flow

rates This great distensibility of the splenic intravascular space is probably due to the opening of the vascular sinuses

In certain mammals (dog, cat, horse, guinea pig) the spleen serves as a reservoir of blood Under ordinary circumstances, blood is stored in the distensible venous sinuses, to be released into the circulation when need arises (as during exercise, anoxia, hemorrhage)

Evidence indicates that this splenic emptying mechanism is under sympathetic regulation (Green et al , 1960) Stimulation of splenic nerve fibers in the dog results in simultaneous decrease in arterial inflow, increase in venous outflow, and decrease of splenic weight The inflow response can be reproduced by intra-arterial norepinephrine injection, while the outflow response can best be reproduced by injection of epinephrine This suggests the existence of separate mechanisms for the control of splenic inflow and outflow a norepinephrine-mediated arteriolar inflow constriction and an epinephrine-mediated emptying mechanism This latter might be due either to venular relaxation causing passive elastic recoil of splenic tissues, or to primary contraction of splenic smooth muscle fibers

In man, there is no evidence to indicate that splenic contractions take place under physiological circumstances, nor do injections of adrenaline raise the circulatory plasma or red cell volumes (Parson et al , 1948) as one would expect if the spleen served as an important blood depot

HEPATIC CIRCULATION

In addition to receiving its arterial blood supply through the hepatic artery, the liver is also perfused by the mesenteric and splenic venous outflow through the portal vein As pointed out earlier, this unique circulatory arrangement leads to considerable complexity of splanchnic hemodynamics, and information regarding the various factors determining blood flow through the liver is still fragmentary The following may illustrate the difficulties encountered

The hemodynamic properties of the portal venous bed of the isolated liver show a great deal of similarity to those of other vascular beds, such as the mesenteric described earlier There is, in particular, a progressive decrease of vascular resistance with increase of perfusion pressures throughout the physiological pressure range (up to 12 to 13 cm. of H_2O) This would indicate that relatively small changes of portal pressure are associated with marked flow effects and that, consequently, portal venous pressure is an important determinant of total hepatic flow

As may be seen from Figure 3 179, however, portal venous pressure is under the influence of a variety of factors Mesenteric and splenic arteriolar tone regulate inflow, while the outflow is determined by venular tone and he patic sinusoidal pressure The latter, in turn, is dependent upon hepatic arteriolar tone and

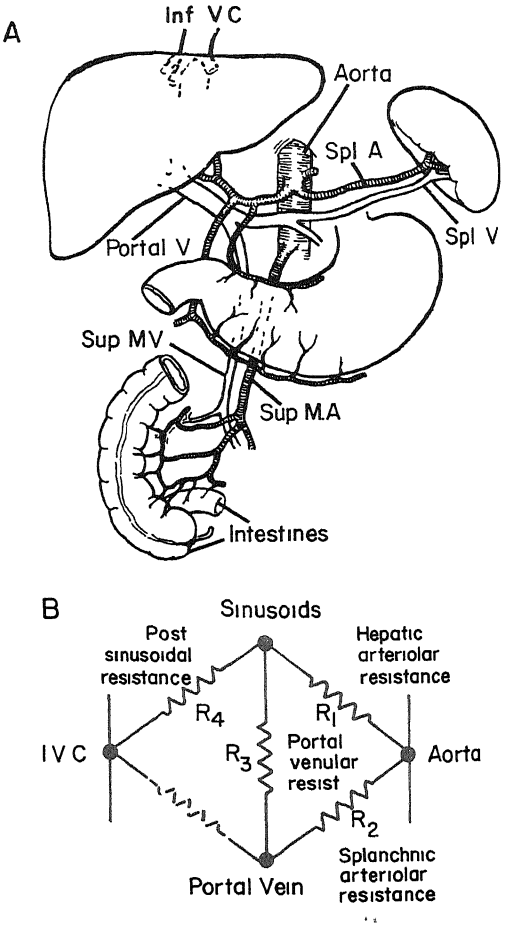

Fig 3 179 The Splanchnic circuits The vascular resistances in the splanchnic bed (*A*) are shown here in diagrammatic form (*B*) The resistances indicated are determinants of pressures in the portal vein and in the liver sinusoids and of flows through the portal vein and hepatic artery R_1 hepatic arteriolar resistance R_2 splanchnic (i e mesenteric pancreatic gastric and splenic) arteriolar resistance R_3, portal venular resistance R_4, postsinusoidal or hepatic venular resistance The dotted line represents a fifth resistance lying in the direct communications between the portal vein and inferior vena cava (From Bradley, 1958)

hepatic venous pressure (determined by inferior vena caval pressure) which regulate inflow and outflow in the sinusoids Active contractions of the portal and hepatic veins are possible additional factors all capable of altering portal venous pressure and thus influencing total hepatic flow

Experimental separation of all these variables has not been possible up to now nonetheless, certain important observations have been made

Continuous simultaneous direct measurements of hepatic arterial and portal venous flows in anesthetized dogs show the contribution of the portal vein to total hepatic flow as being approximately 65% in one study (Selkurt and Brecher, 1956), and 80% in another (Green et al, 1959) The effective portal perfusion pressures under these circumstances are 6 and 8 mm Hg, respectively Unlike the portal venous bed, the hepatic arterial system seems to possess autoregulation—i e hepatic arterial flow tends to remain constant when the perfusion pressure is varied within the physiological range (Torrance, 1961) Splanchnic nerve stimulation causes an increase in both hepatic arterial and portal venous pressures, with a concomitant reduction in the corresponding flows The calculated increases in resistance of the portal venous and hepatic arterial beds approximately equal one another, suggesting an equal degree of splanchnic vasomotor innervation Compared to the mesenteric bed, they are both less sensitive to vasomotor stimulation The effects of epinephrine and norepinephrine are similar to those of splanchnic nerve stimulation, causing, however, a less marked increase in the resistance of the portal bed Thus, even though portal vein and hepatic artery pressures increase and hepatic arterial blood flow diminishes, portal flow does not change much and may even increase (Green et al, 1959) In fact, the net effect of epinephrine in the resting, nonanesthetized human is an increase of total hepatic flow, as estimated by indirect Bromsulphalein retention (BSP) measurements, along with an elevation of portal venous pressure (Bradley et al, 1952) Norepinephrine under similar conditions causes a decrease of estimated liver flow in man (Bearn et al, 1951), while in normal, anesthetized dogs either no flow effect (Smythe et al, 1953) or a decrease in flow (Turk and Shoemaker, 1962) was observed

The hemodynamic properties of the hepatic vascular bed and the nervous and humoral controls exerted on it play an important part in circulatory homeostasis by adjusting splanchnic blood flow in response to varying body needs Blood flow through the splanchnic bed is sufficiently large to enable it to serve as a reservoir The circulating splanchnic blood volume in man at rest and in the anesthetized dog measured by isotope dilution techniques, forms approximately 20% of the total blood volume (about 1000 ml in man) (Bradley et al 1953) The total amount of blood perfusing the liver through the hepatic artery and portal vein, estimated by the BSP method amounts to approximately 1500 ml/min in man or about 20% of the resting cardiac output

CONTROL OF SPLANCHNIC BLOOD FLOW

Changes in splanchnic hemodynamics occur under various physiological and pathological conditions In man, assumption of the erect position is associated with widespread reflex vasomotor adjustments opposing the hydrostatic forces which would lower the blood pressure in the upper half of the body (see Chap 9) The splanchnic bed is an important effector end organ in these reflexes Passive tilting of human subjects from supine to upright position causes a decrease of splanchnic blood flow without similar changes of mean blood pressure, indicating that an increase in splanchnic vascular resistance has occurred (Culbertson et al, 1951) This channels blood to other vascular areas, notably those in the upper regions of the body In subjects with previous splanchnicectomy, the same tilting procedure causes arterial hypotension and a porportional decrease of splanchnic blood flow without changing the vascular resistance (Wilkins et al, 1951) This would indicate that the vasoconstriction is normally mediated through the splanchnic sympathetic nerves

Vasomotor adjustments and redistribution of circulating blood are also prominent during exercise In normal human subjects performing light exercise in the recumbent position, circulating splanchnic blood volume and splanchnic blood flow may decrease significantly (Wade et al, 1956) As exercise is usually associated with an increase in arterial blood pressure and cardiac output (see chaps 5 and 8), the reduction in splanchnic flow must be caused by increased vascular resistance The advantages for the organism of such vascular adjustments are evident, vasoconstriction diverts blood flow to

those organs that need it most (e g , the exercising muscles) Moreover, the extra blood derived from the reduction in circulating splanchnic blood volume serves to boost venous return, thereby contributing to the elevation of cardiac output (see also chap 5)

Finally, the splanchnic circulation plays an important role in the response of the organism to a reduction of circulating blood volume, such as occurs after hemorrhage This response is conditioned to a great extent by the amount of blood lost, and it may vary, accordingly, from transient vasomotor changes to a state of irreversible circulatory collapse resulting in death

It might be expected from the splanchnic responses to tilting and to exercise that blood loss would produce vasoconstriction in the splanchnic bed, in order to maintain flow in other parts of the body such as the brain and heart Actually, observations on the behavior of the mesenteric and splanchnic vasculature in response to hemorrhage are conflicting Splanchnic blood volume and flow are reduced during hemorrhage, but investigators using the BSP method for measuring splanchnic blood flow report no significant change in splanchnic resistance following removal of about one-third of the total blood volume of the anesthetized dog (Reynell et al , 1955) This would indicate that the splanchnic bed, unlike the vasculature of the skin, skeletal muscles and kidneys, does not participate in the systemic vasoconstriction following hemorrhage On the other hand, when superior mesenteric arterial flow is measured directly by means of an electromagnetic flowmeter, moderate, non-shocking hemorrhage produces an immediate increase in mesenteric vascular resistance, proportional to the magnitude of blood loss (Abel and Murphy, 1962) Removal of larger amounts of blood, resulting in irreversible shock, produces more marked but qualitatively similar changes in hemodynamic parameters The metabolic consequences, however, are quite different Splanchnic oxygen consumption is not affected by the moderate blood loss, the diminished flow is compensated for by increased oxygen extraction by the tissues (Hamrick and Myers, 1955) With more massive hemorrhage, however, blood flow is so reduced that this compensation is inadequate and splanchnic oxygen consumption falls, resulting in hepatic hypoxia. Hypoxia of the intestines and liver may be an important causative factor in determining the irreversibility of fatal hemorrhagic shock (Selkurt, 1959)

Renal Circulation

Renal circulation and renal function are so closely interrelated that reference to only one without consideration of the other always has to be artificial and incomplete Also, much of our knowledge about renal blood flow stems indirectly from the behavior of some special functions of the kidney The reader is referred to the chapter on "Urine Formation" where renal function, the anatomy and the clearance method for renal blood flow measurements are considered in detail (sect 5, chap 1)

METHODOLOGY OF RENAL BLOOD FLOW

The renal blood flow in man is usually measured by the clearance technique There are some restrictions necessary in connection with this method *1)* rapid changes in the renal blood flow cannot be detected since a single clearance period covers 5 to 15 min and gives only average values during this time, 2) determinations can be carried out only when urine is produced at the same time, since for the calculation of renal blood flow, it is necessary to know the amount of the clearance substance (usually paraminohippuric acid) which is excreted in the urine For example, in shock and in certain renal diseases, when no urine is produced, renal blood flow cannot be evaluated by this method *3)* Urine formation is also interrupted when the arterial blood pressure is less than 50 mm Hg, since the hydrostatic pressure in the glomerular capillaries is insufficient to produce a glomerular filtrate

In order to get a more exact picture of the renal hemodynamics, it was necessary, therefore, to turn to animal experiments Nearly all the direct and indirect methods for the measurement of blood flow described in Chapter 7 have been applied in these animal experiments However, these methods fail to elucidate the pattern of distribution of the *intrarenal* blood flow Methods have been developed separately to determine the blood flow of the renal cortex and medulla *1)* Under certain circumstances the accumulation rate of a substance in a tissue can be used as a measure of the blood flow This method has been applied

to the determination of blood flow to the different renal areas When radioactive albumin is introduced into the arterial circulation, the radioactivity builds up in the tissue The rate of accumulation of the radioactivity is a function of the blood flow to the region 2) Another method utilizes the translumination of the different parts of the kidney by implanted micro light sources

Regional blood flow rate is calculated by means of local blood volume and local circulation time

$$F\,(\text{ml}/100\text{ g}/\text{min}) = \frac{\text{vascular volume}/100\text{ g}}{\text{mean circulation time}}$$

Local vascular volume is calculated utilizing the ratio

$$\frac{\text{Hemoglobin concentration in tissue}}{\text{Hemoglobin concentration in blood}} = \text{vascular volume}/100\text{ g tissue}$$

To obtain mean circulation times of blood in the cortex and outer and inner medulla, dye-dilution curves in these areas were recorded simultaneously after a single injection of Evans blue or Cardio green into the renal artery (see Fig 3 180) Recordings were taken by small photoelectric probes placed on the cortical surface and on one side of the papilla or further up into a calyx Whereas in the cortex a photoelectric reflectometer was pierced under the capsule, the medullary photocells received light transmitted from a small tungsten bulb at the tip of a hypodermic needle pierced through the tissue Local mean circulation times were calculated from the dye-dilution curves

Thorburne and associates (1963) used the inert gas method in conscious dogs to determine intrarenal blood flow distribution After a single injection of ^{85}Kr into the renal artery, the disappearance curve of the gamma emission was monitored with a scintillation probe placed on the body surface above the kidney Assuming an equilibration of krypton between blood and tissue in a single passage through the capillary bed, and assuming an extremely small recirculation, the rate of disappearance from the kidney will depend upon the nutrient or capillary blood flow (F)

$$F(\text{ml}/100\text{ g}/\text{min}) = (k \times \lambda \times 100)/p$$

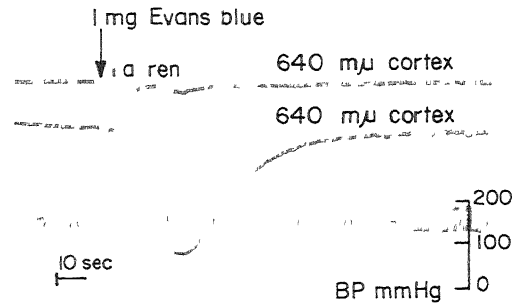

Fig 3 180 Dye dilution curves in the renal cortex and medulla of the dog after rapid injection of Evans blue into the renal artery (↓ i a ren) The passage of Evans blue was measured by small photocells which separately picked up reflected light from the cortex (*upper curve*) and transmitted light through the medulla (*middle curve*) The photocells were sensitive at the Evans blue absorption wave length (640 mμ) The lower curve represents systemic blood pressure (BP) (From Kramer et al 1960)

F = arterial inflow rate per 100 g tissue
k = slope of disappearance curve
λ = partition coefficient for the inert gas between tissue and blood
p = specific gravity of the tissue

In contrast to other organs, the decay curves obtained in the kidney are nonexponential and can be described by a series of exponentials each associated with different blood flow rates through localized regions of the kidney Four regions could be differentiated *1*) cortex, *2*) juxtamedullary cortex and outer medullary, *3*) inner medullary, and *4*) perirenal and hilar fat

NORMAL RENAL BLOOD FLOW

Under resting conditions, in the recumbent position, and with a normal mean arterial blood pressure, about 1200 ml of blood per min pass through both human kidneys, or about 20% of the cardiac output This is called the renal fraction of the cardiac output Since the average weight of both kidneys is about 300 g, normally 1 g of kidney is perfused by 4 ml of blood per min However, this value is only an average for the whole kidney since there are great differences in the distribution of the blood supply within various renal areas Blood flow values per gram of tissue have been found to be similar in dogs (4 to 5 ml /g /min) However, smaller animals have a greater renal perfusion rate Values up to 10 ml /g /min have been obtained in rats by the PAH clearance method For a better comparison of

values obtained from different laboratories, it has become the custom to express renal blood flow in milliliters per gram per minute

In the kidney, there are two capillary beds connected in series the glomerular capillaries and the peritubular capillaries They are separated by the vasa efferentia, which functionally and anatomically behave like arterioles The main resistance to flow in the kidney is divided almost equally between the vasa afferentia (preglomerular) and vasa efferentia (postglomerular), and thus the main pressure drop occurs in these segments (Fig 3 181) It has been demonstrated by micropuncture studies in the cortex of mammalian kidney that the hydrostatic pressure in the peritubular capillaries is usually 14 to 18 mm Hg, and is about the same as the hydrostatic pressure in the proximal tubules At the present time, there are no direct measurements of the hydrostatic pressure in mammalian glomerular capillaries However, by indirect calculations, this pressure has been assumed to be normally in the range of 60 to 70 mm Hg

Ever since the investigations of Wirz and associates (1951) showed the significance of the renal medulla upon the concentrating mechanism of the kidney and the functional difference of this area from the renal cortex, interest has grown in the distribution of total renal blood flow to the component parts of the kidney Up to the present, all the data on the intrarenal distribution of blood flow are the results of experiments in dogs because of the operative procedures involved in obtaining these measurements The results show that the perfusion rate in the renal cortical tissue is much greater than in the medulla (Fig 3 182), and indicate that only 1 to 2% of the total renal blood flow passes through the inner medulla This low blood flow in the inner medulla is associated with a low velocity of the blood in the vasa recta of the medulla The mean circulation time of the blood through the vasa recta is about 50 sec , and only about 2 5 sec through the cortical capillaries (Fig 3 180) On the other hand, the vascular volume in the cortex and in the medulla seems to be the same, in both areas, the vascular volume has been calculated to be about 20 to 22% of the tissue volume. More than one factor is known to cause this low velocity of blood in the vasa recta. The resistance to flow in these vessels is

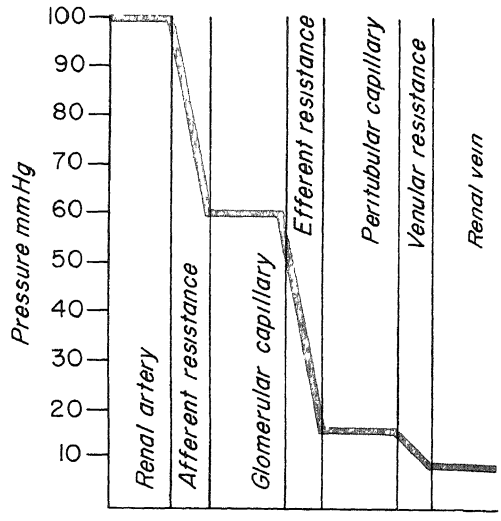

Fig 3 181 Pressure gradients in the mammalian renal circulation

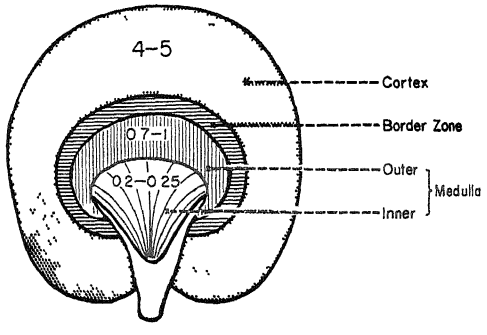

Fig 3 182 Blood flow rates (milliliters per gram per minute) in different areas of the dog kidney

very high because of the unusual length (as compared to other capillaries) of the vasa recta, which may be as long as 20 mm The composition of the blood is changed as it passes through the medulla, especially when the end urine is highly concentrated The medullary blood becomes more and more dehydrated as it reaches the tip of the papilla, by transmembrane shunting of water from the descending to the ascending limb of the vasa recta This water-shunt mechanism results in an increase of the blood viscosity Thus, the unusual length of the vasa recta and increasing blood viscosity all contribute to the low velocity of medullary blood flow Table 3 22 summarizes data on intrarenal circulation times, vascular volumes and blood flow rate

Table 3 22
Intrarenal circulation times vascular volumes and blood flow rate[a]

Source	Weight (% of Total Kidney)	Intrarenal Circulation Times[b]	Vascular Volume		Blood Flow Rates		
			ml /100 g tissue	ml /100 g kidney	ml /100 g tissue/ min	ml /100 g kidney/ min	% of total renal blood flow

INTRARENAL HEMODYNAMICS AND RENAL FUNCTION

Intrarenal hemodynamics and renal function are so interrelated that change in one will always affect the other An increase in the cortical blood flow, if correlated with elevated glomerular capillary pressure, causes an increase in the glomerular filtration rate In these circumstances, the excretion of osmotically active substances will be increased This latter effect is partially caused by an increase in the tubular load, i e , a greater amount of osmotically active substances offered to the tubules by the increased glomerular filtration rate On the other hand, in the presence of an increase in cortical blood flow, there is a concomitant increase in the peritubular capillary pressure which, by itself, may affect the total excretion by means of decreased proximal tubular reabsorption

Medullary blood flow seems to be important for the concentrating ability of the kidney In the renal medulla, the osmotic pressure progressively increases from the base to the tip of the medulla and becomes a determinant in the concentration of the final urine delivered to the renal pelvis. An increase of blood flow in the medulla tends to wash out the osmotically active substances from this area, decreasing the osmotic pressure and causing a lower concentration of the final urine In this manner, renal function is affected by primary changes in medullary blood flow and, conversely, medullary blood flow may be affected by primary changes in renal function In water diuresis, the medullary blood flow is greater than in antidiuresis The cortical blood flow and the glomerular filtration rate are unchanged under these circumstances

AUTOREGULATION OF RENAL BLOOD FLOW

The blood flow (F) in an organ is directly proportional to the arteriovenous pressure gradient (Pa-v), and inversely proportional to the resistance (R), i e , $F = (Pa\text{-}v)/(R)$ In certain organs (e g , the skin or the pulmonary circulation), when only the arteriovenous pressure gradient increases, the blood flow increases more than the increase in pressure gradient, meaning that there has been a concomitant decrease in the resistance caused by the passive distention of the vessels with pressure The pattern of behavior of the renal blood flow is different, it reacts in the manner just described at perfusion pressures only up to 90

mm Hg However, when the arterial perfusion pressure rises above 90 mm Hg, the resistance increases so that the total blood flow in the kidney remains nearly constant (Fig 3 183, curve N) Above 250 mm Hg, the blood flow again becomes directly dependent on the arterial pressure This phenomenon is known as the autoregulation of renal blood flow because it is also present after cutting the renal nerves, after injecting ganglioplegic drugs, and in the isolated perfused kidney

Simultaneous measurements of blood flow in the cortex and inner medulla of the kidney have shown that autoregulation is present solely in the cortex Since only about 1 to 2% of the total renal blood flow passes through the inner medulla, a solitary increase in medullary blood flow does not actually cause a measurable increase of total renal blood flow Therefore, in the presence of a rising arterial perfusion pressure, the total renal blood flow

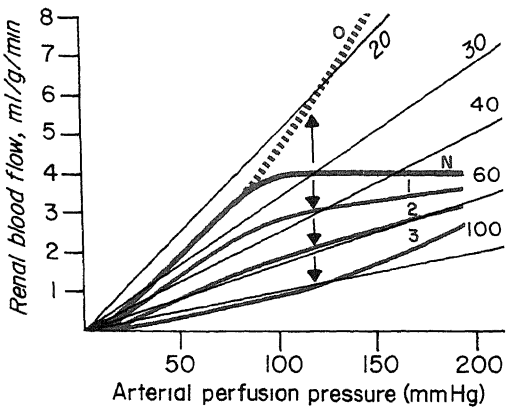

Fig 3 183 Pressure-flow curves in the kidney The thin lines through the origin of the graph represent equal resistances to flow expressed in terms of

$$\frac{\text{mm Hg}}{\text{ml}}$$

per gram per minute

Curve N pressure flow curve under normal conditions The increase of resistance above 80 mm Hg is independent of extrinsic factors (see autoregulation of renal blood flow) *Curves 1 to 3* pressure flow curves with increasing vascular tone secondary to various extrinsic factors such as increase sympathetic stimulation or epinephrine With increasing extrinsically induced vascular tone the pressure flow curves become more and more linear simultaneous to a decrease in autoregulation *Curve 0* pressure flow curve after paralyzing the smooth muscles of the renal vessels Note the abolition of autoregulation also note that under normal conditions (*curve N*), there is no myogenic tone in the renal vessels between 0 to 80 mm Hg

remains nearly constant in spite of an increasing medullary blood flow Hence, it is more accurate to limit discussion of autoregulation soley to the cortical blood flow

There are at the moment, four theories which attempt to explain this special behavior of the renal blood flow

Myogenic Theory When the arterial perfusion pressure is increased, the vessels become distended The smooth muscles, especially in the preglomerular vessels, react to this distention by shortening, thereby constricting the vessels so that a new high resistance is established This implies that the tonus of the vessels is increased by an autonomic myogenic reaction to increasing arterial perfusion pressure [1] It has been demonstrated in the dog kidney that when the arterial perfusion pressure is suddenly increased, the blood flow is only increased passively during the first 3 to 4 sec Following this, the resistance in the vascular bed increases to such an extent that the blood flow nearly ceases at about 15 sec After 20 to 30 sec the blood flow increases to the normal level of the autoregulation (Fig 3 184) This initial latency and the phasic changes of the resistance are in accord with the contracting properties of smooth muscle The autoregulation can be abolished by drugs which paralyze the smooth muscles (potassium cyanide, papaverine, and procaine (novocaine) in high concentration) Likewise, the phasic changes of the resistance, caused by rapid pressure increases, are removed by these drugs (Fig 3 184)

There are experimental indications that the autoregulatory mechanism resides within the preglomerular vessels The glomerular filtration rate is controlled, among other things, by the intraglomerular capillary pressure The constancy of the glomerular filtration rate and its independence from arterial perfusion pressure changes above 90 mm Hg, constitutes

[1] Contraction of the smooth muscles as the result of elevated intravascular pressure has been described for many vascular systems In contrast to the kidney, these myogenic reactions are not powerful enough to constrict the vessel to such an extent that blood flow remains constant in spite of an elevated perfusion pressure It is not necessarily true that the single muscle cell of the renal vessel reacts differently than in other organs A spatial arrangement of the muscle cells, specially oriented, can increase the net effect of the single cell contraction on the diameter of the vessel

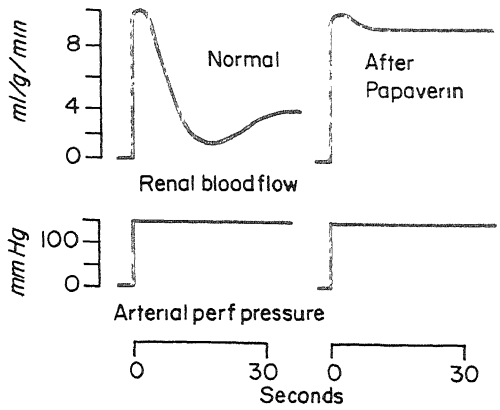

Fig 3 184 Pattern of flow in the renal artery of dogs following sudden increase in the arterial perfusion pressure from 0 to 150 mm Hg before and after vascular muscle paralysis by papaverine The phasic changes in renal blood flow in the normal kidney indicating a concomitant inverse change in resistance can be abolished by papaverine The steady state blood flow of 4 ml/g/min at 150 mm Hg in the control (autoregulated kidney) is increased under papaverine to about 9 ml/g/min (see also Figure 3 183 difference between curve N and curve 0 at 150 mm Hg) (Modified after Thurau 1959)

indirect evidence of a constant, intraglomerular capillary pressure Furthermore, by paralyzing the vascular smooth muscles with papaverine, the glomerular filtration rate now becomes directly proportional to the arterial perfusion pressure Thus, there is strong evidence to support the contention that the autoregulatory mechanism depends upon the integrity and reactivity of the preglomerular vascular muscles

Cell Separation Theory. In a vascular system in which small vessels branch off from a large one, the small vessels receive cell-poor plasma from the outer zone of blood in the large vessel, because the erythrocytes remain in the axial stream of the large vessel This separation of plasma and erythrocytes at the bifurcation of vessels is called plasma skimming or cell separation For the kidney, it is assumed that this cell separation takes place to an unusual degree at the origin of the afferent arterioles The blood remaining in the interlobular arteries becomes more and more concentrated with erythrocytes and flows through special erythrocyte-shunts directly into the veins without flowing through the peritubular capillaries, which are perfused only by cell-poor plasma The degree of the cell separation is supposed to be dependent on the arterial perfusion pressure so that blood with a hematocrit up to about 80% in the distal part of the interlobular arteries can be produced In this range of hematocrit the viscosity of the blood is high and varies greatly with small changes in hematocrit This variable viscosity which is dependent on the arterial blood pressure, is believed to be the cause of the variable resistance responsible for the autoregulation According to this theory, a cell-free perfusion of the kidney should not show any autoregulation However, it has been demonstrated by different investigators that autoregulation does occur even when the kidney is perfused by dextran, a cell-free plasma, or blood with a very low hematocrit It would furthermore, be expected that the oxygen saturation of the blood in the distal peritubular capillaries should be lower than that in the mixed venous blood However, investigations have shown that the oxygen saturation in this area is not different from that in mixed venous blood Also, the passage times of plasma and erythrocytes from the renal artery to the renal vein are the same, but, according to the cell separation theory, they should differ

Intrarenal Pressure Theory. By insertion of a 24 gauge needle into the renal tissue, it was found that the intrarenal tissue pressure measured in this way increases disproportionately with increasing arterial perfusion pressure From this data, it is calculated that the elevated tissue pressure has a clamping effect on vascular geometry and resistance to flow This assumes that the needle pressure selectively measures only normal tissue pressure and that no vessels have been ruptured by the needle insertion In any case, measurements of the intracapillary and intratubular pressures in the rat kidney by the micropuncture technique have shown that these pressures do not change when the arterial perfusion pressure is elevated above 90 mm Hg

Intrarenal Sodium Feedback Theory at the Level of the Juxtaglomerular Apparatus. The single nephron unit in the mammalian kidney is arranged in such a way that the end of the ascending limb of Henle's loop comes in direct contact with the vascular pole of its own glomerulum At the point of contact the renin-containing cells are located in the wall of the afferent arteriole The tubular cells, at the point of connection are called *macula densa cells* and are in contact at their luminal

side with tubular fluid, leaving the ascending limb of Henle's loop, and at the peritubular side with the granular cells of the afferent arteriole Goormaghtigh (1939) suggested the macula densa cells were a sensing device by which changes in concentration of the tubular fluid could regulate the renin release in the afferent arteriole Since renin is the enzyme necessary for angiotensin formation, preglomerular vasoactions could be initiated by such a mechanism Recently it was shown by Thurau and Schnermann (1965) that an increase in sodium concentration in the tubular fluid at the macular densa cells leads to a reduction in glomerular filtration rate Assuming the kidney showed no autoregulation, then the increase in arterial blood pressure would not only increase renal blood flow but also glomerular filtration rate and tubular sodium load In order not to lose the excess filtered sodium, the metabolically linked tubular sodium reabsorption in the proximal tubule would have to increase instantaneously Even if equal fractions of filtered sodium are reabsorbed in the proximal tubule, a greater amount of sodium during increased GFR would be delivered in the more distal tubular segments Sodium concentration at the macular densa cells would therefore increase and reflect the increased GFR and RBF The increased sodium concentration at the macula densa cells lowers the glomerular filtration rate by preglomerular formation of angiotensin which leads to a preglomerular vasoconstriction and concomitantly to a fall in filtration rate On the basis of this mechanism, renal autoregulation would primarily be a phenomenon which keeps sodium load as the major determinant for renal metabolism constant, and autoregulation of blood flow under normal conditions would be a consequence of such a regulation

NERVOUS CONTROL OF RENAL BLOOD FLOW

The highly developed plexus renalis contains sympathetic and parasympathetic fibers However, under normal physiological conditions, not too much is known of the significance of this rich nerve supply to the kidney The interpretation of the results of experiments with regard to the nervous control of renal blood flow is complicated by the fact that the vascular system of the kidney has an autonomous and variable tonus which is independent of any innervation (see autoregulation of renal blood flow) and may interfere with nervous vascular reactions For a better understanding of this vascular behavior, see Figure 3 183, which shows pressure flow curves resulting either from change of nervous vascular tonus or from autonomous tonus

Much investigation has been going on to gain information about the nervous control of the renal blood flow under *resting conditions* Renal blood flow has been measured before and after denervation of the kidney

In *unanesthetized* man and animals in recumbency, the renal blood flow of the denervated kidney does not differ from that of the innervated kidney This implies that under resting conditions there is no sympathetic nervous influence in the renal vascular bed Furthermore, the nonexistence of a sympathetic tone of the renal vascular bed, under resting conditions, has been confirmed by animal experiments in which depressor reflexes in the systemic circulation were produced Stimulation of the reflexogenic areas of the carotid sinus and aortic arch causes vasodilation in the kidney only when a sympathetic tonus of the renal vessel has been *previously* produced by asphyxia or by anesthesia

In anesthetized animals, it has been shown that the renal blood flow may increase after denervation, but, since the sympathetic tone in the peripheral vascular bed is usually augmented during anesthesia, the denervation, therefore, eliminates only the unphysiological sympathetic stimulation produced by the anesthesia, and thereby permits return of the blood flow to normal values Accordingly, in a dog where one kidney is denervated, the renal blood flow decreases only in the innervated kidney during pentobarbital injection The blood flow of the denervated kidney shows no change

Neurogenic vasoconstriction of the renal vessels is produced by severe hypoxia, i e , arterial oxygen saturation below 50% However, in the range of decreasing arterial oxygen saturation between 100 and about 50%, there seems to be no change in renal blood flow, and this is true either in anesthetized dogs or in unanesthetized man The vasoconstrictor effect of severe hypoxia can be eliminated in the dog by abolishing the chemoreceptors in the carotid sinus and aortic arch, indicating that the constrictor response to hypoxia is induced by stimulating the peripheral chemoreceptors.

Vasconstriction in the dog kidney also occurs during hypercapnia while breathing a mixture of 5 to 30% CO_2 in oxygen In these experiments, the pH of the blood simultaneously decreased from 7 49 to 7 21 Since the constriction is abolished by renal denervation hypercapnia and this degree of acidosis seem to produce only neurogenic rather than local vasconstriction

A decreased discharge rate of the pressoreceptors in the carotid sinus or aortic arch in dogs, caused by lowering the intrasinusal or intra-aortic blood pressure, or by damping the pulse pressure in these areas, leads to neurogenic vasoconstriction in the kidney as well as in other organs

In connection with the nervous control of the renal blood flow, the question also arises as to whether or not there exists a nervous control of the function of the tubular cells After denervation of the kidney, an increase of sodium excretion is often found, suggesting a decreased absorptive capacity of the tubular cells However, in nearly all these experiments, the glomerular filtration rate simultaneously increased It is well known that this increase of the glomerular filtration rate can cause an elevated sodium excretion without altered tubular function Moreover, those experiments in which the excretion of electrolytes was increased *without* a corresponding increase in the glomerular filtration rate, by no means prove a primary changed tubular function after denervation As yet, it is still unknown whether changes of the intrarenal distribution of blood flow occur after denervation since, for example, even small changes in medullary blood flow can affect the composition of the end urine

EXERCISE, POSTURE AND CENTRAL BLOOD VOLUME EFFECTS ON RENAL BLOOD FLOW

In the upright exercising man, renal blood flow is diminished when compared to blood flow under resting conditions while supine If, however, exercise is performed in recumbency, the blood flow in the kidney remains nearly unaffected Also, the dog, which usually does not change its posture during exercise, shows no change in renal blood flow when running 5 6 to 10 m.p h at a 15° slope on a treadmill

These findings give rise to the supposition that the upright position per se, in which exercise is usually performed leads to the decrease in renal blood flow Indeed it has been found that the usual response on changing from the recumbent to the standing position is a decrease in renal blood flow Under the extreme conditions of prolonged standing, the renal blood flow may decrease by about 50% of the control value These changes are accompanied by similar reductions in glomerular filtration rate and urine output Since the arterial blood pressure is changed little or is unchanged, the reduction in renal blood flow is primarily caused by an elevated resistance to flow This is only part of a generalized elevation in total peripheral resistance secondary to the upright position This enhanced peripheral resistance is caused by an augmented neural vasoconstriction rather than by a humoral mechanism The afferent mechanisms involved are poorly understood, but it is believed that this can be effected through reduction of central blood volume The central blood volume in the thorax can be reduced to subnormal values by means of positive pressure breathing It has been shown, that under these circumstances, the renal resistance to flow increases Since the blood volume in the chest is also diminished in the upright position, this reduction in central blood volume, induced by changing from the recumbent to the standing position, may be one factor involved in the renal constrictor mechanism Conversely, an increase in central blood volume above normal by blood infusion, tilting of the body to the head down position, or negative pressure breathing, should produce a neurogenic vasodilation in the kidney But, as pointed out in the preceding section on nervous control of renal blood flow, under normal resting conditions there are *no* sympathetic discharges to the renal vessel, and hence a neurogenic vasodilation is nonexistent It is not surprising, therefore, that an increase in central blood volume fails to result in a renal vasodilation However, there is another interesting effect of an increased central blood volume upon the kidney which should be briefly mentioned here It has been found that elevation of central blood volume simultaneously increases the urine output Since renal blood flow and also the glomerular filtration rate are not altered under these conditions, and, since the resultant diuresis is caused primarily by an increased free

water excretion (i e , without concomitant excretion of osmotically active substances), there is strong evidence that an increase in central blood volume inhibits antidiuretic hormone (ADH) secretion of the neurohypophysis It is suggested that this ADH-inhibition is reflexly induced by stimulation of stretch receptors located predominantly in the left atrial wall and sensitive to an increase in central blood volume (see also p 3-186)

Returning to the discussion renal blood flow during exercise in man, there is no doubt that the change to the upright position per se is one factor involved in the decreased renal blood flow But, reductions in renal blood flow down to 20% of the control value, as measured in severe exercise in man, can hardly be explained by this orthostatic mechanism alone It is a matter for further investigations to establish the other factors which determine the changes in renal blood flow during exercise

EFFECT OF SOME PHARMACOLOGICAL AGENTS UPON RENAL CIRCULATION

Epinephrine and *norepinephrine* both have powerful vasoconstrictor effects upon the renal vessels Each drug acts upon smooth muscles, and its action can be abolished by adrenergic blocking agents Single intravenous injection of 2 μg /kg of epinephrine causes complete cessation of renal blood flow During continuous intravenous infusion of low doses (10 to 15 μg /min) of epinephrine or norepinephrine in man, there occurs a 30% decrease in renal flow without change in the glomerular filtration rate The result indicates that low concentrations of the pressor agents predominantly produce efferent arteriolar constriction Since the systemic arterial pressure is concomitantly elevated, a small rise in resistance must also occur in the afferent arterioles or, otherwise, there would occur an increase in the glomerular filtration rate Similar results have been found in the denervated kidney in man The effect of 2 to 10 μg /min of l-norepinephrine, given intravenously, has been studied in the homotransplanted kidney of an identical twin recipient and in the innervated kidney of the donor In both kidneys the renal blood flow decreased 25%, when given 2 μg l-norepinephrine, and 50%, when given 10 μg , without changes in the glomerular filtration rate, revealing the similarity in the response of the innervated and denervated kidney to l-norepinephrine in unanesthetized man Despite the decrease in renal blood flow following minute doses of epinephrine, there occurs a moderate swelling of the kidney Experiments in dogs have shown a simultaneous increase in renal blood volume It has, therefore, been concluded that an increase in resistance to flow also occurs in postcapillary segments (probably venular) which leads to an elevated intracapillary pressure and a resultant distention of the renal capillaries

Pitressin is an extract of the posterior pituitaries of oxen and hogs with an antidiuretic-vasopressor action Infusions of 1 to 2 mμ/kg /hr, with which significant antidiuretic effects can be produced, have no effect upon the renal blood flow in man Higher, nonphysiological doses increase the resistance to flow in the kidney by direct action on the renal vessels Repeated injections elicit tachyphylaxis

The injection of *serotonin* (5-hydroxytryptamine) into the renal artery in dogs, produces constriction of the renal vessels This constrictor effect has been shown in innervated as well as in denervated kidney and persists after the application of sympatholytic agents Thus, serotonin probably acts directly on the smooth muscles However, *intravenously* injected serotonin may be followed by a renal vasodilation reflexly induced by the action of this drug upon depressor receptors whose afferent fibers arise within the chest and are mediated through the vagus nerve In patients with malignant carcinoid, the urinary excretion of serotonin or its metabolic products is elevated secondary to the high circulating blood level In these patients, the glomerular filtration rate and renal blood flow are usually diminished

1-Hydrazinophthalazine (Apresoline) produces a vasodilation in the kidney which persists for hours following a single injection The mechanism of the vasodilatory effect is still unknown It seems that Apresoline has no direct paralyzing effect upon the renal vessels since injection into the renal artery produces an initial vasoconstriction, followed in several minutes by the onset of vasodilation, the latter becoming more marked during the next 30 min and persisting for 2 to 3 hr

REACTIVE HYPEREMIA

In both cardiac and skeletal muscles, and in some other organs, the blood flow temporarily increases over the control value after releasing an arterial clamp This overshoot of blood flow, lasting from several seconds to several

minutes, depends upon the duration of occlusion and may exceed the estimated blood flow debt incurred during the occlusion period If the term reactive hyperemia is restricted to this overshoot, then by definition, the renal circulation does not show this phenomenon After releasing an occlusion of the renal artery there occurs a brief 3- to 5-sec overshoot of blood flow (Fig 3 185), which however is independent of the duration of occlusion and is, in no instance, greater than the estimated blood flow debt Furthermore, after interruption of the renal blood flow for several minutes, the re-established blood flow, following the initial overshoot, usually decreases temporarily to subnormal values

HYPOTHERMIA AND RENAL BLOOD FLOW

At the onset of the cooling phase, as the body attempts to maintain a normal temperature (shivering phase), the renal blood flow increases 20 to 45% above the control value This has been observed utilizing para-aminohippurate (PAH) clearances in both anesthetized and unanesthetized man and animals This initial increase in renal blood flow can be abolished by inhibiting shivering with d-tubocurarine As the rectal temperature falls below 32° C (90° F), the renal blood flow progressively decreases and, at 27° C (80° F) is only 50% of the normal value This decrease in blood flow is also observed in the isolated dog kidney which was perfused by cooled blood, and in which the renal blood flow was directly measured A major part of the decreased blood flow is caused by an increased resistance related to the augmented viscosity of cooled blood, but this factor alone, however, is insufficient to explain the degree of change in blood flow It is still unknown which other nervous or humoral factors are involved

Regional cooling such as the immersion of an extremity into ice water for some minutes, sufficient to produce a painful sensation, in man is attended by a 20% decrease in renal blood flow This is probably caused by a nervous reflex, stimulating sympathetic discharges to the renal vessels

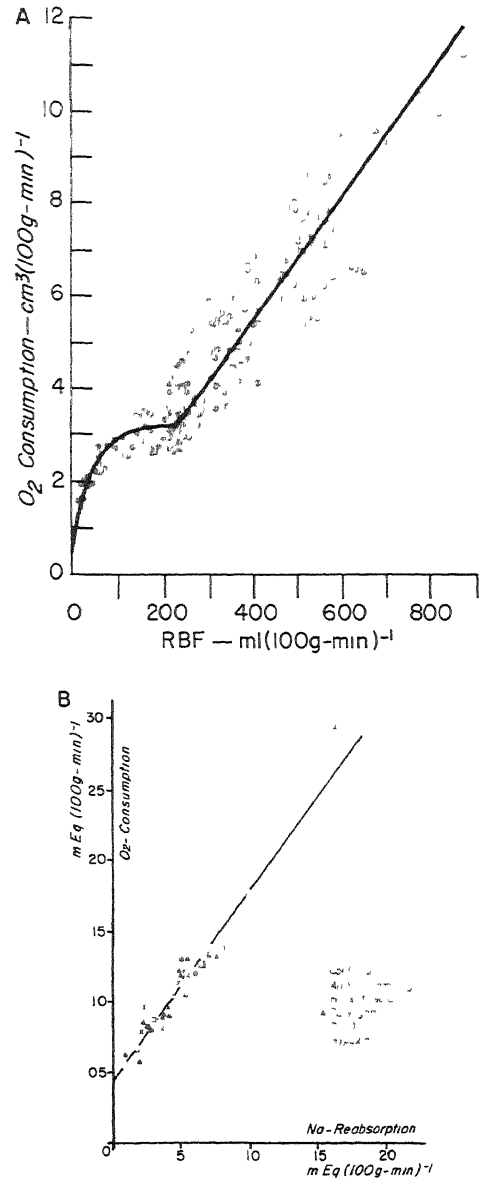

Fig 3 185 Correlation of renal oxygen consumption with renal blood flow (A) and tubular sodium reabsorption (B) Note the exponential increase of oxygen consumption at low renal blood flow values Sodium reabsorption was varied by decreasing glomerular filtration rate (aortic clamp) hypertonic sodium chloride infusion saluretic drugs and hypoxia (From Kramer and Deetjen 1961)

ARTERIOVENOUS OXYGEN DIFFERENCE AND OXYGEN UPTAKE OF THE KIDNEY

The oxygen difference between arterial and venous blood in the human kidney (AV oxygen difference) is about 1 7 ml /100 ml of blood, which is small compared with an AV oxygen difference of 4 to 5 ml /100 ml of blood between arterial blood and mixed venous blood of the right heart From the renal AV oxygen difference and the total renal blood flow (1200

ml /min), the oxygen uptake of both human kidneys is calculated to be about 21 ml /min In isolated dog kidney, as well as in dogs' kidneys in situ, the AV oxygen difference has been found to be fairly constant in spite of renal blood flow changes, which means that the oxygen consumption in the kidney parallels the blood flow

The observation of Zerahn (1956) that the oxygen uptake of an isolated frog skin above a resting level is proportional to active sodium transport, paved the way for an explanation of the direct relation between RBF and oxygen consumption It is well established that renal sodium reabsorption is an active process and represents the overwhelming fraction of all tubular processes Since under normal conditions, GFR varies with RBF, tubular sodium reabsorption is high at high RBF and accounts for the elevated oxygen consumption (see Fig 3 185) The constant AV difference of oxygen only above 60 mm Hg BP is consistent with the onset of glomerular filtration at this range of BP, whereas below this pressure the AV difference of oxygen is inversely correlated to RBF as in most other organs It is clear that a direct correlation between RBF and oxygen consumption is only obtained as long as GFR changes with RBF In osmotic diuresis and during ureteral occlusion oxygen consumption is lowered at an increased RBF since GFR is diminished

The AV oxygen difference in the renal medulla of anesthetized dogs has also been indirectly calculated by means of the oxygen tension of the final urine, which is assumed to be in equilibrium with the medullary venous blood Usually, the oxygen tension in the urine is less than in the mixed renal venous blood and in these experiments, the difference during air breathing was 25 ± 3 mm Hg Thus, by this method, the AV oxygen difference in the medulla has been calculated to be 8 5 ml /100 ml of blood, which would indeed be very high However, there are indications that oxygen pressure in the medulla may also be influenced by the counter-current exchange mechanism In this case, oxygen pressure would progressively decrease to the tip of the medulla by transmembrane shunting of oxygen from the descending to the ascending limb of the vasa recta The low oxygen tension of the final urine would represent only the low oxygen pressure at the tip of the medulla rather than the oxygen pressure of the medullary venous blood and, therefore, could not be used for calculations of the medullary AV oxygen difference

CONCLUSIONS

Renal hemodynamics exhibit certain peculiarities which need re-emphasis Under basal conditions, there exists no neurogenic tone in the renal vessels, and the kidney is protected against elevations of arterial blood pressure by an autonomous mechanism which usually maintains the cortical blood flow, the glomerular filtration rate and the intrarenal capillary pressure at constant levels A neurogenic vasodilation is generally nonexistent and only vasoconstriction can be produced via the nervous system Renal hemodynamics are poorly understood solely by using measurements of *total* renal blood flow The renal artery supplies blood at varying flow rates to the differently functioning areas, and function and blood flow seem to be mutually interdependent, this has only been demonstrated in animals The human kidney, however, still holds secret its distribution of intrarenal blood flow

Fetal and Neonatal Circulation

In Figure 3 186, diagrams of the fetal, transitional (neonatal) and adult circulations are shown In the fetus, the left and right heart halves act essentially as parallel pumps, discharging blood into the systemic and placental circuits Blood from the right heart largely bypasses the lung circulation by flowing through the *ductus arteriosus* into the aorta In contrast, the two sides of the heart in the adult pump chiefly in series, blood passes sequentially through the right heart and pulmonary circulation to the left heart and systemic circulation It is only after birth that a large pressure differential develops between the pulmonary and systemic arterial systems Consequent to this the relative work load (pressure × volume) of the left heart is increased greatly over that of the right This difference is reflected in the relative masses of the adult left and right ventricles (about 2 1) The transition from fetal to adult circulatory patterns is accomplished by functional and anatomical closure of fetal flow paths (*ductus arteriosus, foramen ovale, ductus venosus*), expansion of the pulmonary circuit with expansion of the lungs,

and interruption of the placental circulation Failure of *ductus arteriosus* or *foramen ovale* closure are frequent congenital cardiac defects with hemodynamic consequences proportional to their degree of ultimate patency Functional closure of these fetal bypass routes is almost complete in the early neonatal period, but anatomical closure requires weeks or months (Fig 3 187)

CIRCULATION IN THE FETUS

The placenta serves as the "fetal lung" and access port to the maternal circulation for uptake of nutritional substances and excretion of metabolic wastes The major circulatory circuitry of the fetus is diagrammed in Figure 3 186 (*upper*)

Most studies on the physiology of the fetal and neonatal circulation have been carried out on sheep and goats These species differ from man in having two umbilical veins rather than

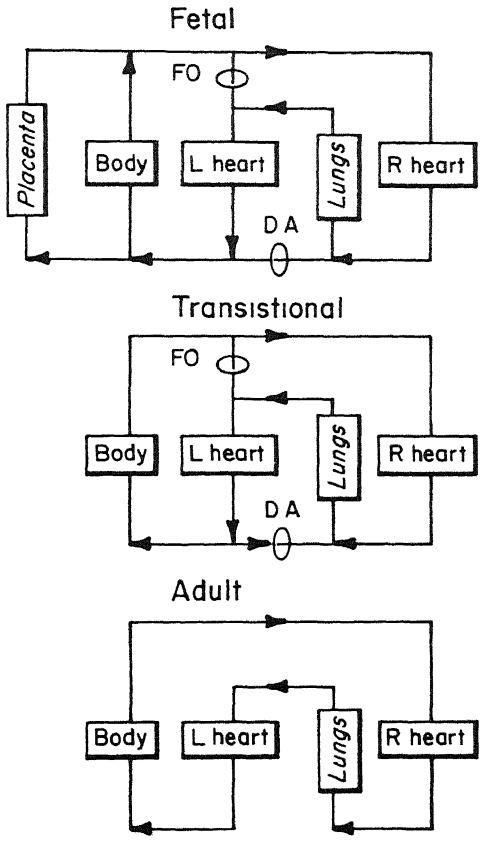

Fig 3 186 The fetal transitional (neonatal) and adult types of circulation (Redrawn from Dawes, 1968)

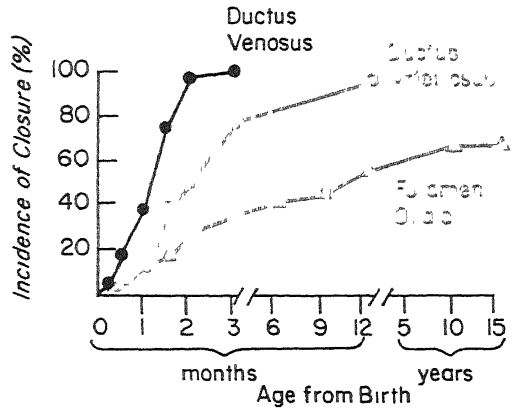

Fig 3 187 Anatomical closure of the special vascular channels of the fetus after birth (Redrawn from Dawes 1968)

one They possess cotyledonary placentas and have a relatively smaller brain Results and interpretations reported in the literature contain unresolved differences in certain details (Dawes, 1968, Assali, 1968)

In the fetus, the combined outputs of the left and right ventricle are about equally divided between the placenta and fetal membranes and the body of the fetus itself These two circulations are arranged in parallel (Fig 3 186 *upper*) and the following percentage distributions of flow have been calculated from data on lambs (Dawes, 1968)

Placenta and fetal membranes	57%
Fetal lungs	10%
Foreparts of the body	15%
Hindparts of the body	18%

The blood circulating through the placenta, enters with an oxygen saturation of about 58% and returns in the umbilical veins 80% saturated (contrasted with 98% oxygen saturation of maternal arterial blood) The fetal *ductus venosus* carries some of this blood directly into the inferior vena cava, bypassing the liver Blood from the lower trunk and extremities (26% saturated) and from the liver flow together with the umbilical vein blood in the inferior vena cava.

Anatomically, the foramen ovale opens directly off the inferior vena cava so as to favor flow of blood into the left atrium There is evidence that the edge of the interarterial septum, the *crista dividens*, divides the inferior vena cava blood into two unequal streams According to this view the larger stream is

composed mainly of umbilical vein blood and is shunted through the *foramen ovale* into the left atrium The smaller stream mixes in the right atrium with superior vena cava blood from the upper body and with blood from the heart This less saturated blood largely passes into the right ventricle and is pumped out the pulmonary artery Pulmonary arterial resistance is relatively high, the pressure about 5 mm Hg above that in the aorta and, consequently, more than two-thirds of right ventricular output flows through the *ductus arteriosus* into the aorta This blood enters the aorta at a point distal to the origins of the arteries to the head and upper limbs, and is thus directed to the posterior body and umbilical arteries The larger stream of highly oxygenated blood from the *foramen ovale* and blood entering the left atrium from the pulmonary veins mix and are pumped out of the left ventricle into the ascending aorta This blood reaches the arteries supplying the upper extremities and head before mixing with the highly desaturated blood from the *ductus arteriosus* and about one-third of it passes to the upper body Insofar as this separation of inferior and superior caval flows takes place, the greater will be the percentage of oxygenation of the blood reaching the upper body and brain However, a difference in percentage oxygen saturation of carotid and descending aortic blood is not always found experimentally and fetuses with cardiac malformations preventing such separation, survive to term

Fetal hemoglobin has a greater affinity for oxygen than adult hemoglobin so that at equal oxygen tension fetal blood carries more oxygen than maternal blood Also fetal tissues are more resistant to hypoxia than are adult These two factors make possible adequate oxygen supply to fetal tissues, despite a relatively low oxygen tension in blood leaving the placenta

CHANGES AT BIRTH

With separation from the placental circulation, the peripheral resistance rises and asphyxia develops in the infant The pressure in the aorta rises and gasping respiratory movements expand the lungs Constriction of the muscular umbilical veins squeezes up to 100 ml of blood into the fetal veins ("placental transfusion") and ventilatory movements aid venous return. With lung expansion, pulmonary blood flow increases as pulmonary vascular resistance falls below one-fifth the *in utero* value Pulmonary venous return to the left atrium increases left atrial pressure over right atrial pressure and the valve of the *foramen ovale* is closed In response to the increased blood oxygen tension in blood flowing through the *ductus arteriosus* the smooth muscle constricts and the *ductus* is narrowed Aortic pressure now exceeds pulmonic artery pressure and flow through the *ductus arteriosus* is reversed This is the transitional (neonatal) state of the circulatory system Functional closure of the ductus is complete within 1 or 2 days after birth Anatomical closure of the *foramen ovale* and *ductus arteriosus* may take several weeks (Fig 3 187) However, normally there is little flow through these channels after the first few days With complete closure the adult separation of pulmonary and systemic vascular systems is accomplished (Fig 3 186, *lower*) with the two halves of the heart pumping in series The only shunt remaining in the adult is that through the bronchial artery and capillary system from which a small amount of blood returns to the left heart via pulmonary veins, without having gone through the right heart

SUMMARY

Fetal circulation is especially arranged to meet the needs of a rapidly growing organism living in a state of relative hypoxia These requirements include high cardiac output, partial bypass of the lung circulation, and high placental blood flow At birth, the fetus abruptly becomes an air-breather, hypoxia disappears, blood-gas exchange occurs in the lungs and the large placental flow is abolished As a result cardiac output is reduced, pulmonary artery pressure drastically declines, and the two sides of the heart function serially, rather than in parallel Blood oxygen tension is the chief determinant of the pattern of fetal blood flow distribution and the changes in this distribution which occur at birth

The *ductus arteriosus* permits up to 70% of the right ventricular output to enter the aorta and thus provides a major source of blood which flows to the posterior fetal body and placenta Because of the parallel arrangement of left and right ventricles in the fetus, both contribute to the high systemic flow required for the fetus and placenta

Blood flow to the lungs is minimal because

of the differential effect of low oxygen tension on lung vessels and *ductus arteriosus* Hypoxemia dilates the latter and constricts the former, thus favoring flow away from the collapsed fetal lungs where peripheral resistance is high and toward the aorta (and placenta) where peripheral resistance is low At birth the reciprocal effect of increased oxygen tension on *ductus arteriosus* and lung vessels results in constriction of the former and dilatation of the latter, pulmonary vascular resistance also decreases owing to expansion of the lungs with the onset of breathing Interruption of the placental circulation increases peripheral resistance in the systemic circuit Thus, pulmonary peripheral resistance and arterial pressure decrease, arterial peripheral resistance and pressure increase, shunting of blood from pulmonary artery to aorta through the ductus arteriosus is curtailed, reverses and finally ceases and cardiac output decreases

The primary function of the *foramen ovale* is probably not as was once thought to shunt highly oxygenated blood to the left ventricle aorta and head but rather to supply blood to the left ventricle, insuring that it works mechanically and develops adequately to accomodate the abrupt increase in work load at birth

The function of the *ductus venosus* is uncertain and this structure is absent or disappears early in fetal life (horse, pig) in certain species The concept that it supplies a route for direct return of highly oxygenated umibilical venous blood unmixed with fetal venous blood, is not supported by recent studies (Assali, et al 1968)

Blood and Lymph

PREFACE

In this section on the blood and lymph these fluids will be treated in respect to their transport of nutrients, waste products, chemical communications system, cellular and humoral defense system, and the means by which the milieu intérieur of Claude Bernard is maintained. In developing the function of the blood and lymph which interconnects all tissues of the body through the vascular system, the regulation of the fluctuating steady-state systems through feedback loops will be considered. Many of these feedback loops are considered in detail in the other chapters involving the kidney, lungs, brain, and endocrines. Only those that relate directly to those elements of the blood will be considered. The general plan of attack will focus on the functions related to the red cell, the granulocytic leukocytes, the lymphoreticular system, megakaryocytic-platelet system, the proteins related to blood coagulation and hemostasis, and the humoral aspects of immunity. The nature of the steady-state cell proliferation will be developed conceptually with reference to how it is studied and controlled.

BLOOD AND LYMPH

Blood: Composition and Functions

Phylogenetic and ontogenetic study of species indicates that life commenced in some simple form in a primitive sea, and evolved from single organisms to the complex Metazoa Single cell organisms such as Protozoa and bacteria exist primarily in a fluid medium Such organisms acquire small molecules required for metabolism by direct diffusion from the environment through membranes and into the cell Diffusion is a two-way street with products of metabolism diffusing outward In some, if not all organisms, in addition to diffusion, material is ingested by phagocytosis and pinocytosis The ingested material is incorporated into phagocytic vacuoles into which hydrolytic and oxidative enzymes are injected breaking down offensive material or particulate nutrients to simple products that can then be either excreted or utilized in the general metabolism of the cell

As organisms progress from single cell to multicellular organisms with complex structure, diffusion, pinocytosis, and phagocytosis are inadequate to provide the small molecular needs of each cell Tubules, propulsion systems of cilia, and ultimately a pump with a closed circulatory system develops and transports nutrients and waste products As complex structures that break down incoming food develop, the biochemical, structural, and transport systems become increasingly complex Each segment of the increasingly complex system undertakes specific and multiple functions and so maintains the internal environment within the range permissible and compatible with life irrespective of the external environment

In the mammal, the blood performs various specific functions

1) Respiratory. An essential function is the transport of oxygen from air in the lungs to the tissues, and the carbon dioxide from the tissues to the lungs

2) Nutritive. Blood conveys food materials, glucose, amino and fatty acids, vitamins, electrolytes, and trace metals from the alimentary canal to the tissues

3) Excretory Blood transports the waste products of metabolism such as urea, uric acid, creatinine, etc

4) Homeostasis of Water, pH, and Electrolyte Concentration. There is constant exchange of all molecules in the body between blood, interstitial fluid and cells These exchanges are in dynamic equilibrium With the exception of deoxyribonucleic acid (DNA) in the nondividing cells, all constituents of cells are in a continual steady-state turnover at different rates This turnover is mediated through the blood being in direct contact with cells through the interstitial fluid and lymph

5) Regulation of Body Temperature A major function of the blood is heat transport This is essential to the preservation of the very narrow range in body temperatures that is compatible with life This is considered in greater detail elsewhere in this text Water is pre-eminently fitted to fulfill the purpose of heat transport

1) High Specific Heat The specific heat of a substance is defined as the number of calories required to raise 1 g of the substance 1° C The specific heat of water is much higher than that of any other liquid or solid, and this buffers sudden changes in temperature A man of average weight generates 3000 kcal within 24 hr This amount of heat, if it were all retained in the body, is capable of raising the temperature of his tissues, which are 80% water, only about 32° C. Heat elimination (radiation, etc) normally dissipates this heat production, and the body temperature varies only slightly within narrow limits If the tissues had a low specific heat of most substances, 3000 kcal would raise the temperature of the body by 100 to 150° C (Henderson, 1913)

2) High Conductivity The thermal conductivity of water is greater than that of any other ordinary liquid The advantage of this in heat transport from deep organs to the surface,

even without the circulation of blood, is obvious

3) High Latent Heat of Evaporation More heat is required for the vaporization of water than for any other liquid Fluid is being constantly evaporated from the lungs and skin Through this process a large amount of heat is lost

The circulation of blood transporting heat from within the body to the lungs, the surface and the various vascular shunts that increase and decrease the circulation through the skin serves to accelerate the loss of heat or to retain the heat when needed

6) Chemical Communication and Protection. In addition to the nervous system that communicates from the brain to the various organs, there are sensitive chemical homeostatic systems The concentration of various substances in the blood is regulated through feedback loops that sense changes in concentration and trigger the synthesis of hormones and enzymes which initiate the synthesis of substances needed in various organs Furthermore, the entire complex of humoral antibodies important in defense against infection, initiation of inflammation, and the regulation of hemostasis circulate within the blood These will be considered in detail in other chapters

The Composition of Blood

Blood is a complex non-newtonian fluid in which several different types of cells are suspended The specific gravity varies among individuals from 1 050 to 1 060 and its viscosity is roughly 5 to 6 times that of water If blood clotting is prevented by addition of substances that bind calcium or inhibit later stages in the coagulation process, the cellular elements can be spun down by centrifugation The supernatant material is called *plasma* and contains a wide spectrum of proteins, organic and inorganic substances in solution, hormones, antibodies, and substances not yet adequately defined The specific gravity of plasma is roughly 1 027 but varies with the concentration of protein in health and disease over wide ranges In health, the cells constitute about 46% by volume of human blood, and the plasma 54%

If blood is permitted to clot, the fibrin mesh traps the cells and retracts When this is centrifuged the supernatant material is called *serum* and is identical to plasma with the exception of the removal of fibrinogen and other clotting factors

Whole blood
- *A)* Cells
  - *1)* Red corpuscles (erythrocytes)
  - *2)* White corpuscles (leukocytes)
  - *3)* Platelets (thrombocytes)
- *B)* Plasma
  - *1)* Water, 91 to 92%
  - *2)* Solids, 7 to 9%
    - *a)* Proteins, 7% Serum albumin, globulins, and fibrinogen
    - *b)* Inorganic constituents, 0 9% Sodium, calcium, potassium, magnesium, phosphorus, iodine, iron, copper, etc
    - *c)* Organic constituents (other than *a)* and *d)* Nonprotein nitrogenous substances, (urea, uric acid, xanthine, hypoxanthine, creatine ~~*a)* and *d*)~~ Nonprotein nitroge amino acids) neutral fats, phospholipids, cholesterol, glucose
    - *d)* Internal secretions, antibodies, and various enzymes, (amylases, proteases, lipases, esterases, etc)

INORGANIC CONSTITUENTS

Plasma is relatively rich in sodium and calcium but poor in potassium and magnesium (Table 4 1), whereas the reverse is true in cells These gradients are maintained by dynamic energy-consuming processes All of the constituents are in a steady-state exchange that can be shown only by the movement of radioactively labeled materials The iron in cells is confined to hemoglobin and porphyrin enzymes The iron and copper of plasma are transported and bound by specific metal binding proteins These play a very important role in hemopoiesis

PHOSPHORUS

Phosphorus exists in blood in four main forms Most of it is present as organic esters in the red cells The importance of these is considered in chapter 4 The phosphorus fractions in organic combinations are

1) Ester phosphorus, e g , diphosphoglycerate, adenosinetriphosphate, hexose phosphates, glycerophosphate and a whole host of red cell enzymes,

Table 4-1
Chemical composition of peripheral lymph (cervical) and blood plasma from the dog

From Heim 1933
[a] Tr , trace

2) *Lipid phosphorus*, e g , the phosphatides lecithin, cephalin, sphingomyelin

3) *Nucleic acid phosphorus* is distributed between deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) The former is almost exclusively in nuclei as the genetic material of the chromosomes, although a tiny amount of DNA is in mitochondria of the cytoplasm RNA is distributed between nuclei and cytoplasm in the form of messenger RNA, transfer and ribosomal RNA, the chemical messengers, and the protein synthesizing machinery

4) *Inorganic phosphorus* is distributed between cells and plasma, and is considered in other chapters

The inorganic and ester fractions are extracted from blood by the precipitation of the proteins with trichloracetic acid and filtration The phosphorus contained in the filtrate is the acid soluble phosphorus Upon extraction of blood with alcohol-ether the lipid phosphorus is obtained The phosphorus of blood is therefore separated into two classes

1) The acid soluble fraction which includes
   a) Inorganic phosphorus
   b) Ester phosphorus
2) The alcohol-ether soluble, i e , lipid phosphorus

The ester and lipid phosphorus constitute the organic phosphorus of blood

The organic phosphorus compounds are exceptionally important in energy transfer processes considered in Sect 1, Chap 4

PLASMA PROTEINS

The total concentration of proteins in the plasma and the proportions vary from species to species and within a species during good health Variation compatible with good health is relatively narrow

Classically proteins were divided into heterogeneous fractions—*albumin* and *globulins* In the development of knowledge on plasma proteins, the nomenclature has varied tremendously being based on methods of detection, fractionation and chemical properties The tendency now is to name plasma proteins on the basis of their function once they have been isolated and characterized, even though an empirical nomenclature continues to exist There seems to be a specific function for each protein that is separated and characterized The major functions of plasma proteins include the maintenance of colloid osmotic pressure, pH and electrolyte balance, and the transport of metal ions, fatty acids, steroids, hormones, and drugs The proteins are in part available as a nutritional source of amino acids for tissues There is an entire family of proteins related to hemostasis and the prevention of intravascular thrombosis There is another

system of proteins that is related to defense against infection The proteins with coenzymatic function exist in inactive forms (proenzymes) There are complex systems of activators and inhibitors which turn the systems on and off as required

Plasma proteins are of great interest in the study of evolution and phylogenetic relationships (Engle and Woods, 1960) In studies of the course of the evolution of vertebrates, it has been shown that cyclostomes lack hemoglobin and fail to produce γ-globulins and ceruloplasmin (Papermaster et al , 1962) Immunochemical procedures are now demonstrating that there may exist a high degree of genetic polymorphism of the plasma proteins in addition to a congenital absence or decrease in several proteins These differences are used to great advantage by human geneticists in study of races and their inherited traits related to disease

The biosynthesis and metabolism of the various serum proteins is beyond the scope of this chapter These topics have been reviewed by Anker (1960) The techniques of separation, identification, purification, and characterization of plasma proteins have progressed tremendously From the traditional salting out techniques, a whole series of chemical and physical techniques has been added, including electrophoresis, ultracentrifugation, combination of cold, ethanol, pH and ionic concentrations, paper electrophoresis, gel and column electrophoresis in addition to new techniques that are being developed regularly Details are available (Neurath, 1965)

Characteristics and Function of Important Plasma Proteins. A series of techniques has become exceptionally valuable in clinical medicine to characterize the normal pattern and variations in disease These techniques are *1*) the Tiselius or free boundary electrophoresis, *2*) paper electrophoresis, *3*) starch gel electrophoresis, and *4*) immunoelectrophoresis These are illustrated in Figure 4 1

The amino acid composition of plasma protein varies considerably (Putnam, 1960) The 18 common amino acids plus the 3 derivatives asparagine, glutamine, and cystine appear to be present in all proteins. The amino acid analysis and sequence determines primary structure The secondary, tertiary, and quaternary structures are responsible for function such as transport (O_2, Fe, Cu, etc.) and enzymatic activity Disease is due to abnormal structure, e g , in sickle cell anemia

There is considerable variation in the end groups and terminal sequences, all of which bear on structure, conformation, and the reactivity of the protein and its function In addition, proteins contain substances other than amino acids, which will be discussed in more detail under the specific plasma proteins

Serum Albumin. Albumin is in the greatest concentration, its obvious major functions are osmotic pressure control and transport Although albumin is considered to be a single homogeneous protein there is a rare hereditary condition in man called bisalbuminemia in which two electrophoretically different forms are observed (Gitlin and Janeway, 1960) There is some variation in the estimate of the molecular weight of serum albumin An average value is 65,000

Albumin has a high content of basic and acidic groups and very little tryptophane Albumin has a free sulfhydryl group which combines with cysteine or glutathione by a disulfide linkage The reactive sulfhydryl group explains the capability of albumin to form dimers with divalent mercury or organic mercurials This reactive sulfhydryl plays an important role in governing the properties of serum albumin

Albumin has a very strong affinity for anions and many other substances with which it can interact Albumin is the major plasma protein involved in the blood transport of anions, cations, dyes, drugs (antibiotics, barbiturates, digitonin, salicyate, sulfonamides etc), thyroxine, and some enzymes such as cholinesterase

Glycoproteins (Mucoproteins). These proteins contain carbohydrate covalently bound Most contain hexose, hexosamine, and sialic acid but little uronic acid Glycoproteins are distributed throughout all of the globulin fractions Glycoproteins have a wide range in molecular weight and carbohydrate concentration and some of the specific ones will be discussed separately Further details on these proteins are available (Neurath, 1965)

Lipoproteins. These proteins are of considerable importance in lipid transport and metabolism They appear to be intimately related to arterial vascular disease They are separated by ultracentrifugal flotation methods They are easily denatured They are classified on the basis of their ultracentrifugal separation into

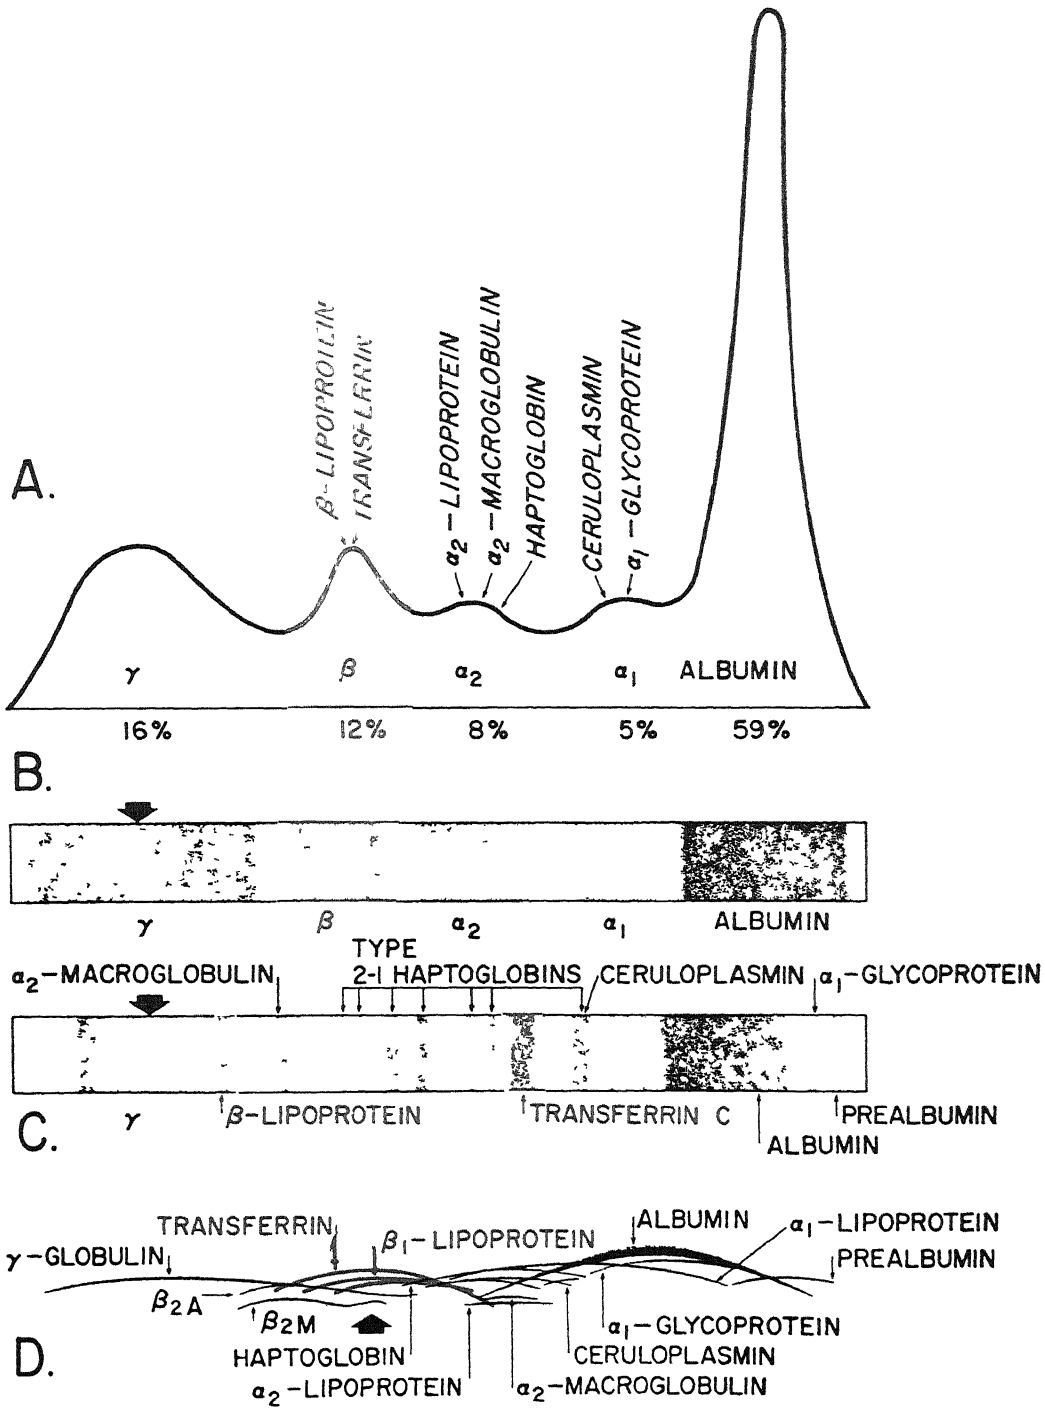

Fig 4 1 Schematic representation of the electrophoretic patterns of normal human serum in pH 8 6 buffer as obtained by four methods *A*) Tiselius or free boundary electrophoresis, *B*) paper electrophoresis, *C*) starch-gel electrophoresis, and *D*) immunoelectrophoresis The broad vertical arrow indicates the starting point in each case β_{2M}-Globulin remains in the starting slot in starch-gel electrophoresis but moves in the γ- to β-range in other methods

low density lipoproteins and high density lipoproteins The low density fractions contain a large amount of glycerides As the density increases, glycerides decrease, and cholesterol esters and phospholipid increase In cardiovascular disease, obesity and liver disease, these proteins are of growing importance

Transferrin. Transferrin is a glycoprotein, molecular weight of roughly 90,000 It has the specific property of iron binding, in which each transferrin molecule combines with two atoms of ferric ion The combining is reversible It transports iron from the gastrointestinal tract to the bone marrow and tissue storage organs Transferrin is intimately related to the regulation and control of iron absorption Its concentration is the limiting factor of iron absorption, thus playing a role in protection against iron intoxication Transferrin is colorless in the absence of iron and pink in its presence It has absorption maximum at 370 mμ and minimum at 410 mμ

There are numerous genetic variations of human serum transferrin The genetically determined polymorphism of human and primate transferrins has been reviewed by Giblett (1962) There are 14 different molecular species of human transferrin characterized by starch-gel electrophoresis under specific conditions The phenotype transferrin C has a high frequency in all populations There are variants in the Chinese, American Indian tribes, Caucasians, Negroes, and other racial groups

Haptoglobins. The haptoglobins constitute a family of glycoproteins which are found in the α-2 globulin fraction of many mammalian species and which have the capability of forming specific stable complexes with hemoglobin (Jayle and Boussier, 1954) Haptoglobin has two very important functions First, haptoblobin binds free hemoglobin, thus preventing loss of iron through urinary excretion It is also believed to protect the kidney from damage by hemoglobin, and regulates the renal threshold for hemoglobin The clinical importance is described in Chapters 4 to 6

There are also marked genetic polymorphism and racial differences in the haptoglobins (Giblett, 1962)

Ceruloplasmin. This copper-binding protein with oxidase activity was named ceruloplasmin because of its blue color It is a glycoprotein present in the α-2 globulin fraction that firmly binds more than 90% of the serum copper The crystalline protein has a copper content of 0 34% with about 8 atoms of copper per mole of protein (molecular weight 150,000 g) The chemical and physical properties of ceruloplasmin have been described by Deutsch et al (1962)

In Wilson's disease (progressive hepatolenticular degeneration), there is a marked deficiency of ceruloplasmin The condition is inherited as an autosomal recessive trait The frequency of the abnormal gene is very low, it is usually the result of consanguineous marriages The total plasma copper is remarkedly reduced, the ceruloplasmin concentration is very low and there is very high urinary copper excretion along with a high concentration in the liver

Fetuin. Fetuin is a protein found in the fetuses and the newborn, first identified in the calf This protein has a molecular weight in the vicinity of 45,000 It has a high sialic acid content It is of great interest in cell proliferation because it is a growth promoting requirement for mammalian cells in tissue culture

Coagulation Factors. These will be discussed in a Chapter 8

The Immunoglobulins These will be discussed in Chapter 10

VARIATIONS IN PLASMA PROTEINS

The protein fractions of plasma change in value independently of one another with or without alterations in the quantity of total protein In some diseases the albumin and globulin fractions may change in opposite directions In hemorrhage there is a loss of all of the fractions of plasma protein The initial restoration of blood volume is by the passage of a solution of low protein from tissue spaces into the blood stream, hence, the concentration of all plasma proteins will be diminished In burns and various diseases of the gastrointestinal tract, the total plasma protein content is reduced as a result of a leakage of blood and plasma from the denuded surface of the skin and into the tissues in the region of the burned area There may be greater loss of fluid than protein, and one may find an elevation in the protein concentration of the plasma Such also occurs in severe dehydration as a result of deprivation of water, or loss of water following excessive urine production as in diabetes insipidus

There may be a reduction of serum albumin in severe malnutrition chronic liver disease cirrhosis of the liver exudative diseases of the gastrointestinal tract, and in severe nephrotic syndrome in which there is an excessive loss of protein via the kidney As the plasma oncotic pressure is reduced because of a decrease in albumin concentration, there is a concomitant loss of fluid into the tissues which may produce a decreased plasma volume Physiologically, there is a low plasma albumin in pregnancy and in the newborn

Plasma fibrinogen is made solely in the liver Hypofibrinogenemia is a rare congenital disease In certain diseases such as carcinoma of the prostate, and occasionally following extensive pulmonary and cardiac surgery, there is a marked decrease in fibrinogen concentration associated with an increased fibrinolysis This is most marked in disseminated intravascular coagulation which will be discussed in Chapter 8 Fibrinogen is increased in acute infections, malaria, tissue injury chronic infection, and physiologically in pregnancy and menstruation Whenever there is an increase in fibrinogen or one introduces an asymmetric molecule into the blood (such as high molecular weight dextran), there is an increased erythrocyte sedimentation rate

The γ-globulin shows an absolute increase in several diseases such as multiple myeloma, cirrhosis of the liver, subacute yellow atrophy of the liver, acute hepatitis and nephritis, systemic lupus erythematosis, and in some acute and chronic infections

THE BIOSYNTHESIS OF PLASMA PROTEINS

Early in the embryo, plasma proteins are synthesized, the albumin fraction first As the blood vessels form, the embryonic plasma floats the primitive blood cells In the adult, it is established that the liver is the primary site of the production of plasma albumin and fibrinogen also is almost exclusively produced in the liver Their concentration in plasma is reduced following injury to the liver The lymphoreticular system, and in particular the plasma cells, synthesize the entire spectrum of immunoglobulins It is easy to demonstrate the synthesis of immunoglobulins by lymphocytes and plasma cells of all degrees of maturity The removal of plasma proteins by plasmapheresis[1] results in a decrease in their concentration Upon cessation of the procedure the concentration increases quickly towards normal, suggesting a tissue reserve pool that can be mobilized quickly This is followed by a slower increase to normal showing that an increased rate of synthesis has been induced These and other studies confirm that there is a dynamic state of body proteins with an equilibrium between production and destruction (Borsook and Keighley 1935)

The general concept that there is a dynamic state of body constituents has been experimentally demonstrated (Schoenheimer 1942) In fact all biological molecules with the probable exception of DNA in the nondividing cells (brain muscle, cells etc) are in a steady state between synthesis and degradation The measurement of the turnover rates of proteins and other biological substances is made possible by the labeling of precursors with stable or radioactive nuclides When a carbon-14 or nitrogen-15 labeled amino acid is introduced into an animal, its incorporation rate into diverse proteins can be measured By the transfusion of labeled pure proteins into intact animals one can measure the degradation rates From the mathematical analysis of the data and the dilution of the labeled material into the total body "pools" one can calculate the pool sizes and the amounts of material synthesized and degraded per unit time per kilogram of body weight Details of these techniques are available (Putnam, 1960)

Proteins have a specific amino acid sequence and structure that is genetically controlled In the normal steady state, messenger RNA is being formed at a steady rate on the genomes that carry the code for the specific protein The messenger RNA flows into the cytoplasm where its message is read by the ribosomes and the required amino acids are activated and brought to the ribosome by transfer RNA where each is incorporated into the polypeptide in proper order When there is a need for accelerated protein synthesis for any reason, it can be accomplished in principle by a longer mean life span of the messenger RNA or an increased rate of messenger RNA synthesis

[1] Whole blood is removed and centrifuged The supernatant plasma is thrown away and the cells returned to the subject This procedure is called plasmapheresis

For details of this process see White, Handler, and Smith (1968)

NONPROTEIN NITROGEN (N P N)

By the term, nonprotein nitrogen, is meant the nitrogen of those substances, e g , urea, uric acid, creatinine, etc , listed in Table 4 2 They may be extracted from blood or plasma by treating either of these with a reagent, such as trichloracetic acid, which precipitates the proteins, and then by filtering and determining the nitrogen in the filtrate These substances are in part absorbed with, or derived from the food, and in part are the waste products of tissue catabolism The total N P N of whole blood amounts to from 28 to 40 mg /100 ml It constitutes from 1 to 2% of the total nitrogen of the blood Its concentration in the cells is nearly double that in the plasma The proportions of the different constituents are given in Table 4 2

The term, undetermined nitrogen, embraces the nitrogen of ammonia, purines, and other nonprotein substances of unknown or undefined nature

Pathological Variations. The N P N of blood at any given level represents the balance struck between nitrogenous materials formed in the intermediary metabolism of ingested and tissue protein and the excretion of these products in the urine In renal insufficiency, therefore, the nonprotein nitrogen is elevated, and in certain cases may be 10 times the normal On the other hand, a rise in the N P N occurs in conditions which are associated with excessive tissue catabolism, such as infections, fevers, thyrotoxicosis, starvation, or severe malnutrition It is also increased following hemorrhage into the stomach or upper intestinal tract In the later months of pregnancy the N P N is reduced The reduction has been attributed to the diversion of nitrogen to the growing fetus and the reduction of protein catabolism in the maternal tissues

The chief conditions associated with an elevation of the N P N of the blood are adrenal insufficiency, dehydration, hemorrhage into the gastrointestinal tract, infectious fevers, lobar pneumonia, intestinal obstruction, parathyroid intoxication (in animals), peritonitis, and renal insufficiency

CHOLESTEROL

This sterol is present in serum in the free form and as cholesterol esters It is carried in the β-globulins, which contain almost all the lipoproteins The value for total serum cholesterol exhibits wide ranges in the normal population, it varies from 100 to 250 mg per

100 ml. The esterified cholesterol is about 72% of the total, and this ratio varies within a rather narrow range. Its concentration is increased in several diseases, notably in hypothyroidism and lipid nephrosis and in some cases of atheromatosis. Keys et al., (1956) found that within fairly wide limits (2 to 3 g. of cholesterol weekly) the content of the sterol in the diet exerted little effect upon the total serum cholesterol.

2 / HEMOPOIESIS

A Vital Cell Renewal System

Introduction

You are a pediatrician You have just seen a child with high fever, swollen glands, and a sore throat The parents believe she has a "strep throat" You diagnose acute lymphocytic leukemia This child will die within months to a few years The chemotherapy of leukemia, as well as the leukemia, will suppress normal production of blood cells making the child susceptible to hemorrhage, infection, and anemia Before death, this child will require antibiotics, transfusions of blood, platelets, and granulocytes There may be major problems with fluid and acid base balance To manage judiciously the treatment of this child, you must understand the stem cell, kinetics of hemopoiesis, fluid, and electrolyte balance Leukemia is a disease of the stem cell The family must be helped to protect the child from knowing life is limited You must make it possible, as long as possible, for the child to play and go to school just as a well child To do this, you must be able to impart your knowledge and concepts of the disease and its management to the parents They must partake in the care of their child Without understanding these can not be done Without understanding of what is known, further progress in the treatment and eradication of this dread disease can not be made

---

The term "cell renewal system" has been suggested as a general way of describing all of those body systems in which the cellular elements are continuously being replaced (Leblond and Walker, 1956) The steady-state cell renewal systems include not only the hemopoietic cells, but also cells of the skin, gastrointestinal tract, lining of the pulmonary system, and the testes These systems are to be contrasted with the relatively immortal cells that are not replaced after completion of growth of the organ (central nervous system, cardiac, and skeletal muscle, etc) and those organs and cell systems in which cellular proliferation is triggered by injury (connective tissues, liver, kidney, etc)

Life depends upon hemopoiesis The red cells transport oxygen and carbon dioxide The neutrophilic granulocytes are a first line of defense against invasion by bacteria The platelets play a crucial role in preventing blood from oozing out of the vascular bed and are essential to staunch bleeding after injury The monocytes play a central role in cellular immunity against specific bacterial infections (tuberculosis, brucellosis, etc) The lymphoreticular system (thymus, spleen, lymph nodes and their relation to the bone marrow) controls the synthesis of specific antibodies against bacterial and viral invaders and foreign tissue, and probably provides a surveillance mission to recognize harmful mutant cells (cancer, etc) and initiate the measures to destroy these clones

Our modern environment may expose man to ionizing radiation in industrial accidents, nuclear warfare, and in the course of treatment of cancer The major cause of death following overexposure to ionizing radiation is suppression of blood cell formation with the concomitant increased susceptibility to infection, hemorrhagic tendency, anemia, and a suppressed humoral immunity All of these alone or in combination may be lethal Aside from ionizing radiation there are many industrial intoxicants that can suppress or eradicate all or part of the blood cell production and produce death Regrettably, many of the drugs that are essential in the practice of medicine may suppress the entire marrow production or selective cell production Lastly, there is a whole series of genetic diseases that result in abnormal function and production of red cells, granulocytes, platelets, or lymphocytes Many of these diseases are either markedly disabling or may result in death early in life

A study of blood occupies a central role in

evaluating the hazards of environment and new and old drugs used in the practice of medicine Accordingly, the physician and physiologist are concerned with the origin of the blood cells and the mechanisms by which their orderly delivery from their sites of manufacture to the peripheral blood is achieved and regulated It is assumed that the reader is familiar with the names and morphology of the mature cells of the blood and of their immediate histologically-identified precursors

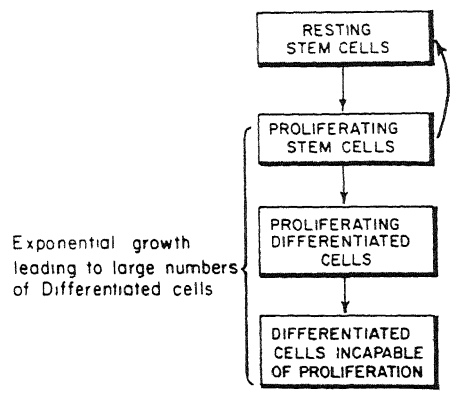
ANATOMICAL SITES OF THE FORMATION OF THE BLOOD CELLS

The bone marrow produces red cells neutrophilic, eosinophilic and basophilic granulocytes, platelets, lymphocytes, and monocytes In late fetal life, blood cell production goes on throughout the bone marrow and also within the liver After birth, this function is limited largely to the bones With growth there is a progressive retreat of blood cell production from the distal ends of the long bones, such that in the adult human being, marrow proliferation usually occurs only in the skull, vertebrae, pelvis sternum, and the proximal ends of the long bones Under conditions of prolonged increased demand as in chronic hemolytic anemias, however, blood formation may also return to all of the long bones, out into the fingers and toes, and may erode the cortical bone weakening it to the point that fracture may occur

The lymphocytic-plasma series of cells is formed within the lymphoreticular system consisting of the thymus, spleen, lymph nodes, tonsils and Peyer's patches, and within the bone marrow The interrelationships of the various segments of the lymphoreticular system will be considered in Chapter 10

THE HEMOPOIETIC SYSTEM AS A CELL RENEWAL SYSTEM

The presence of mitosis proves the production of cells within the hemopoietic tissues In the case of the red cell, the average life span has been determined with accuracy to be about 120 days The minimum birth rate of cells can be expressed by the following equation



$$\text{Minimum birth rate} = \frac{\text{Total number of red cells}}{\text{Mean life span}}$$

It will be increased if there is any loss in the production line Details on the production will be outlined in the section on erythropoiesis

A Generalized Concept of Hemopoiesis

The functional cells in the peripheral blood contain molecules granules and structures which permit them to perform specific functions These functional cells are the descendants of progenitor cells within the bone marrow which do not contain the molecules or structures characteristic of the mature cell The process by which cells change and develop the capacity to carry out specific functions is called differentiation

The next important difference between mature cells in the blood and their progenitors in the bone marrow is that the mature cells are incapable of mitosis while the progenitor cells divide several times The process of blood formation consists therefore of two essential ingredients *1)* cell *proliferation* and 2) cell *differentiation* In Figure 4 2, a generalized model for the origin of blood cells is shown As the process of cell differentiation proceeds, the

MODEL OF THE ORIGIN OF BLOOD CELLS

Fig 4 2 This is a schematic diagram of the relationship between stem cells and their differentiated descendants Each box represents a population of cells At the top of the figure is a population of stem cells resting either in the G_0 state or in state of prolonged cell cycle Members of this population may pass into a different physiological state characterized by rapid proliferation Cells derived from this proliferation may either retain stem cell properties and return to the resting compartment or may differentiate Many of the cells in the differentiated compartment can divide several times but finally a state is reached in which cell division is no longer possible Cells in the proliferating compartments are growing exponentially so that the differentiated cells greatly outnumber the stem cells

capacity for cellular proliferation decreases The most primitive progenitors have extensive capacity for proliferation and are able to give rise to a large number of differentiated descendants These differentiated descendants have the capacity to fulfill specific functions but have lost the ability to renew themselves Between these two extremes are found the majority of the nucleated cells in the bone marrow These are the cells which have started on the course of differentiation, contain some of the features which will finally define them as functional elements, and are capable of a limited number of cell divisions These are likewise the cells the clinical hematologist recognizes in blood smears obtained from bone marrow, and it is upon their numbers and characteristics that most clinical diagnoses are made

The progenitor cells with almost unlimited capacity to proliferate and also to produce differentiated descendants are called "stem" cells The identity of these cells is subject to controversy Since the stem cells are not yet differentiated, they do not contain the specific cytological features by which they might be easily recognized Stem cells constitute a very small fraction of the cells of hemopoietic tissues Because they have extensive capacity for proliferation, they are greatly outnumbered by their differentiated descendants It has been estimated in the mouse that about one in every thousand cells of the bone marrow is a stem cell Controversy over the stem cell has centered around not only their identity, but also their capacity to give rise to one or more classes of differentiated descendants A vast literature, primarily polemics, based on morphological techniques as to whether there is a single stem cell for hemopoiesis or multiple cells in adult life exist (Bloom, 1938) Today as a result of the elegant studies of the Canadian investigators (Till et al , 1967, Wu et al , 1967, Wu et al , 1968, and Whang et al , 1963), it is known that stem cells with characteristic abnormal karyotypes do differentiate into the erythropoietic, granulocytic, and lymphocytic lines

The identity of the stem cell remains obscure. In the past the existence of pure aplasias of one cell type or another in human disease was used as an argument for the loss of the stem cell for that particular line It seems more likely now that in aplasia either there is a loss of the specific inductor for differentiation of that cell line by induction of the common stem cell, or the stem cell has mutated so it can no longer respond Much is known about the stem cell Radiation protection studies have clearly shown that the common stem cell passes through the blood Yet, the only source for the common stem cell is the bone marrow The stem cell has been described, respectively, as a small, dense mononuclear cell in the bone marrow, and as a small mononucleated lymphocyte-like marrow cell not found in lymph nodes The stem cell is also believed to be a monocytoid cell in the blood (Tyler and Everett, 1966) Aside from the failure to have specific differentiated characteristics, it is probable that the stem cell's appearance changes during its life cycle—proceeding from the resting to the active, proliferating state Since cells double their mass, their size does change To double the mass requires all of the protein synthesizing machinery [ribosomes, messenger ribonucleic acid (mRNA) and transfer ribonucleic acid (tRNA)] to be synthesized and switched on along with the aerobic metabolic machinery (more mitochondria) It seems logical, therefore, that stem cells may have a varying size and appearance as they go through their proliferative cycle

Perhaps more conclusive than arguments from morphology are certain functional tests for the recognition of stem cells Two properties have been described they are the capacity for almost unlimited self perpetuation, and the capacity to give rise to differentiated descendants Without unlimited self-perpetuation of stem cells, marrow function would eventually cease Stem cells must also be able to respond to the normal control mechanisms

An old concept of the stem cell involves what has been called homoplastic and heteroplastic hemopoiesis (Maximow and Bloom, 1948) *Homoplastic hemopoiesis* is the process in the adult where the stem cell for granulocytopoiesis, erythropoiesis, and megakaryocytopoiesis is the youngest member of the series and perpetuates itself, thus providing cells which go through a limited number of mitoses Under physiological conditions requirements are met by homoplastic hemopoiesis During embryonic and later growth, however, or in severe stress or in regeneration from aplasia, the requirements for each cell line are met by

heteroplastic hemopoiesis, a process in which new erythroblasts and myeloblasts are supplied by a pluripotent stem cell (in the parlance of Maximow, a hemocytoblast) This cell is different from the type that in modern terminology is designated by the term, committed stem cell This latter term refers to a cell that responds to stimuli which increase production rate of a specific cell line but is unable to differentiate into all cell lines upon transplantation into fatally irradiated animals The newer concept is that increased erythropoiesis or granulopoiesis due to specific stimuli does not require an input from the pluripotent pool of stem cells, although the latter are responsible for regeneration after aplasias or for regneration upon transplantation into the fatally irradiated animal with aplastic marrow

Before proceeding further with an analysis of cell proliferation in the hemopoietic system, it is necessary to look at the sequence of events that transpires between successive mitoses

THE CELL CYCLE

The cell cycle of mammalian cells is shown in Figure 4 3 Before a cell can divide and increase its number by one, the cell must proceed through a series of stages in which cell organelles, the genetic material [deoxyribonucleic acid (DNA)], enzymes, and structural proteins are doubled The crucial stage in the cell proliferation cycle is DNA synthesis (*S*) during which the chromosomes are replicated precisely so as to transmit all of the genetic information of the species to each of the daughter cells Following the *S* period another series of synthetic events takes place in which the mitotic apparatus is synthesized At mitosis, the cells divide into two identical daughters each of which carries the entire genetic information of the species The cells then enter a period called G_1, a metabolically active period during which enzymes, structural proteins, and cell organelles are synthesized [1] Evidence for this synthesis can be shown by the incorporation of labeled amino acids It has been suggested that hemopoietic stem cells have the capacity to exist in a resting physiological state named G_0 Cells are believed to enter the G_0 state after mitosis This suggests that a collection of cells may consist of a number of cells that constitute a resting, nondividing compartment and another number that represent a dividing compartment (Lajtha et al, 1962) Major advances in the study of cell proliferation were the development of radioactive tritiated thymidine (^{3}HTdR), a specific precursor of DNA and its use in study of mammalian cell proliferation (Hughes et al, 1958) With it, the cohort of cells in DNA synthesis can be labeled and studied by a combination of cytological and radioautographic[2] techniques

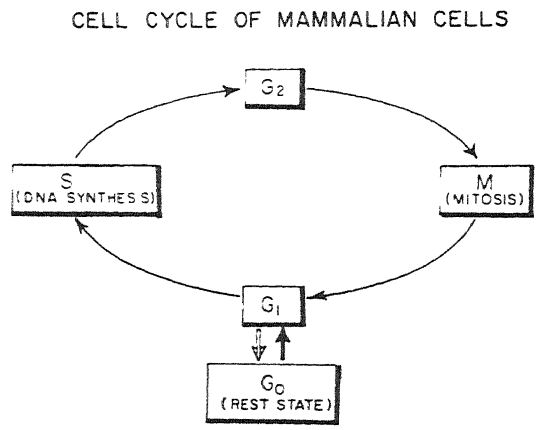


Fig 4 3 A diagrammatic representation of the various phases of the cell cycle

Since one can identify the total population by cytological criteria and the labeled population in S by radioautography, one can define an index of labeling (I_L) as

$I_L = N_s/N$

N_s = Number of labeled cells

N = Total number of this cytological type

It follows that

$I_L = t_s/t_G$

t_s = Average DNA synthesis time and

t_G = Average generation time or the time between sucessive mitoses

[1] The letter *G* stands for gap, in some literature *R* is used representing a rest Since many metabolic activities are in progress throughout cell cycle, the notion of gaps before and after *S* indicating a time period when one sees neither *S* nor mitosis is preferable

[2] Radioautography is a procedure in which a specimen containing a radiation-emitting isotope is placed under a photographic emulsion in such a manner as to permit cells and organs to "take" their own picture The labeled cell is recognized by black reduced silver grains overlying the cell

Similarly one can identify mitosis so that the index of mitosis (I_M) is

$$I_M = N_M/N = t_M/t_G$$

where N_M = Number in mitosis Therefore, the ratio of I_L I_M is

$$I_L/I_M = t_S/t_M = N_S/N_M$$

By serial sampling of cells after the administration of ^{3}HTdR, one can observe the flow of labeled cells through mitosis This is illustrated in Figure 4 4 for a cell cycle without variance and one with variance In the invariant system, for a period of time equal to G_2 no mitotic figures will be labeled As the leading edge of the labeled cohort of cells enters mitosis, the fraction of labeled cells in mitosis will increase, after a time equal to duration of mitosis 100% of the mitoses will be labeled The percentage will remain at 100% until the leading edge of unlabeled cells that were in G_1 enters mitosis, at which time the percentage of labeled mitoses will decrease and after a period of time equal to the mitotic time fall to zero If the various subdivisions of the generative cycle were invariant in a stem cell system there would be repetitive waves as shown in top of Figure 4 4*a* In real life a variance does occur in all biological systems, including in duration of the subdivisions of the generative cycle This produces a rounding out of the ascending and descending curves, and ultimately the fraction of mitoses that are labeled is modulated out to the ratio of the time for the synthesis (t_S) to the time of the generative cycle (t_G) as shown in the middle of Figure 4 4*b* In the bottom of Figure 4 4*c* is shown an actual example of human granulocytic precursors flowing through mitosis From an an analysis of these curves one can in principle estimate the duration of G_2, M, S, and the generative cycle The ascending curve represents the range in the sum of $G_2 + M$ The time between the 50% point on the ascending curve and the descending curve approximates the average DNA synthesis time if the variation in time conforms to a Gaussian distribution

As discussed earlier, there is a reason to believe that the stem cells can be divided into G_0, a nondividing class, and the cells in cycle This situation is illustrated in Figure 4 5 For arithmetic simplicity, half of the population is considered proliferating (D) and half nonproliferating (ND) The index of labeling of the entire population will be equal to the area in synthesis divided by the area of the nondividing

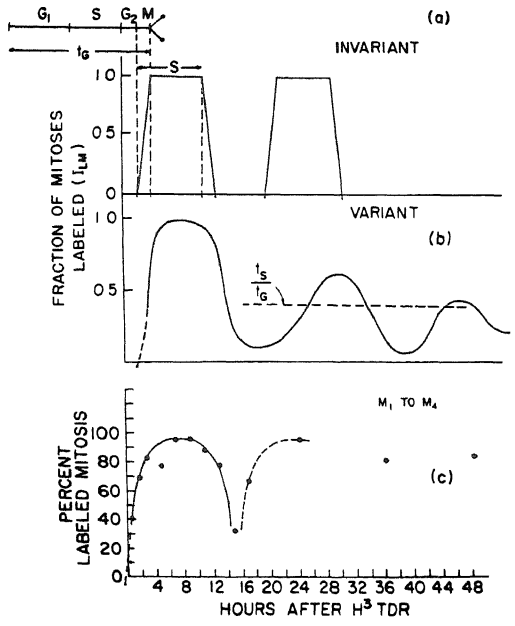

Fig 4 4 *1)* a schematic illustration of the flow of labeled cells through mitosis showing changes in the fraction of labeled mitosis in a self-perpetuating cell system in which there is no variation to phases in the cell cycle *2)* the introduction of biological variability introduces a rounding out of the curves with an ultimate modulation to the ratio of the DNA synthesis time to generative cycle time, *3)* shows the flow of labeled myelocytes of human bone marrow through mitosis from which an average DNA synthesis time of 12 hr is deduced

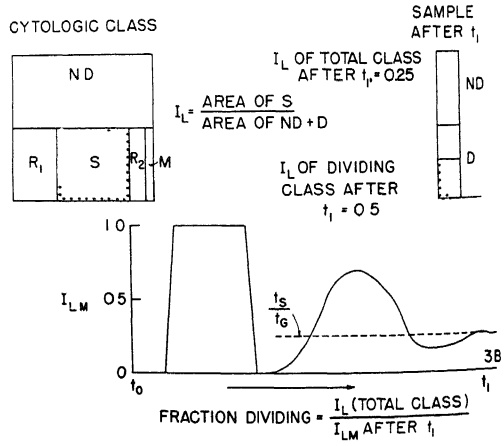

Fig 4 5 Hypothetical cytological compartment consisting of a combination of proliferating cells and non proliferating cells in transit through the compartment showing the means of determining the fraction of cells that is proliferating

plus the dividing populations If one looks only at the cohort of labeled cells moving through mitosis after the minimum duration of $G_2 + M$ the fraction of labeled mitotic figures will rise promptly to 100% and remain there until the unlabeled cells that were in S arrive Then after an interval equal to M the fraction will fall to zero In a system with variance in each subdivision of the generative cycle the fraction of mitotic figures that are labeled would ultimately become modulated to a constant value equal to the ratio of the DNA synthesis time (t_s) to the generative time (t_c) after an interval (t_1), which is the time it takes for the index of labeling to become a constant At this time the I_L of the dividing class under the conditions established would equal 0.5 Arithmetically it can be shown that the fraction of cells that is dividing is equal to the I_L of the total class divided by the fraction of the mitoses labeled (I_{LM}) after t_1 Therefore one can calculate the fraction of cells that are in G_0 (Mendelsohn, 1963, Cronkite, 1964a) Another technique to determine the fraction of cells in cycle is the radioactive thymidine "suicide" technique (Bruce and Meeker 1965) Enough radioactive thymidine is given to kill those cells in S that are incorporating the ^{3}HTdR This technique has shown that about 15% of stem cells in the mouse are in DNA synthesis However, upon transplantation of the surviving G_0 cells into a fatally irradiated mouse, the G_0 stem cells rapidly enter cycle proliferate, differentiate, and restore the bone marrow

CONCEPT OF PROLIFERATION IN THE STEM CELL POOL

The stem cell pool has been visualized as a cytological compartment with autonomous proliferation in which the dividing population doubles with each generation so that the following equation describes the growth (Johnson, 1961)

$$N = N_0\, 2^{t/t_c} = N_0\, (e^{0.693})^{t/t_c}$$

and the growth constant (λ)

$$\lambda = 0.693/t_G \text{ or}$$
$$N = N_0\, e^{\lambda t}$$

where

t_G = generation time
t = time from t_0 to t_1
n = the number of generations or mitoses (n)
λN = λN

the growth rate in an expanding population or the number of cells produced per unit time

If from death or differentiation the rate of removal from the expanding population is $\lambda_1 N$ then the net rate of change is

$$dN/dt = \lambda N - \lambda_1 N$$

and in the steady state is zero

If there is a demand for more stem cells to be differentiated into functional lines to compensate for hemorrhage or a need for more granulocytes to fight infection the demand can be met by a reduction in t_c. This increases λ and t/t_c, the number of mitoses (n) which may take place in the same interval (t) and thus multiplies the output of stem cells The same result can be accomplished by a shifting of more G_0 cells into cycle thus increasing N and with same t_c the dN/dt increases In either case there will be more cells in cycle and the number of stem cells susceptible to agents that kill in S will be increased Such has been observed when the marrow is stressed or when marrow is transplanted into an animal that has an aplastic bone marrow from prior irradiation

If there is not an increased rate of differentiation or death this stem cell compartment will increase in size Something comparable to the latter may be occurring in leukemia

If $\lambda_1 N$ exceeds λN and the stem cell compartment does not sense the need for more stem cells the system will soon become exhausted—a situation which may resemble some hypoplastic marrow states

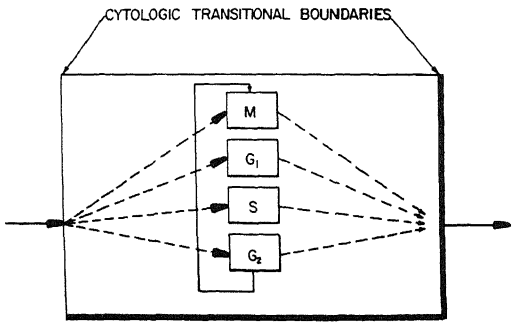
In this mathematical model one can visualize considerable flexibility, providing that the stem cell pool is "size conscious" Following an unexpected drain of cells by differentiation one can imagine that the remainder may not be susceptible to differentiation until the size is restored by proliferation and restoration of the G_0 population This implies that differentiation probably takes place from the G_0 population The temporary restriction of no differentiation with the same or shorter generation time will permit the G_0 fraction of the stem cell pool rapidly to rebound In fact, one might conceive of its rebounding to larger than the normal size before it is modulated back to preperturbation size In fact, such has been observed experimentally by Lajtha et al (1969)

PROLIFERATING POOL OF DIFFERENTIATED CELLS

The flow of cells is illustrated schematically in Figure 4 2 The structure of a proliferating differentiated compartment is shown in more detail in Figure 4 6 The main characteristic that is imparted to a differentiated pool is multiplication but inability for self perpetuation If the input fails, the compartment vanishes as maturation continues (The compartment is defined in terms of cytoplasmic and nuclear structure) Cells may divide within the cytological compartment one or more times, or may be in transit through it while maturing The mitosis that is seen in some cells shows that division does occur within the compartment Since "flash labeling" by ^{3}HTdR is observed, some cells spend at least some of the time within the cytological phase in DNA synthesis There is no way to determine if all cells that enter a cytological phase divide within this phase one or more times, or if they divide at all Conceptual and mathematical problems concerned with compartment and intracompartmental growth are discussed in detail elsewhere (Johnson, 1961, Killmann et al , 1962, and Quastler and Sherman, 1959)

Within a cytological compartment, the boundaries of which can be determined by morphological criteria, one can observe the fraction of cells that are in mitosis and the fraction of cells in DNA synthesis If the boundary of a cytological compartment is terminated by mitosis, the following simple relations pertain as shown earlier in this chapter

$$I_M = t_M/t_G \qquad I_L = t_S/t_G$$



and

$$I_M/I_L = t_M/t_S$$

If one can then determine in a system the index of mitosis and labeling and synthesis time, one can compute the time for mitosis and then substitute in the appropriate equation for calculation of the time for generation

In cell compartments where mitosis occurs between the cytological boundaries, the above simple relationships do not hold For a detailed discussion see Killmann et al , (1963)

In steady-state catenated, proliferating cellular systems, one can determine the relative production rate of cells in each successive cytological compartment normalized to the relative abundance of the most immature definable compartment The first step is the determination of the proportional distribution of cells from the most immature to the most mature in the cell compartment by counting and identifying enough bone marrow cells Next, from the "flash" labeling and mitotic index of each cytological compartment, one can determine the relative number of cells in DNA synthesis or mitosis In Figure 4 6, K_B, the flux of cells from a preceding compartment and the flux out of the compartment under consideration are represented by K_{in} and K_{out} K_b of the intracompartmental birthrate by mitotic division is equivalent to the number of cells in DNA synthesis (N_s), which in turn is equal to the fraction of cells labeled (I_L) times the relative number in the compartment (N) divided by t_S Thus, the outflow from the compartment (K_{out}) equals the birthrate within the compartment (K_B) plus the influx into the compartment, assuming that no death occurs within this compartment In these computations no assumption is made as to whether a cell dies within the compartment or leaves the compartment in some subdivision of the cycle An essential datum for these calculations is the average time for DNA synthesis The method of obtaining this was shown earlier in the discussion in Figure 4 4, the average DNA synthesis time is approximated by the time between the 50% labeling of mitotic figures on the ascending curve and 50% labeling

Fine Structure of a Proliferating Compartment

Fig 4 6 Schematic presentation of a proliferating cytological compartment within the differentiated proliferating pool There is no capacity for self-perpetuation only multiplication Entering cells may cycle one or more times or proceed through only a part of the cell cycle depending upon the rate of maturation or time before they resemble the next cytological class (From Quastler and Sherman, 1959)

on the descending curve of labeled mitosis In Figure 4c, this time is about 12 hr for DNA synthesis in the granulocytic precursors of human bone marrow

The next essential datum is the rate of replacement of the nondividing compartment by labeled cells flowing from the last dividing compartment This was shown in principle in figure 4 6 From the slope of the increasing labeling index of the nondividing compartment, one can estimate the average turnover time of this compartment

The following are clear for any compartment between the stem cell and the first nonproliferating compartment

$$K_{out} = K_{in} + [N_{m \text{ or } s}/t_{M \text{ or } S}]$$

Where K_{out} equals the rate of leaving the compartment, K_{in} equals the rate of entry, $N_{m \text{ or } s}$ equals the number in mitosis or synthesis Therefore,

N_m/t_M or N_s/t_s
= the intracompartmental growth rate (K_B)

The entire proliferating pool as shown in Figure 4 2 consists of a series of cytological phases If the stem cell input K_{in} is known, then the efflux K_{out} from the terminal dividing cytological phase can be expressed as follows

$$K_{out} = 2^n K_{in} = 2t/t_G K_{in}$$

Where t equals the sum of the cytological phase transit times, t_G equals generation time, and n equals the average number of mitoses of t/t_G

FLOW THROUGH A NONDIVIDING STORAGE COMPARTMENT

The rate of replacement of nondividing cells by labeled cells flowing from the proliferative compartment is a measure of the replacement rate A schematic example is shown in Figure 4 7 As the labeled cells move into the nondividing cytologically identifiable compartment the I_L increases From the slope of this curve one can calculate the turnover time[3] of the nondividing compartment If unlabeled cells

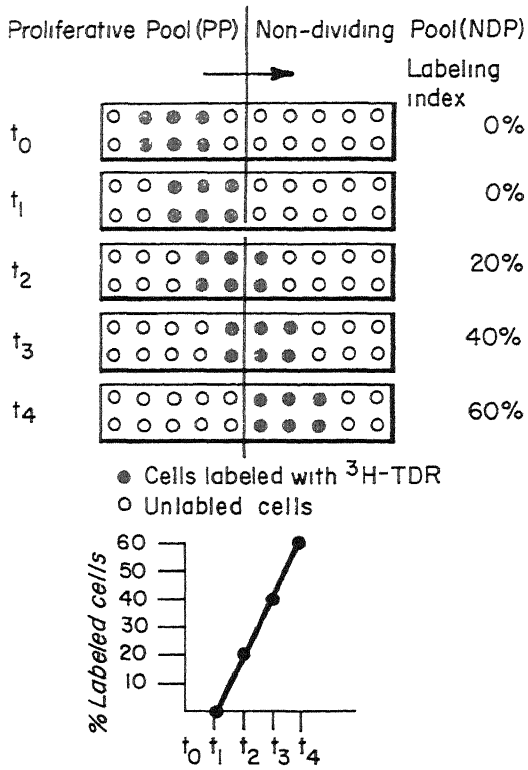


Fig 4 7 Schematic representation of the transition of cells from a proliferating pool (PP) to an initially unlabeled nondividing pool (NDP) Open circles unlabeled cells Filled circles labeled cells 7 *a* From a certain time only labeled cells enter the subsequent compartment It is assumed that the pools have identical turnover times (From Messner, et al 1969)

were to make the transit with labeled cells the turnover time would be less and turnover rate greater than estimated It is also evident that the turnover time for constant input rate is directly related to the size of the compartment that is being replaced (Cronkite et al., 1960a, Messner et al , 1969) For example, if 100 cells/hr enter a compartment containing 100 cells the turnover time is 1 hr —if the compartment has 500 cells the turnover time is 5 hr The reciprocal of the turnover time is the turnover rate in percentage or fraction per unit time, e g , 100%/hr or 20%/hr In the case of successive compartments of varying size flowing from one to another, the average turnover time is proportional to the ratio of the sizes For example if three compartments, A, B, and C, vary in the ratio of 1·2:3 and the turnover time of A is 10 hr., the turnover times of B and C are 20 and 30 hr., respectively.

[3] Turnover time is the time it takes to replace a number of cells equal to the number in the compartment at time zero This does not mean that every cell in the compartment at time zero is replaced, there may be stragglers Nevertheless, a number equal to those present are replaced

LIFE SPAN AND TURNOVER STUDIES IN A FUNCTIONAL NONDIVIDING COMPARTMENT

The classical method in hemopoiesis is to transfuse a known number of immunologically identifiable red cells into the blood, and by immunological differential agglutination techniques determine the time it takes for the transfused cells to disappear By this technique Ashby (1919) established the mean life of the human red cell to be 120 days Several isotopic techniques have been developed to study life span of red cells, granulocytes, lymphocytes, and platelets and will be discussed in Chapters, 3, 7, 8, and 10

Methods of Study of Hemopoietic Stem Cells

It has long been known that one can transplant genetically identical bone marrow into an otherwise fatally irradiated animal whose bone marrow has been eradicated by large doses of ionizing radiation In these hosts, the transplanted cells proliferate and differentiate, providing the recipient animals with the functional cells necessary for their survival from radiation damage Marrow transplantation in mice has been used to obtain populations of hemopoietic cells, each derived from a single cell (Till and McCulloch, 1961) By analysing such clonal populations it is possible to examine the properties of the cells of origin, and in this way to determine the extent to which such cells may be considered hemopoietic stem cells (Till et al , 1964) The technique used to obtain clones is as follows Heavily irradiated animals are injected with genetically identical bone marrow cells derived from healthy donor mice. After 9 to 14 days, the recipient animals are killed, and their spleens are found to contain discrete nodules, which, on histological examination prove to be colonies of proliferating and differentiating hemopoietic cells

Evidence that spleen colonies are clones was obtained by the use of the following experimental techniques (Becker et al , 1963) Recognizable and unique chromosomal abnormalities (markers) were induced by irradiation in some of the cells used to initiate the growth of colonies. When the colonies had developed, their dividing cells were examined for markers In any colony where a particular marker was present, this same marker was found in all of the dividing cells of that colony This provided excellent evidence that all of the cells of such a colony were derived from a single progenitor possessing this marker Enough colonies with markers were found to establish the proba bility that all or almost all spleen colonies are clones

Analysis of clonal populations obtained by the spleen colony technique provides evidence that the cells from which the colonies grow are indeed stem cells First, after 10 days growth, spleen colonies contain more than a million cells, indicating their origin from cells with extensive proliferative capacity Second, spleen colonies have been shown to contain cells themselves capable of colony-formation, indicating that self-renewal has occurred Third, many spleen colonies contain recogniz able erythroblasts, granulocytes, and megakar yocytes, showing that the original cells could differentiate along these three lines Finally, the colony-forming efficiency of cells from the marrow and spleen of normal mice remains relatively constant during adult life, indicating that cells capable of colony formation respond to homeostatic control mechanisms Thus, cells with colony-forming potential have the properties of stem cells, and it appears justifi able to refer to them as hemopoietic colony-forming stem cells

Other assays for stem cells such as radioprotection, erythropoietic repopulation, granulocyte response, marrow cellularity, erythropoietin assay, autorepopulation, and in vitro colony assay are useful, and have been reviewed by Lajtha (1970) and with his associates, (1969)

CHROMOSOMAL EVIDENCE FOR A COMMON STEM CELL FOR ERYTHROPOIESIS GRANULOCYTOPOIESIS AND PLATELET FORMATION

The evidence given in the preceeding sections shows that hemopoietic colony-forming stem cells have capacity to differentiate along erythrocytic, granulocytic, and megakaryocytic lines Evidence for stem cells in man with similar capacity for differentiation has been obtained from the study of chronic myelogenous leukemia In this condition, there is a great increase in bone marrow cell proliferation with the production of large numbers of granulocytic cells at various stages of development

Recently, techniques have been devised which permit detailed study of the chromosomes of mammalian cells (Nowell and Hungerford 1960). They applied these techniques to the cells of patients with chronic myelogenous leukemia and found a specific abnormal chromosome in almost all these leukemic cells. The abnormal chromosome is usually called the Philadelphia chromosome, after the city in which it was first recognized. Whang et al. (1963) have combined chromosomal analysis with other functional tests, and found that the Philadelphia chromosome is present not only in the cells of the granulocytic series but also in the progenitors of erythrocytes, and certain large polypoid cells, almost certainly megakaryocytes. Because these relatively differentiated progenitors of red cells and platelets have only limited proliferative capacity it was concluded that they are the partially-differentiated descendants of leukemic progenitors. Since the Philadelphia chromosome, a specific marker, is found in granulocytic erythrocytic, and megakaryocytic cells, but not in other dividing cells of the body, a single progenitor must possess the capacity to differentiate in these three different directions. The existence of a pluripotent leukemic cell is strong evidence that there also exists a normal human stem cell with capacity for differentiation towards erythrocytic, granulocytic, and megakaryocytic pathways. These plus earlier discussions suggest that there is a pluripotent stem cell. Committed stem cells will be discussed in Chapters 3 and 7 on erythropoiesis and granulopoiesis, respectively.

There are two clinical situations in which stem cell potential and kinetics are of major importance. In genetically identical animals, it has been shown that bone marrow transplantation will save the life of otherwise fatally irradiated animals. There are numerous drugs in addition to radiation that may produce bone marrow failure. An example is aplastic anemia produced by the toxic effects of an antibiotic, chloramphenicol, which is used in therapy of some bacterial infections. If aplastic anemia develops the patient is in danger of dying because he lacks the class of stem cell which differentiates along erythrocytic, granulocytic, and megakaryocytic lines. From animal experimentation, the physician knows that production of these cells can be re-established by transplantation of genetically identical bone marrow. Yet both animal and clinical studies show that in attempting such a transplantation one also transplants cell with immunological capability that will flourish, proliferate, and grow out cells that recognizing the immunological difference of the host, will launch an immunological attack upon the patient. This disease is called a "graft vs host reaction," and will be discussed in more detail in the section on the lymphoreticular system (chap. 10). If the recipient's immunological system is likewise functioning, or becomes reestablished, it can then recognize and launch an immunological attack against the transplanted stem cells and by rejecting the transplant thus defeat the purpose of the attempted therapy. The trick then is to transplant the common stem cell so as to permit differentiation into erythropoiesis, granulopoiesis and thrombopoiesis, but to suppress simultaneously its differentiation into immunologically competent cells that attack the host. Furthermore the reaction of the host's immunological system against the foreign transplanted cells which will reject the life saving graft must also be suppressed. To attain all of these objectives at the same time is extremely difficult. Nevertheless, major efforts are now underway in attempts to transplant bone marrow and immunologically competent cells as a means of treating otherwise fatal diseases of man.

The other situation in which stem cell potential and kinetics is vital is in the chemotherapy of leukemia. All of the drugs used to treat leukemia are nonspecific and promiscuously injure proliferating normal and leukemic cells. If it were possible to put the normal stem cells into a more resistant phase of cell cycle during treatment there would be a greater probability of eradicating the leukemia without eliminating the stem cells required for life. To date this has not been accomplished. The apparent leukemic cures result from the fact that stem cells for normal hemopoiesis tend to recover more rapidly than the leukemic stem cells (shorter generation time in normal than leukemic stem cells), and thus may establish a relatively normal hemopoiesis for variable periods of time while the leukemic clones of cells are growing out again more slowly. Further understanding of stem cell behavior and kinetics in man is essential for handling of several diseases of major importance.

Certain types of anemia in the mouse are genetically controlled. Detailed studies using the marrow transplantation technique of Till and McCulloch have shown that one inherited anemia is produced through deficient colony formation by stem cells, whereas, another inherited trait is characterized by a situation in which the stem cells are normal but a host factor essential for the growth of its stem cells or normal transplanted stem cells is deficient (McCulloch et al., 1964). It is reasonable to expect that some of the fatal anemias of man will also prove to be genetically determined defects in stem cells or host factors.

3 / THE ERYTHROCYTE

Normal Erythropoiesis

A continual delivery of oxygen to the tissues is essential for life This transport is accomplished by hemoglobin, a respiratory pigment capable of accepting, transporting, and releasing oxygen to the tissues The hemoglobin is enclosed within the red cell Serious diseases are produced by aberrations in the structure of hemoglobin, abnormality in the structure of the red cell envelope in which the hemoglobin is enclosed, or abnormalities in the red cell assembly line Under normal circumstances in adult man, all blood cell production takes place inside of the bone marrow Nutrient arteries lead through the cortex of the bone and into the marrow cavity Within the cavity they branch into distributing arterioles, which in turn give rise to the sinusoidal bed The diffuse, fragile, sinusoidal bed coalesces into a central vein that proceeds to a foramen and exits from the bone The sinuses form a system of vessels running radially from the periphery toward the central longitudinal vein .Hematopoietic tissue lies between the sinuses The fully formed sinusoidal wall is trilaminar and consists of an endothelial lining cell, basement membrane and adventitial cells In areas there may be only the lining endothelial cell Sometimes the wall is bilaminar consisting only of lining cell and basement membrane, or lining cell and adventitial cell These latter cells may be phagocytic They also contain fat droplets and may accumulate large deposits of fat characteristic of fatty marrow By electron microscopy, it is seen that cells proliferate outside of the sinusoids, and megakaryocytes can be seen to discharge platelets through mural apertures In some places large segments of the sinus wall may become attenuated, pierced by apertures Normoblasts, reticulocytes, and granulocytic leukocytes enter the circulation by passing into a sinus; they may pass through existing apertures or create an aperture by pressing into a sinus wall. A segment of the sinus wall may disappear permitting extravascular cells to exude into the circulation It is believed that the sinuses and extrasinusoidal cords form a system wherein portions become vascular or extravascular depending upon the requirements for hematopoiesis The blood flow is regulated through the arterioles and delivery of cells to the blood (Weiss, 1965)

Erythropoiesis is one of the better understood cell renewal systems of man There is a clearly defined flow of cells from the primitive, common stem cell to the mature red cell in the blood (see Fig 4 8) In the past, the accepted concept demanded an undifferentiated stem cell pool which is acted upon by erythropoietin, a specific inductor that directs stem cells irreversibly down the erythropoietic pathway (see below) In recent years, however, evidence has accumulated indicating that there are two functional, if not morphological levels of stem cells (see Fig 4 9) One stem cell is pluripotent (not sensitive to erythropoietin), and one is committed to erythropoiesis and is responsive to erythropoietin This dual notion is similar to the very old concept that there may be homoplastic hemopoiesis, the production of mature cells by young elements of the same type, and also heteroplastic hemopoiesis, when increased demands are met by increased production from the common pluripotent stem cell (Maximow and Bloom, 1948) The committed stem cell has been shown to be predominantly in a proliferative cycle, whereas, the pluripotent stem cell is mainly in a resting stage (G_0) as would have been expected by Maximow and Bloom This newer concept is derived from studies in which agents that destroy cells in deoxyribonucleic acid (DNA) synthesis (hydroxyurea and tritiated thymidine, ^{3}HTdR) were used. Administration of these materials drastically reduced the number of cells capable of responding to erythropoietin, but did not significantly influence the transplantability of the undifferentiated colony forming stem cells and their ability to restore all lines of hematopoiesis (Morse et al., 1969,

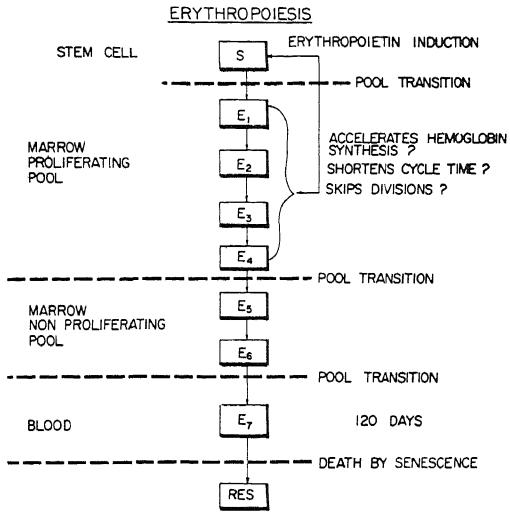

Fig 4 8 Schematic presentation of flow of cells from the common stem cell through the proliferating and non-proliferating cells to ultimate death by senescence Alleged points of action of erythropoietin are indicated (From Cronkite 1964 b)

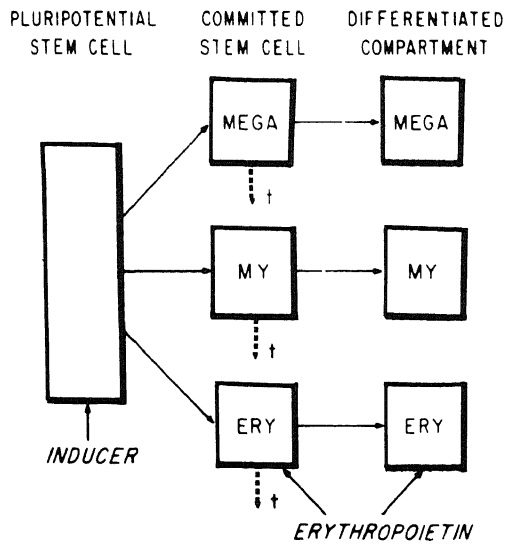

Fig 4 9 A schematic model of hematopoiesis Meg megakaryocytic MY myelocytic ERY erythropoietic Dashed line and cross indicate cell death (From Stohlman 1970)

Iscove et al , 1970) (see chap 2) Although the factors regulating the pluripotent cell are poorly understood, it has been clear that these cells can circulate in the blood stream under stress (Brecher and Cronkite, 1951). It has been suggested that the pluripotent stem cells are in a dynamic equilibrium with tissue stem cells and settle out and grow where there is a favorable microenvironment (Kretchmar et al , 1970) To date, it appears that the pluripotent stem cells are not under humoral control A short range cell-to-cell type of interaction has been postulated as being the method of regulating proliferation and differentiation of pluripotent cells This has been related to the histocompatibility surface antigens and other factors (McCulloch and Till, 1970, Cudkowicz and Stimpfling, 1964) Whether these short range cell interactions are stimulatory or inhibitory remains obscure The concept of the relationship between the pluripotent stem cell and committed stem cells in the differentiated cell lines is shown in Figure 4 9 It is not clear whether dedifferentiation of a committed stem cell back to the pluripotent cell is possible Erythropoietin has been postulated to decrease the cycle time at the expense of the G_1 phase It might be pointed out here that as mechanisms for increasing the cell output, there are three possibilities *1*) increasing the input of stem cells down the differentiated cell pathway with the same number of mitoses during the same period of time, this will increase the production rate in proportion to increased stem cell input and will require additional space, *2*) shortening the generative cycle with more mitoses in the same period of time, this will increase production rate in proportion to the additional number of mitoses, or *3*) a combination of both (See Chapter 2 for discussion of principles involved)

Upon entering the erythropoietic compartment, the stem cell rapidly assumes cytological characteristics of the differentiated line [1] As the cytological characteristics of the nucleus and cytoplasm change, the cells receive successively different names—proerythroblasts (E_1), large basophilic normoblasts (E_2), small basophilic normoblasts (E_3), polychromatophilic normoblasts (E_4), late nondividing normoblasts (E_5), reticulocytes (E_6), and the erythrocyte (E_7) During the stages of E_1 through E_4, one can observe mitosis and "flash" labeling of DNA by ^{3}HTdR in a clearly defined fraction of each cytological class It is generally assumed and/or implied that each cell that enters erythropoiesis divides in each successive stage This has not been proved

[1] See standard hematology atlases for description of cell types

[g] K_b, hourly birth rate of cells within a compartment
[h] K_{out}, hourly rate of exit of cells out of a compartment

Some cells (as will be discussed later) may jump all the way from an E_1 to an E_4 or E_5 without intervening mitoses

At the level of E_5, mitosis and DNA synthesis are rarely if ever seen The switching off of cell proliferation is thought to be due to the increasing concentration of hemoglobin which, when it attains about 20%, is believed to suppress further cell cycling It is known that an equilibrium exists between the intranuclear and cytoplasmic hemoglobin through nuclear pores It is plausible though not proved that the concentration of this specific protein inhibits further cell proliferation (Stohlman, 1970) Within about 9 hr after the cells cease cycling, the nucleus of the E_5 cell is ejected and the cell becomes a reticulocyte (Bond et al , 1962)

Utilizing the principles described in Chapter 2, the relative production rates of red cell precursors is shown in Table 4 3 In the calculation of birth rates, a DNA synthesis time of 12 hr was used (Stryckmans et al , 1966) The transit rate from E_4 to E_5 was determined by the movement of the labeled cells from the proliferating compartment into the first segment of the nonproliferating compartment (see chap 2, Fig 4 6 for principles) In Table 4 3, the replacement rate of E_5 by labeled E_4 was 2 91%/hr. for a maximum turnover time[2] of 34 hr If unlabeled cells made the transit in parallel, the turnover rate would be faster and turnover time shorter

If the rate of entrance of cells into E_5, the first nondividing compartment, equals the rate of production of cells in E_4, there is no loss of cells by death in the assembly line, if more cells are produced in E_4 than appear in E_5,

[2] Reciprocal of turnover time is turnover rate.

there is a loss of cells These data show that there was an apparent loss between E_4 and E_5 of 15 to 35% (average of 25%) for the three individuals This is a very crude preliminary estimate However, some ineffective erythropoiesis would have been predicted (Finch, 1959)

After loss of the nucleus, the cell is called a reticulocyte because it contains residual ribonucleic acid (RNA) (ribosomes, messenger and transfer) which stains with new methylene blue or brilliant cresyl blue and thus makes it possible to identify morphologically this cell type Reticulocytes mature to red cells in the peripheral blood with an average maturation time of 33 hr in vivo (Stryckmans et al , 1966)

Further insight into the kinetics of red blood cell formation in man can be obtained by looking at the turnover of red cells If one assumes a red cell concentration of 5×10^6/mm ^{3}, an average life span of 120 days and a blood volume of 6 9% of body weight, the turnover rate of red blood cells (RBC) in the blood (RTR) is

$$\text{RTR} = \frac{\text{Red cell per unit volume} \times \text{blood vol /kg body weight}}{\text{RBC life span in days} \times 24} \quad (1)$$

$$= 5 \times 10^6 \times 10^3 \times 0\,060 \times 10^3/120 \times 24$$

$$= 12 \times 10^7 \text{ red cells/kg /hr}$$

Since data discussed earlier suggest a loss of 25% of nucleated red cells in the assembly line, the estimated red cell precursor marrow production rate (RPR) is

$$\text{RPR} = \text{RTR}/0\,75 = 16 \times 10^7/\text{kg /hr}$$

The total number of nucleated red cell precursors has been measured (Donohue et al , 1958), there are $5\,3 \times 10^9$ nucleated red cell precursors per kilogram By pooling data in Table 4 3, one finds that 0 43 of the nucleated red cells are in the proliferating pool (E_1 to E_4) Hence, this pool is $2\,3 \times 10^9$ cells/kg The ratio of dividing erythropoietic precursors to dividing granulopoietic precursors is (2 3 2 6) or 0 88 The granulocyte turnover rate is blood is $6\,8 \times 10^7$/kg /hr. (chap 7) The ratio of these two turnover rates in the blood cells is $12 \times 10^7 - 6\,8 \times 10^7$ or 1.76 This means that for each respective precursor about two red cells are being destroyed in the blood for each granulocyte. Since there is an apparent loss of some cells in red cell pathway more than two are being made. (It has been suggested by Patt and Maloney, (1964) that some are lost in myelopoiesis) The erythropoietic machinery is producing cells faster, whereas, the granulopoietic machinery appears to be throttled back

The average I_L from the proliferating E_4 compartment is about 0 54 The average t_G is roughly 22 hr The sum of t_S, t_{G2} and t_M is 16 (12 + 3 + 1) hr , hence, t_{G1} is about 6 hr

As mentioned earlier, red cell production can be increased by *1*) an increased number of mitoses in the same period of time between the stem cell and E_5, the nondividing compartment, *2*) an increased flux of stem cells into the erythropoietic line, or *3*) a combination of *1*) and *2*) A doubling of stem cell input of each additional mitosis doubles the output and doubles the space required for erythropoiesis within a rigid bony box if transit time remains the same The space can come from encroachment on other cell lines, sinusoids, and yellow fatty marrow If the generation or transit times decrease, space occupied by the erythroid marrow will diminish and so permit an increased stem cell input or increased number of mitoses in the same space with a consequent increase in red cell output Chronic blood loss or chronic hemolysis is compensated by an obvious increase in the size of the erythroid marrow, and red cell turnover rates six times normal have been observed

If erythroid generation time can be shortened at expense of G_1 and if there are roughly four sequential mitoses, there is a possibility, at least in principle, that the marrow could accommodate another mitosis so as to double the erythrocyte output Further increases would require an increased stem cell input and more marrow space

If there were more extensive comparable data on absolute cellularity of the bone marrow and the fraction in DNA synthesis, one could estimate by principles elaborated in Chapter 2 the "steady-state" stem cell influx into erythropoiesis, the average number of mitoses from the stem cell to E_5, and the average transit time from the stem cell to E_5 Preliminary estimates suggest an average of 2 27 mitoses and an input of stem cells of $3\,3 \times 10^7$/kg /hr It is believed that a small fraction of E_1 or E_2 may proceed directly to the nondividing pool (Alpen and Cranmore, 1959), a notion also described as "skipping mitoses," which is believed to be more frequent when

erythropoiesis is stressed (Stohlman, 1970) Their observations and the failure to compute a whole integer for the number of mitoses suggest that cells divide a variable number of times after commencing down the erythropoietic pathway—a notion inconsistent with most diagrams for hemopoiesis which show a mitosis at each stage of hemopoietic development The presence of mitoses or DNA synthesis only demonstrates that cells can divide or commence replication at that stage but does not prove that they do in fact divide (Killmann et al , (1963) An extra mitosis will double output only if each cell divides an additional time If a significant number of cells proceeds from E_1 to E_5 without this or with even fewer divisions the total output will not be doubled

Emphasis has been placed upon the functional study of the stem cell, and upon the measurement of erythropoiesis by labeling cells with ^{3}HTdR while they are in DNA synthesis and observing their subsequent flow as described earlier There are many other ways of examining erythropoiesis For example, most of the iron used in hemoglobin synthesis is incorporated into the cell at the E_1 and E_2 stage If radioactive iron is used as an in vivo label, grain counts can be made by radioautography of cells that are young, and then subsequently of cells in the later stages Each mitotic division decreases the grain count of a labeled cell by one-half Approximately three mitotic divisions with a generation time of about 20 hr occur during the transit from an E_1 to and E_4 cell (Alpen and Cranmore, 1959) However, some cells apparently jump from E_1 to E_5 without further mitosis

The preceding discussion and calculations are based on very few observations and probably have a large error The examples serve to show principles involved and approaches to an understanding of a complex cell renewal system Further observations may change considerably the actual values for the time parameters of the cell cycle and the cell fluxes

REGULATION OF ERYTHROPOIESIS

The *erythron* is a term used to indicate the combined mass of immature red cells within the bone marrow and mature cells in the blood (Castle and Minot, 1936) Under conditions of health, the erythron is maintained quite constant However, it is very responsive to changes in oxygen tension hemorrhage, hemolysis and disease It was predicted by Paul Bert in 1878 that high altitudes or low oxygen tension would demand a compensation in the mass of hemoglobin in order to transport more oxygen This prediction was fulfilled and vividly observed in the striking effects upon the concentration of red cells in human beings living at high altitudes such as in the Peruvian Andes or the Himalayan mountains The first convincing evidence that there was a substance circulating in the blood that stimulated erythropoiesis came from the studies on parabiotic rats in which it was found that a similar degree of normoblastic hyperplasia and increase in the red cell mass occurred when one rat breathed air at atmospheric pressure and one breathed air with a low oxygen tension (Reissmann, 1950) Clinical studies in patients with right to left flow through a patent ductus arteriosis and consequently, with cyanosis and hypoxia of the lower part of the body and normal oxygen tension in the upper part of the body, have shown that the degree of erythropoietic hyperplasia in specimens of the bone marrow from the upper and lower part of the body are identical (Stohlman et al , 1964) These observations made untenable the hypothesis that oxygen alone directly controls red cell production and produced very strong evidence that as a result of hypoxia there is a material produced that circulates in the blood and controls the rate of red cell production

The presence of a nondialyzable substance in the serum of rabbits rendered anemic by bleeding or made hypoxic by low oxygen tension of the inspired air, a substance that causes reticulocyte responses and increases in nucleated red cells in the marrow when injected intravenously to normal homologous recipients, was demonstrated by Erslev (1959) *Erythropoietin* is now recognized as a glycoprotein hormone and to be an important regulator of erythropoiesis in mammals It is detectable in increased amounts in the body fluids of animals subjected to various forms of hypoxia as well as in oxygen deficiency states in man Erythropoietin is involved in accelerating erythropoiesis in the panic states following massive hemorrhage or exposure to severe hypoxia as a result of high altitude, severe hemorrhage, hemolysis, or cardiopulmonary disease In addition, it presumably plays an essential role in the day-to-day replacement of

red cells The evidence for the twofold role is overwhelming Furthermore, hypertransfusion by red cells will almost completely suppress erythropoiesis

The kidney has been established as a principle although not the exclusive site of production of erythropoietin Nephrectomy in animals results in a marked diminution in the production of erythropoietin following the induction of anemia or low oxygen tension of the inspired air The failure to extract erythropoietin from kidneys led investigators to determine whether it was present in the form of a precursor It has now been shown that there is a factor, called renal erythropoietic factor (REF), which is not related chemically to erythropoietin (Gordon and Zanjani, 1970) This factor is capable of generating erythropoietin when incubated in vitro with normal serum It is present in the mitochondrial fraction of kidney, hypotonic extracts of this fraction contains significant quantities of the material It is now believed that the REF is an enzyme that cleaves a part of the serum substrate to produce functional erythropoietin The system appears to be analogous to the renin-angiotension mechanism

Conceptually, the steady state can be described as in Figure 4 10 Starting with the blood compartment which transports oxygen, one can visualize that as the red cell mass diminishes the delivery of oxygen decreases and allows a tissue hypoxia to develop This results in secretion of the precursor of erythropoietin and its activation by the renal erythropoietic factor The active erythropoietin stimulates the committed stem cell compartment to proliferate, possibly decreases the generation time of erythrocytic precursors and also accelerates the synthesis of hemoglobin throughout the proliferating compartment There is a time

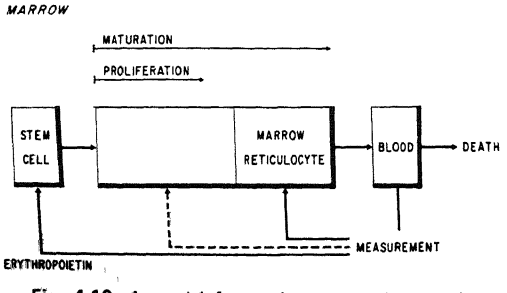

Fig. 4.10. A model for erythropoiesis showing feedback relationship with peripheral blood (From Stohlman 1970)

delay of several days from differentiation through the maturation and proliferation compartments to the reticulocyte and the appearance of the mature red cell in the peripheral blood Whether the disturbance in oxygen delivery has occurred as a result of a decrease in the number of red cells, changes in the oxygen association curve or blood flow, there is a time delay before this disturbance can be corrected It can be argued that such a system, because of the long time delay, will tend to over correct and thus oscillate, the oscillation will have a period of twice the time delay In the case of erythropoiesis, however, because the lifespan of the red blood cell in the peripheral blood is much longer than the stem cell to red cell transit the oscillation will be damped, yet it can be detected by measuring oscillations of the reticulocyte count in the blood (Moreley and Stohlman, 1969) The preceding observations show that erythropoiesis (and, in fact, all hemopoiesis as will be discussed in chap 7) is not a continual steady state in which production at any one moment equals destruction, but rather a controlled state of sustained oscillations in which the production and destruction rates are equal when averaged over an interval equal to the duration of the cycle

Red Cell Structure and Functions

For many years the red cell was considered to be a nonliving cell that transports oxygen It is estimated that in its average 120 day life span it travels 170 miles to deliver oxygen to the tissues The complexity of the red cell was greatly underestimated until relatively recently During its development in the marrow approximately 4×10^8 molecules of hemoglobin are synthesized comprising 95% of its dry weight and 30% of its wet weight The red cells transport about 250 ml of oxygen/min to the tissues in the average man in a basal state It has been estimated that the average blood cell spends about 1 78 sec in a pulmonary capillary and that the oxygenation takes place within about one-third of this time The total surface area of the circulating erythrocytes is 1500 times the body surface (Harris, 1970)

THE SIZE, SHAPE AND STRUCTURE OF THE RED CELL

Human erythrocytes are biconcave, nonnucleated disks having a mean diameter of 7 2

μm (6 to 9 μm, see Fig 4 11) and a thickness of about 2 2 μm (2 to 2 4 μm) at the thickest part i e near the circumference, and about 1 μm at the center As a result of osmotic changes and the consequent passage of water into the cell the diameter increases with a shift in the acid-base balance of the blood toward the acid side The cell is, therefore slightly larger in venous than in arterial blood its diameter is increased by about 0 5 μm in muscular exercise and is decreased by forced breathing The central portion of the cell is much thinner than its edges which appear heaped up into a circumferential mound around a central depression This construction gives it a biconcave contour or a roughly dumbbell outline when viewed edgewise (Fig 4 11) The average area of a red cell is 120 μm and the volume 85 μm

The biconcave disk is uniquely suited for the transport of oxygen A sphere has a surface that is equidistant from the center, and also has the smallest surface area in relation to its mass A thin disk on the other hand presents an almost maximal surface area in relation to its bulk, and diffusion distances are shorter This form secures the advantages of equal and rapid diffusion of oxygen to its interior and a relatively large surface area for the absorption of the gas The biconcave form also gives the blood cell a mechanical advantage, in that the changes in volume which the cell goes through from time to time can be accomplished with a minimal amount of tension being placed upon the cell membrane (Hartridge, 1920)

The red cell consists of 71% water, 28% hemoglobin, 7% lipid (cholesterol, lecithin, and others), and a 3% mixture of sugars, salt, enzyme, protein, and glutathione The ultrastructure of the red cell membrane is very complex The membrane is birefringent indicating a patterned molecular structure Electron microscopy shows the surface of the human red cell to be covered by a layer of circular plaque-like structures approximately 100 × 500 × 30 Å These plaques are believed to be related to channels or pores that allow for the ingress and egress of water and electrolytes The hydrophobic groups of the plaques are projected outward and impart a very strong negative although not necessarily uniform charge to the surface of the cell Beneath the plaque, proteins are arranged in long fibrillar elements called elanin A, B, O and C, D, E antigens are

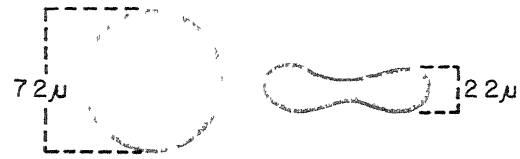

Fig 4 11 Diagram showing dimensions of the red cell

associated with the elanin fractions The membrane is exceptionally well structured at the surface and contains practically no hemoglobin Towards the center there is less order and the concentration of hemoglobin increases Knowledge of the structure of the red cell membrane is the result of 30 years of electron microscopy, where the appearance of membranes at high resolutions is related to the methods used to obtain the pictures The new technique of "freeze cleaving' electron microscopy has permitted considerable progress in study of the membranes of cells Figure 4 12 shows a concept of the red cell structure as revealed by this technique Note that the membrane associated particles may extend through the full thickness of the membrane Although great progress has been made in studying the structure of the membrane chemically and ultrastructurally, the relationship of structure to function is not clearly demonstrated

THE RED CELL AT WORK

An amazing fact is that the red cell does no "work" in fulfilling its primary function of oxygen and carbon dioxide transport Oxygen and carbon dioxide are transported to hemoglobin by diffusion These vital transport functions are passive and do not require energy One may ask then, why does the red cell contain the set of enzymes necessary to carry out anerobic carbohydrate metabolism and the hexosemonophosphate shunt? In addition, it possesses a wide spectrum of enzyme systems capable of directing the utilization of potential energy of the various high energy compounds that are produced This energy is presumably used to maintain the cell as a functioning unit

Figure 4 13 shows the general metabolic pathways of adult erythrocytes Most of these enzymes are phosphate containing The interrelations and the role of these enzymes is shown schematically The red cell retains only two carbohydrate pathways The energy for

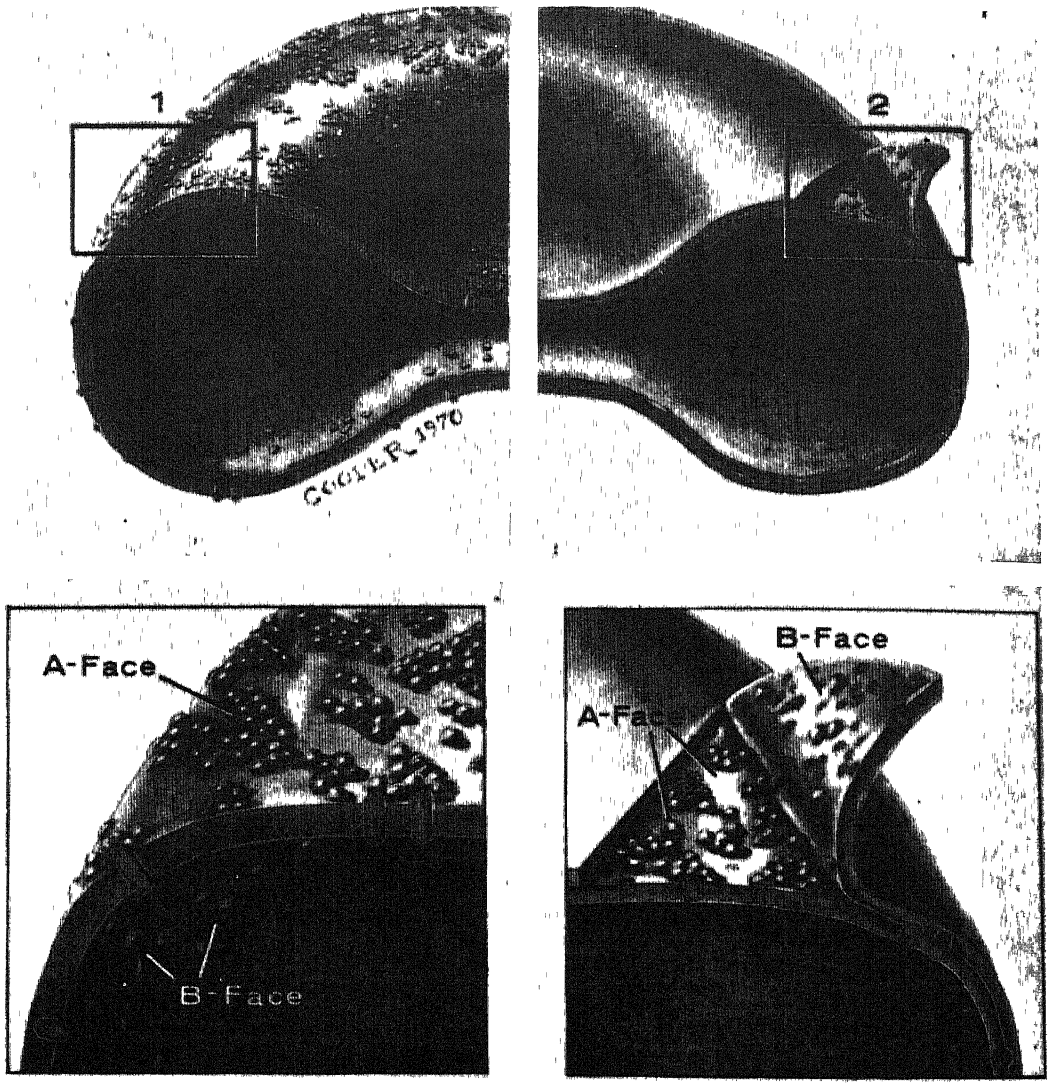

Fig 4 12 Artist's concept of the alternative interpretations of the location of the A-Surface and B-Surface of red cell membranes demonstrated with freeze-cleaving Interpretation 1 shows the membrane-associated particles on the true outer (*Face-A*) and inner (*Face-B*) surfaces of the membrane The two surfaces face in opposite directions Interpretation 2 shows the fracture entering the membrane and passing through its interior *Face-A* and *Face-B* point toward each other within the membrane (From Weinstein and McNutt 1970)

maintaining cellular integrity and the high internal concentration of potassium, and for prevention of the oxidation of heme is provided by these two pathways

a) The *Embden-Meyerhof pathway* carries out, through a series of phosphorylated intermediates, the anerobic conversion of glucose to lactate with the net production of potential energy in the form of two moles of adenosine triphosphate (ATP) for each mole of glucose The ATP's stored energy is essential for maintaining the normal cation concentration and balance of the red cells Reduced diphosphopyridine nucleotide (DPNH) is also produced in this pathway, it is essential for the function of methemoglobin reductase

b) The *phosphogluconate pathway* oxidizes 1 mole of glucose to carbon dioxide and water and produces 2 moles of a compound with a high reductive capacity, reduced triphosphopyridine nucleotide (TPNH) Red cell survival in the circulation is related to the action of

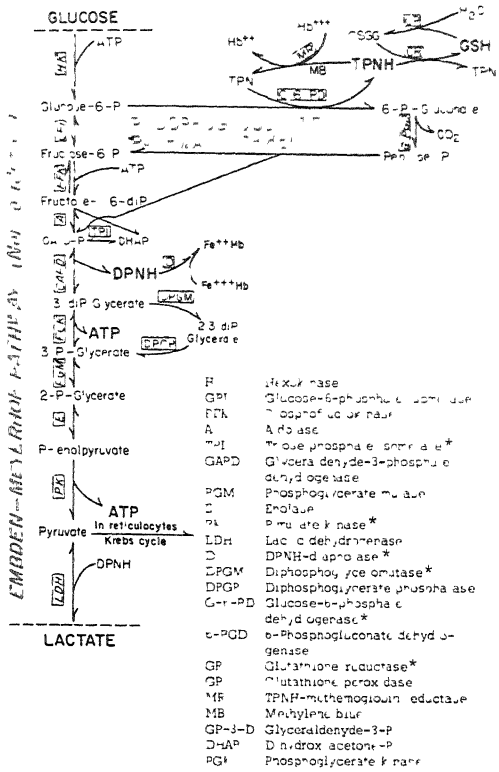

Fig 4-13 Erythrocyte metabolic pathways in adult erythrocytes Asterisks indicate recognized hereditary enzyme deficiencies In the glycolytic pathway deficiencies of pyruvate kinase triose phosphate isomerase and diphosphoglyceromutase are responsible for shortening cell survival In the oxidative pathway deficiencies of glucose-6-phosphate dehydrogenase glutathione reductase or GSH itself provide a liability to exogenous or endogenous oxidative stress and thus to acute hemolysis with oxidant drug exposure or if severe enough to chronic hemolysis without oxidant drug administration (From Simon et al 1966)

glutathione reductase upon thiols of the red cell membrane (see below)

The glycolytic pathway utilizes about 10 times as much glucose as the phosphogluconate shunt With aging of the adult red cell in the circulation, the activity of some of the enzymes of both pathways declines along with the lipids of the red cell envelope Certain deficiencies in the red cell enzymes are inherited and may produce severe hemolytic anemias, sensitivity of red cells to drugs, and short life span of the red cells It is beyond the scope of this chapter to go into details on the energy production and utilization in the red cell, but it seems to be reasonably well demonstrated that the energies developed are used for *1)* running the sodium and potassium pump to maintain the plasma red cell gradients *2)* keeping the hemoglobin in a functional state capable of reversible deoxygenation, and *3)* maintaining the normal equilibrium between oxidized and reduced glutathione participation in the maintenance of a lipid turnover and functions not yet described

Abnormalities in the phosphogluconate oxidative pathway are clinically important, even though only 10% of the glucose used is metabolized via this pathway Abnormalities in this shunt may result in acute or chronic hemolytic anemia The exact mechanism is not known but it is believed to be related to the function of this shunt in maintaining normal concentrations of thiol compounds in the red cell and its membrane One type of abnormality is a deficiency of glucose 6-phosphate dehydrogenase (G6PD), which may be present in as many as 100,000 000 persons The most severe of the hemolytic anemias are produced by drugs in individuals with G6PD deficiency In a few persons a chronic hemolysis may occur without prior drug sensitization

An example of a severe drug effect in G6PD deficiency is the condition that may occur in the treatment of malaria with Primaquine, where some individuals develop severe acute hemolytic anemia Negroes are more susceptible to the hemolytic effect of this agent than white people The susceptibility resides in the subject's red cells, since following the transfusion of tagged red cells from a sensitive subject into a nonsensitive subject, there occurs a striking reduction in their lifespan when Primaquine is then given to the nonsensitive recipient G6PD activity, reduced in the blood cells of Primaquine-sensitive individuals, is concerned with regeneration of TPNH and is required in the reduction of oxidized glutathione The glutathione level of sensitive cells is consistently lower than that of nonsensitive cells, and a rapid fall in the red cell glutathione level occurs in vivo when Primaquine is administered to sensitive individuals, but not when it is given to insensitive persons

Many other drugs may produce hemolysis in G6PD deficient individuals, rarely, even aspirin The observation that the eating of fava beans produces severe hemolytic anemia in G6PD deficient Caucasians but not in Negroes shows that at least two different biochemical defects exists

THE RED CELL LIFE SPAN AND ITS MEASUREMENT

The first reasonable estimate of the life span of the red cell was made by Ashby (1919) Her technique involved a transfusion of compatible but immunologically distinct red cells that could be identified by agglutination at regular intervals Techniques available now are the cohort labeling methods (glycine labeled with nitrogen-15, carbon-14, tritium or radioiron) and the random labels (immunological marker $DF^{32}P$, tritium, carbon-14, ^{51}Cr) The indirect methods of plasma radioiron clearance and red blood cell radioiron uptake, carbon monoxide excretion and bilirubin production are useful but more cumbersome (Berlin et al , 1959, Berk et al , 1970)

The *cohort method* depends upon the labeling of the red cell by biosynthetic incorporation of a precursor into hemoglobin in the marrow This method has the requirement that the precursor's specific activity must be decreased rapidly by degradation so that there is essentially a "flash" labeling of the cohort of cells One can then observe these cells as they emerge from the marrow, live out their life span and die

The *random method* involves the labeling of cells of the peripheral blood in vitro (irrespective of their age), followed by autotransfusion and then regular estimates of their survival

The *indirect methods* deduce the rate of synthesis of red cells by mathematical interpretation of iron kinetics or the rate of elimination of hemoglobin catabolites such as CO and bile pigments (Berk et al , 1970)

All of the methods for determining red cell survival depend on the assumption of a steady state equilibrium between entrance and exit of red cells from the blood The indirect methods are acutely sensitive to diversions from a steady-state equilibrium, and are applicable only when the total red cell mass is constant or where the rate of change of the total red cell volume is known

In Figure 4 14, examples of cohort and random labeling curves are shown The glycine cohort labeled curve discloses the emergence of labeled cells into the blood The specific activity rises to a maximum, and then falls very slowly for 3 to 4 months due to random loss, and then is terminated by a more rapid decrease in a falling sigmoid curve that represents the integral of the frequency distribution of the individual red cell life spans (Shemin and Rittenberg, 1946) The midpoint on the descending curve signifies the mean life span It cells are being produced with a shortened life span, the curve is shifted to the left If there is a random destruction of cells as they emerge into the peripheral blood, one sees an immediate diminution in the concentration of the cohort labeled cells, only a small fraction survives to attain the mean life span of the normal red cells The DFP curve is similar to an Ashby curve and represents the disappear ance of a population of cells that is random is respect to their age from birth The older cells commence disappearing promptly, and there is a linear decline as cells age with the curve crossing the axis at approximately the mean life span of the red cell in the blood If there is a shortened life span, the curve will be linear with a steeper slope With random destruction there will be a curvilinear disappearance The ^{51}Cr curve is curvilinear because there is a slow, steady elution of Cr from the labeled cell Although this complicates the interpretation, ^{51}Cr labeling with $Na_2{}^{51}CrO_4$ is the technique generally used clinically because of the simplicity of the procedures

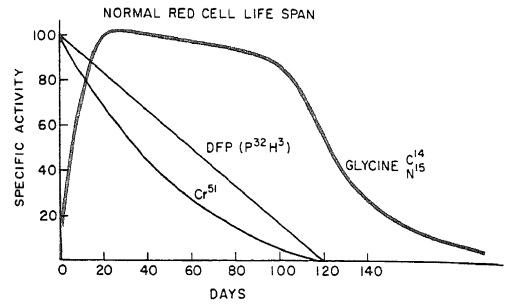

Fig 4 14 The specific activity of red cells in normal subjects after labeling with glycine DFP or ^{51}Cr (From Berk et al 1970)

VARIATIONS IN SIZE SHAPE, NUMBER AND STRUCTURE OF RED CELLS

Under physiological conditions, little change in shape of the red cell occurs although a few fragmented cells may be found in normal blood A slight change in volume, about 7 5% occurs due to osmotic changes incident to the respiratory cycle The red cells at birth and in early infancy are larger than in adult life This as well as the higher cell count is responsible

for the high packed cell volume (54%) of the infant's blood

In disease where the red cell is subject to many changes in size shape and structure examination of the blood and the identification of the various forms of abnormal cells is an important means employed in diagnosis of the different anemias Only the more outstanding abnormalities can be touched upon here An increase in the number of *reticulocytes* may be seen These young red cells resemble the ordinary cells in every way except that after supravital staining (alcohol solution of brilliant cresyl blue added to blood in the fresh state) a fine reticulum of basophilic material can be seen in the cytoplasm In normal blood, the reticulocytes are from 0 to 2% (av 0 8%) of the total red cell count They are increased after hemorrhage at high altitudes, by exercise, and in pernicious anemia following specific treatment A rise in the reticulocyte count indicates an increased activity of the blood forming tissue—the bone marrow—which as a result of a specific stimulus turns out a larger number of young cells

Shrinkage of the contents of the red cell (*crenation*) with wrinkling of its limiting membrane results from immersing the cells in a hypertonic solution In pernicious anemia, in particular, the presence of cells of unequal sizes (*anisocytosis*) and of deformed outline (*poikilocytosis*) is common The poikilocytes may assume the most bizarre forms, mulberry, target, flask, or hammer shapes may appear Erythrocytes with a globular form (*spherocytes*) or of an eliptoid or crescentic shape (*eliptocytes* and *sickle cells*) are found in certain types of anemia In sickle cell anemia, the red cells contain an abnormal type of hemoglobin (Pauling et al, 1949) In the deoxygenated form this is insoluble and forms crystalline "tactoids" within the cell membrane *Macrocytes* and *microcytes* are terms denoting red cells of larger and smaller size, respectively In certain conditions, e g, lead poisoning, fine dots of basophilic material appear throughout the cell, giving it a stippled appearance This abnormality is known as *punctate basophilia* In certain types of anemia, rings or twisted strands of basophilic material may be seen near the periphery of the cell These are derived from the nucleus and are known as Cabot's rings At other times small nuclear fragments Howell-Jolly bodies are present in the cytoplasm

Anemias

CLASSIFICATION ON BASIS OF RED CELL SIZE AND HEMOGLOBIN CONTENT

Mean Corpuscular Volume (MCV). This expresses the volume of the individual red cell in μm^3 (1 $mm^3 = 10^{12} \mu m^3$). The mean corpuscular volume in μm^3 is obtained by dividing the volume of packed cells expressed in ml/liter by the red cell count in millions/mm^3 (e g 450/5 - 90 μm^3)

Anemias may be classified according to the MCV as macrocytic (over 96) normocytic (86 to 96) and microcytic (under 80)

Mean corpuscular hemoglobin (MCH) is the hemoglobin per red cell expressed in $\mu\mu g$ (10^{-12} g) This may be obtained by dividing the hemoglobin per red cell expressed in $\mu\mu g$ (10^{-12} g) This may be obtained by dividing the The mean corpuscular hemoglobin may vary with the concentration of hemoglobin within the cell and with the volume of the cell

Mean corpuscular hemoglobin concentration (MCHC) is the hemoglobin in g/100 ml of blood divided by the packed cell volume of 100 ml expressed as a percentage e g

$$(15/45) \quad 100 = 33\%$$

Above 30% is normal (normochromic), below 30% is hypochromic

In Table 4 4, the normal values and standard errors of red cell dimensions are tabulated The hemoglobin is best determined by a cyanmethemoglobin method The volume of the

Table 4 4
Normal values for red blood cells

	Males	Females
Red cell count/mm^3	5 4 ± 0 8	4 8 ± 0 6
Hemoglobin (g/100 ml)	16 0 ± 2 0	14 0 ± 2 0
Volume packed red cells (%)	47 0 ± 7 0	42 0 ± 5 0
Mean corpuscular volume MCV (μ^3)	87 ± 5	87 ± 5
Mean corpuscular hemoglobin MCH ($\gamma\gamma$)	29 ± 2	29 ± 2
Mean corpuscular concentration MCHC (%)	34 ± 2	34 ± 2

From Wintrobe 1967

packed red blood cells is determined by centrifuging blood to a constant volume of the red cells Variations in these indices are very useful in studying physiological processes that influence erythropoiesis, and also in the diagnosis of disease In Figure 4 15 the frequency distribution of red cell volumes for normal and microcytic red cells is shown

The red cell concentration in the past was counted microscopically by direct vision in a hemocytometer Determination of the size distribution of red cells was a tedious microscopic procedure of measuring visually several hundred cells on stained smears Electronic gating methods now determine the number and volume of particles rapidly and quickly, and may yield a graph of the size distribution within 100 sec (Brecher et al , 1962) In addition, more sophisticated, automatic electronic methods determine hemoglobin and red count, and print out red cell constants

Examples of abnormal red cells are shown in Figure 4 16

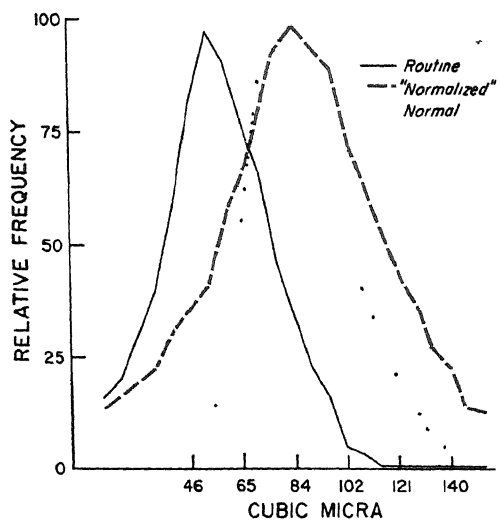

Fig 4 15 Normalization of microcytic curve for estimate of coefficient of variation (anisocytosis) Note microcytic curve has slightly narrower base than normal curve in routine run i e slightly smaller S D For estimate of coefficient of variation (C.V) however peak must be shifted by changing amplification to coincide with normal peak In the present case, C V is markedly greater than normal as can be seen from the much broader base of "normalized" curve (From Brecher et al 1962)

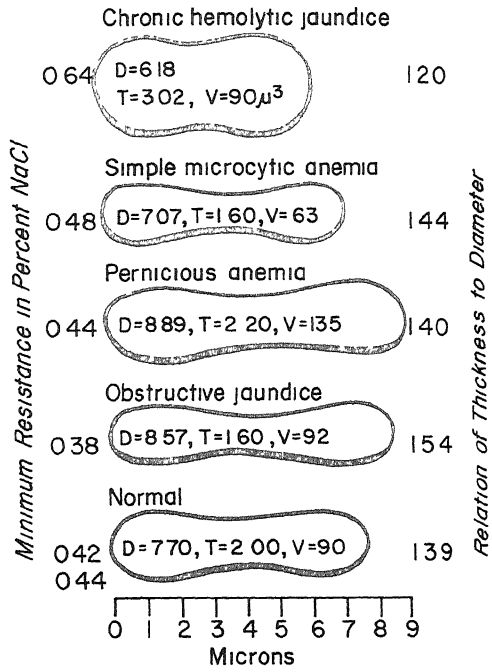

Fig 4 16 Red cell diameter thickness and volume in various clinical conditions compared with the normal *D* diameter *T* thickness *V* volume

HYPOCHROMIC MICROCYTIC ANEMIAS—IRON DEFICIENCY

In this group of anemias the essential defect is one of hemoglobin formation The hemoglobin percentage of the blood is reduced to a greater extent than the number of red cells The latter, indeed, may show only a slight reduction The MCH is considerably below the normal, which means that each red cell has received less than its normal quota of pigment The erythrocytes are also smaller than normal, so the MCV is also low The low MCH is in part the result of the smaller size of the red cell but also of a reduced concentration of pigment throughout the red cell's substance Some of the corpuscles are so pale that they either resemble "ghosts," or only the peripheral zone of the cell is colored (anisochromasia)

Iron deficiency is the cause of almost all the anemias belonging to this class The deficiency may result from increased iron requirements coupled with either a relative or absolute inadequacy of iron in the diet, or from defective absorption of the metal from the food Hypochromic anemia occurs most frequently in women of childbearing age in whom the dietary intake of iron is insufficient to meet their needs The anemia is aggravated by the losses of iron incident to menstruation or repeated pregnancies. In adult males the usual cause of this type of anemia is blood loss

Anemia of Infants. The fetus accumulates a

store of iron in the liver in the later months of gestation This serves as a reserve that is drawn upon for the manufacture of hemoglobin in infancy The high red cell concentration with which the infant comes into the world also contributes to the iron reserves In the normal infant the iron stores are sufficient for the manufacture of hemoglobin for the first 6 months or so Growth, however, makes heavy demands on the iron supplies, and after the first ½ year it is necessary to provide a diet that contains adequate amounts of iron in order to guard against the development of hypochromic anemia Cow's milk is very poor in both iron and copper If the iron stores are deficient at birth as in premature infants or as a result of maternal anemia, anemia may occur in the very young infant

The hypochromic anemias respond in a spectacular fashion to the administration of inorganic iron (e g , ferrous sulphate or carbonate, etc) The administration of copper is never necessary since this occurs in sufficient quantity in the diet and as an impurity in iron preparations

PERNICIOUS ANEMIA (ADDISON S ANEMIA) AND RELATED MACROCYTIC ANEMIAS

Pernicious anemia is due to a defect in the formation of the red blood cells Its chief features are

1) There is a great reduction in the number of red cells and consequently in the hemoglobin percentage The red blood cell counts in a very severe case may be less than 10% of the normal

2) The MCH is nevertheless elevated because the numbers of the red cells is reduced to a greater extent than is the hemoglobin percentage The MCHC is normal

3) The cells are large, the average diameter of the cells being increased to between 8 and 9 μm These large cells are called *macrocytes* The average volume of the individual red cells (Fig 4 16) is about 135 μm^3 (normal about 90 μm^3) *Normoblasts* and earlier forms may be present in the circulation , A characteristic large nucleated cell containing basophilic material in its cytoplasm and little or no hemoglobin is a feature of the bone marrow picture This cell, known as the *megaloblast*, differs chemically and morphologically from any cell of the normal erythrocyte series found either in bone marrow or blood

4) A great variation is found in the size of the cells—*anisocytosis*, the cells range from those smaller than normal to the large cells mentioned above *Poikilocytes* are markedly increased in frequency

5) There is an increase in iron and bilirubin of the plasma with increased excretion of pigment (urobilin, see below) The increase in plasma iron is due to its decreased utilization for the formation of red cells The increased plasma bilirubin is the result of increased red cell breakdown

6) Achlorhydria almost always exists

7) The tongue is sore and shiny, with atrophy of lingual papillae

8) There may be a combined degeneration of the spinal cord

9) There is an atrophy of the mucosa of the fundus and body of the stomach

In pernicious anemia the influx of cells into E_5 is only 5 to 15% of the K_{out} from E_4 indicating a very marked death in the production line In addition, the rate of replacement of E_5 by E_4 cells is drastically reduced from 2 91% to 0 3 to 1 67%/hr (Messner et al , 1969) An increased proportion of E_4 cells is found in G_2 (tetraploid DNA) and in cells between diploid and tetraploid that do not label with ^{3}HTdR in vitro and hence are shown to have stopped DNA synthesis (Wickramasinghe et al 1968) The in vivo and in vitro studies quite clearly demonstrate an abortion of cells in the production line This assertion is substantiated by the observation that this ineffective type of megaloblastic hemopoiesis declines for 2 to 2 5 days after vitamin B_{12} therapy during which it is replaced by normal erythropoiesis from the stem cell This interval sets perhaps a minimum time of 2 days for normal transit from the stem cell to the normal reticulocyte (Hillman et al , 1968) When erythropoiesis in guinea pigs is suppressed by induction of polycythemia there remain almost no reticulocytes in marrow or blood When the animals are then bled to induce new erythropoiesis, approximately 2 5 days are required for transit from the erythropoietin-sensitive stem cell to the reticulocyte (Griffiths et al , 1970)

The hematological aspects of this disease are cured by injections of vitamin B_{12} The progression of neurological complications is stopped but not reversed The pathogenesis will be discussed later

Red Cell Destruction, Normal and Abnormal

Under normal circumstances the red cells are subjected to trauma as they are deformed in passing through the capillary circulation For example, some of the splenic blood vessels may be only 3 μm in diameter compared to 7 μm for the red cell The capability of the red cell to undergo this deformation and return to the normal biconcave shape has been long appreciated Moreover, it can be deformed by relatively small forces The deformability and flexibility are exceptionally important in its physiological function Shear processes and deformation contribute to fragmentation of red cells Normal aging storage of red cells as in a blood bank, abnormalities in hemoglobin synthesis, sulfhydryl inhibitors, on inherited disorders of the membrane result in loss of intrinsic membrane deformability, or may alter the shape or the rigidity of cellular contents Within the spleen the pH may decrease and the cell membrane become stiffer, and this increases the probability of the cell's being removed from the circulation Alterations in the deformability of red cells appears to be a common precursor to destruction in all of the hemolytic anemias (LaCelle, 1970)

The destruction of red cells may take place intravascularly or extravascularly In the case of intravascular hemolysis, the hemoglobin is liberated and is bound by the haptoglobin The more usual type of destruction of red cells is extravascular and results from some alteration in the red cell membrane that is recognized by the reticuloendothelial system and causes the abnormal cells to be removed as they go through the spleen, lymph nodes, and bone marrow The most striking removal is by the spleen

The red cell defects that may lead to a short life because of cell removal may be due to an intracorpuscular abnormality that may be inherited or acquired Examples of the intracorpuscular abnormalities are hereditary spherocytosis, thalassemia, and hemoglobinopathies (about 40 have been described), sickel cell disease is a prime example Hereditary defects in carbohydrate metabolism also are important The extracorpuscular abnormalities are usually due to antibody coating of red cells, this is seen in transfusion reactions, erythroblastosis fetalis, or autoimmune hemolytic disease In addition, there is toxic nonimmunological hemolysis by phenylhydrazine, surface active compounds, heavy metals, infectious agents that produce hemolysins such as *Clostridum welchii*, malaria, other chronic infections, and malignancies There also may be combinations of intracorpuscular and extracorpuscular ab normalities

STRUCTURE OF THE SPLEEN RELATED TO REMOVAL OF AGING AND ABNORMAL RED CELLS

The first important fact about the spleen is that is constitutes a very large filtration bed In the normal adult about 2 liters of blood per minute pass through the spleen The structure of the organ is ideal for the detection and removal of abnormal or nondeformable cells (Fig 4 17) The splenic artery breaks up into trabecular arteries which continue to divide and penetrate into the parenchyma of the spleen Branches of a trabecular artery enter the white pulp of the spleen The dense white pulp consists of a network of loose reticular connective tissue whose interstices are packed with small lymphocytes and other cells This condensation of lymphocytes around the central arteriole is called the periarterial lymphatic sheath Some tiny branches of a central arteriole penetrate into and end in the lymphatic sheath However, most of the arteriolar branches penetrate through the sheath and terminate in the marginal zone or may continue into the red pulp In some areas there will be Malpighian corpuscles, these are produced by immunological stimulation and are shown to be sites of antibody production Some of the tiny arterioles that penetrate to the outside of the periarterial sheath of lym-

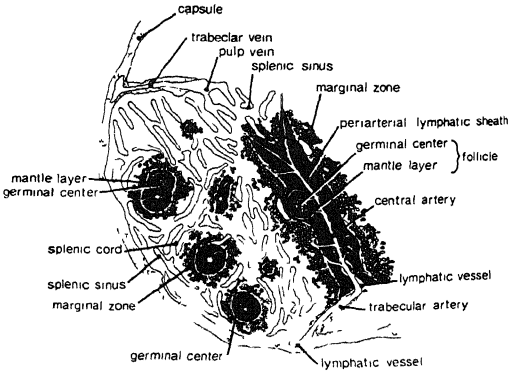

Fig 4 17 Plan of the structure of the spleen (From Weiss and Tavassoli 1970)

phocytes may end in splenic sinuses in an area called the marginal zone Other arterioles end blindly in the fine meshed reticular connective tissue of the marginal zone so that the cells of the blood migrate through the filtration network to the large number of venous sinuses in contact with the outer edge of the periarterial lymphatic sheath The marginal zone is continuous with the cords of the red pulp The reticular lacework of the marginal zone is jammed with macrophages, lymphocytes plasma cells and red cells The function of the marginal zone is filtration, as can be shown by the accumulation of particulate matter that has been injected into the splenic artery This area is filled with many phagocytic cells that will have the opportunity to recognize abnormalities and ingest these cells The central arteriole becomes smaller and finally enters and ends in the red pulp, rarely if ever connecting to venous sinuses The red pulp consists of vascular sinuses and cords The sinuses are thin walled venous vessels that anastomose into the venous system draining the red pulp

There are many hazards to cells traversing the spleen The splenic arterioles at their terminal ends are smaller than a red cell and possess a high endothelium between which the cell must squeeze Older cells are more fragile than young cells and may be broken in transit The less deformable cells, such as the spherocyte and sickle cells, may also be broken up Flow through the red pulp is irregular and there may be considerable stasis The stasis is associated with a decrease in oxygen content and pH, with a resulting shift in the oxygen dissociation curve that further lowers the oxygen tension All of these factors tend to cause the red cell to become more spherocytic and thus more susceptible to mechanical injury Antibody-coated cells are detected and removed by the phagocytes

Most red cells circulating through the spleen pass into the marginal zones and directly into the sinuses In doing this they pass through "windows" in the basement membrane and squeeze between the endothelial cells of the sinuses They may lose small bits of their cytoplasm in this transit and thus become smaller and more spheroidal and so less deformable on the next transit (Weiss, 1962, Weiss and Tavassoli, 1970).

It has been demonstrated that perfusion of the normal spleen by a mixture of normal and spherocytic red cells results in the removal of the spherocytes In addition, if one damages red cells by antibody or heat they are also trapped and removed in the spleen this can be determined by utilizing radio chromium labeled cells and external counting techniques Furthermore abnormal cells in transit through the spleen have inclusions removed from them Following splenectomy there is no detectable change in the life span of the red blood cell nevertheless, the number of abnormal red cells in the blood increases Consequently there is no doubt that the spleen is the major site for removal of aged and abnormal cells

CHEMICAL CHANGES RESULTING FROM INCREASED DEGRADATION OF HEMOGLOBIN

Hemoglobin degradation takes place within the entire reticuloendothelial system (A complete description is beyond the scope of this chapter) Globin is broken off the porphyrin ring is opened at the α-methene bridge, and iron is lost from the molecule but is very efficiently retained within the body for new hemoglobin synthesis When the porphyrin ring is opened at the α-methene bridge, 1 mole of carbon monoxide is formed for each mole of hemoglobin degradated (Nyman et al., 1959) The straight chain resulting from the cleavage of the porphyrin ring is reduced to bilirubin, a very insoluble material normally transported by an α-1 globulin When large amounts are produced the spill over is transported by albumin to the liver Within the liver, bilirubin is conjugated into glucuronide, a soluble form, that is excreted into the bile Normally a tiny amount leaks into the blood stream or perhaps is absorbed from the gastrointestinal tract The bilirubin glucuronide can be detected chemically because it reacts with Ehrlich's diazo reagent producing what is called a *direct reaction* showing the presence of conjugated bilirubin The unconjugated protein-bound material reacts only after treatment with alcohol to solubilize it and produce the color reaction This is called the *indirect reaction* Higher than normal indirect reaction indicates a hemolytic process Higher than normal direct reactions indicate an obstruction or malfunction of the liver and biliary tracts that permit leakage into the blood stream Within the gastrointestinal tract, the bilirubin is degraded

further by bacteria to a series of compounds known as urobilinogens Some of the material is reabsorbed into the blood stream but with the properly functioning liver they are rapidly cleared from the blood and little is found in the systemic circulation or the urine The presence of abnormally high amounts in the urine and stools is indicative of an increased hemoglobin catabolism

In normal man with red cell lifespan of 120 days, some 0 83% of his red cells per day are destroyed, representing about 6 g of hemoglobin Hemoglobin has a molecular weight of 66,000 and yields 4 molecules of urobilinogen Each gram of hemoglobin can produce 35 mg of urobilinogen The excretion of urobilinogen is theoxetically in the vicinity of 210 mg /day Substantial increases over this are indicative of a hemolytic process

RESPONSE TO HEMOLYTIC PROCESSES

Hemopoiesis is regulated primarily at the stem cell level When there is an increased peripheral destruction of cells from any hemolytic process there is a compensation within limits by increased red cell production that may prevent anemia The active red marrow may extend into the normally yellow fatty bone marrow For long periods of time the marrow can compensate for a reduction in life span of the red cell to one-sixth of the normal value This requires six times the normal production This is accomplished by an increased input of stem cells, possibly with a decrease in the generation time of the proliferating erythropoietic cells, and conceivably with an additional mitosis or two between the stem cell and the first nondividing red cell precursor A decrease in generation time of the red cell precursor at the expense of G_1 is conceivable It is doubtful whether S would be decreased In any case the reduction in time by itself could not accomplish a sixfold increase in production rate

When the red cell lifespan is shortened to less than one-sixth, it is certain that a hemolytic anemia will develop One sees a low hemoglobin and red count, the shortened red cell lifespan, increased reticulocyte count, possibly nucleated red cells in the peripheral blood, increased iron turnover rate and a markedly increased excretion of the products of hemoglobin destruction In addition, the extension of the marrow out into the long bones can be detected by radioisotopic techniques In severe sickle cell anemia and thalassemia the marrow may actually erode into the cortical bone producing typical x-ray pictures

EXAMPLES OF DISEASES WITH AN INTRACORPUSCULAR DEFECT

Hereditary Spherocytosis. This disease is inherited presumably as a single Mendelian dominant It is characterized by *1)* acholuric jaundice, *2)* fragile red cells spherocytic in shape, osmotically sensitive with intrinsic defective metabolism and structure, *3)* splenomegaly, and *4)* hemolysis with variable anemia The osmotically fragile red cells, being spheres, are not deformable and are easily removed in the transit through the spleen Thus, the lifespan of the red cell is randomly reduced, producing anemia if the marrow can not compensate for the shortened red cell life A large spleen develops, it is probably due to hyperplasia as a result of the extensive amount of red cells and hemoglobin that are being removed and degraded

The disease is always strikingly improved by splenectomy, because this operation removes a major hazard to the abnormal red cell The spleen itself, however, is not abnormal, since it can be shown by the Ashby technique of differential agglutination that normal cells transfused into a patient with hereditary spherocytosis both before and after splenectomy have a normal lifespan The defect then is related directly to an abnormality of the red cell

Thalassemia In Greece, a young married couple may bring to the Children's Clinic a child who is listless and pale with a prominent facies, and who has a hypochromic microcytic anemia with hyperplastic bone marrow There is elevated fetal hemoglobin and the other signs typical of the disease, *thalassemia major* This child will have a short and miserable life This disease is a national catastrophe in Greece and other parts of the Mediterranean littoral The only treatment is blood transfusion, but it will eventually cause trouble through "iron loading" from the destruction of the transfused red cells, and will lead to harmful deposits of iron (hemosiderosis) in liver, heart, brain, and other tissues.

This is an inherited disease Thalassemia major is the homozygous form, Thalassemia minor the heterozygous The latter gives relatively few symptoms, but the trait is detect-

able There is an intracorpuscular defect of the red cells, which have a very low MCV and MCHC There are abnormalities in hemoglobin synthesis and red cell formation and a large spleen Although there is no chemically defined abnormality in hemoglobin, the fetal type and A-2 variety of hemoglobin are present in abnormal quantities and at unusual ages Ineffective erythropoiesis is marked by red cell hyperplasia but inadequate red cell production The red cells show both an increased osmotic resistance and a marked shortening of lifespan upon transfusion into normal individuals or as measured in the patient In the homozygous form, the red cell lifespan is decreased so much that the marrow, even with extension into and erosion of the bones, is unable to keep up with cell destruction and a severe anemia occurs

Examples of extracorpuscular abnormalities that produce shortened red cell life span, such as mismatched transfusions and acquired hemolytic disease of the autoantibody type, are described in Chapters 6 and 7

Sickle Cell Anemia: A Molecular Hemolytic Disease. A negro child, normal at birth, developed somewhat slowly Intermittent periods of aching in the joints, severe chest and abdominal pain commenced in midchildhood An anemia developed The extremities were long and thin There was poor development of secondary sex characteristics This child has sickle cell disease, a chronic hereditary hemolytic disease due to the inheritance from each parent of a gene for hemoglobin S There is little, if any, normal hemoglobin, the fetal hemoglobin of red blood cells being replaced by hemoglobin S The pathology is molecular, It is based on a mutation with a substitution of valine for glutamic acid in the β chain of hemoglobin (Pauling et al, 1949, Ingram, 1956) The substitution involves only the β chain, and this explains why children with the homozygous form of the disease do not show the sickling phenomenon until adult hemoglobin S predominates over fetal hemoglobin (see chap 4) When the red cells are well oxygenated, the hemoglobin behaves physiologically But, when these cells are deprived of oxygen they assume sickle and other bizarre crescentic shapes When hemoglobin S is deoxygenated its solubility falls strikingly (Harris, 1959) This decrease in solubility results in a viscous semisolid cell that loses almost all of its deformability The rigid cells become trapped in the smaller blood vessels, where stasis further deoxygenation and reduced pH accentuate the situation Plugs and masses of erythrocytes occlude vessels and thrombosis and infarction follow A vicious cycle thus leads to more sickling The clinical results are severe painful crises resulting in multiple infarcts of bone, spleen, liver and to chronic leg ulcers (The repeated infarcts of the spleen may lead to an autosplenectomy) A chronic compensated, hemolytic anemia develops When the anemia becomes severe, the only therapy is blood transfusion The latter ultimately leads to difficulties through the increased iron intake as described in thalassemia Splenectomy does not improve the disease

A hazard to the individual with sickle cell disease is the possibility that a mistaken diagnosis of the painful crises may lead to emergency and unnecessary surgery

Pathogenesis of Pernicious and Megaloblastic Anemias

Whipple and his associates received the Nobel Prize in 1935 for having demonstrated that liver is the most effective food for the treatment of anemia in dogs Minot and Murphy (1926) gave lightly cooked liver (up to 1 lb/day) to patients with pernicious anemia with considerable improvement Shortly thereafter, it was found that meat incubated with normal gastric juice and then fed to a subject with pernicious anemia produced a striking effect (Castle et al, 1930) My introduction to hematology as a medical student and house officer was concerned with incubating hamburger with normal gastric juice and then feeding it to patients with pernicious anemia by stomach tube Today one gives a simple injection of vitamin B_{12} There has been progress for patient and physician

INTRINSIC AND EXTRINSIC FACTORS VITAMIN B_{12}

In pernicious anemia, there is an abnormality in gastric mucosa with a reduced volume of gastric secretions (achylia) and absence of hydrochloric acid in these secretions Also there is a lack of an *intrinsic factor* which normally acts on *extrinsic factor* that is present in meat and other foods. The extrinsic factor is now known to be vitamin B_{12}, a red-

dish compound possessing a cobalt-containing tetrapyrrolic ring that is synthesized by various bacteria It is available to man in meat from animals whose intestinal bacteria synthesized the material or consumed it in their diet The efficient absorption of dietary vitamin B_{12} requires an interaction with a glycoprotein of molecular weight 70,000 secreted by the fundus of the stomach, the intrinsic factor This factor binds strongly to vitamin B_{12} The complex then attaches to specific receptors that are on the intestinal wall and that facilitate the transfer of the vitamin B_{12} to the circulation, primarily through the upper part of the ileum In a normal individual with adequate amounts of intrinsic factor, approximately 70% of the ingested vitamin B_{12} is absorbed, whereas, in individuals such as those with pernicious anemia who have an absence of the intrinsic factor, less than 2% is absorbed The vitamin B_{12} that is absorbed through the gut is carried through the bloodstream by a specific protein carrier The serum concentration of vitamin B_{12} in normal individuals is 200 to 900 $\mu\mu$g /ml The total body vitamin B_{12} content in the normal adult is about 5,000 μg , about 1700 μg is stored in the liver Symptoms characteristic of pernicious anemia described earlier do not begin to appear until the total body B_{12} content drops to less than 500 μg The average daily requirement for vitamin B_{12} in the normal adult is approximately 2 5 μg During growth and severe demands on hemopoiesis the requirements may be increased It is beyond the scope of this section to describe the entire biochemical mechanism by which vitamin B_{12} exerts its effect on DNA synthesis and cell replication so as to eliminate the marked abnormalities in morphology and the inability of the cells to progress through the cell cycle that results in the marked ineffective erythropoiesis described earlier Since large amounts of thymidine will give a partial remission in pernicious anemia, it is believed that the defect may be focused on the synthesis of the DNA precursor, thymidylic acid.

The specific diagnosis of pernicious anemia requires the demonstration of the absence of intrinsic factor This is accomplished by using radioactive cobalt labeled vitamin B_{12} When the material is given without intrinsic factor, if there is no absorption into the body it is presumptive evidence of an absence of intrinsic factor Next, the radioactive vitamin B_{12} is incubated with a preparation of intrinsic factor and then given by mouth to the individual and the absorption measured again If now there is absorption, it is definite evidence of a deficiency of intrinsic factor

The technique of determining vitamin B_{12} absorption described by Schilling (1953) required the oral administration of radioactive vitamin B_{12} followed at an interval by a large quantity of nonradioactive vitamin B_{12} given intravenously to flush the radioactive material into the urine, where one estimated absorption on the basis of urinary excretion The alternative was to collect feces for a few days and measure the amount excreted The whole body counter makes it much simpler Cobalt-60 vitamin B_{12} is given by mouth followed by water to wash out the stomach Next cobalt-57 vitamin B_{12} is incubated with intrinsic factor and given by mouth The total body cobalt 60 and 57 are determined A few days later the radionuclide content of each in the body is determined If cobalt-60 has been absorbed in substantial amounts, the patient has his own intrinsic factor If only cobalt-57 was absorbed the patient has an absence of intrinsic factor If neither was absorbed significantly there is a defect in the small bowel that prevents absorption (Reizenstein et al, 1961)

FOLATES

The folates are also essential in DNA synthesis and normal cell proliferation In the absence of folates or inability to absorb them, macrocytic anemias may develop also The folates are synthesized by plants and are found in many vegetables and also in liver Most of the natural folic acid is in conjugated form and must be split by intestinal conjugases for absorption to proceed A normal diet contains daily from 1 to 2 mg of folic acid It is estimated that the normal daily requirement is about 50 μg During marked hemolysis, pregnancy, etc , the requirements are much higher Deficiencies develop in severe alcoholics

Folates are reduced by specific enzymes to tetrahydrofolic acid which accepts methyl groups and acts as a methyl transfer agent and coenzyme in the synthesis of some purines and pyrimidines required by DNA

The abnormalities in DNA synthesis induced by deficiency of vitamin B_{12} or folate affect all of the cell renewal systems The appearance is abnormal as shown by the mega-

loblast and the hypersegmented neutrophils in the blood Abnormalities in cell division in the other cell renewal systems account for the changes in the mouth stomach, vagina and skin The neurological damage is related specifically to vitamin B_{12} but how the vitamin B_{12} deficiency results in injury to neurons is not known

IRON METABOLISM

Iron is essential for the synthesis of hemoglobin and iron containing porphyrin enzymes The major abnormal loss of iron comes through hemorrhage If an individual must receive transfusions because of ineffective hemopoiesis due to suppression of the marrow or inadequate production of red cells, the total body iron content continues to increase in proportion to the number of transfusions given The only method normally available for regulating the total body iron content is through the regulation of intestinal absorption, there is no mechanism for regulating total body iron content by increasing its excretion

Most of the iron is absorbed through the upper jejunum, although small amounts can be absorbed anywhere from the stomach to the colon A considerable amount of the iron in food is released by peptic digestion in the stomach, and in the presence of the high acid content becomes ionizable inorganic iron (Jacobs and Greenman, 1969, Hoglund 1970) As the gastric contents flow into the jejunum and are neutralized, the ionized iron binds with other substances present in the lumen or is precipitated Iron complexes with phosphate, and other substances that are nonabsorbable may be produced. It is believed that some of the inorganic iron as ions is bound to gastric mucopolysaccharide which appears to act as a carrier enabling iron to remain in solution at the neutral pH in the small intestinal lumen (Jacobs and Miles, 1969) Heme iron of food is released from hemoglobin by digestion in the stomach, and apparently enters intestinal epithelial cells at which point it is degraded and the iron released to form intraepithelial complexes

The rate of iron absorption is regulated by the needs of the body A mucosal "block" theory has proposed that a regulatory mechanism for iron absorption resides entirely within the mucosal cells It was believed that the iron was bound by apoferritin into a highly insoluble form ferritin which was released according to the need for iron within the body (Granick 1946) The notion of regulation at the epithelial cell level in the small intestine has been questioned (Brown, et al, 1958), and has been replaced by the concept that control resides primarily at the level of the mucosal cell (Conrad and Crosby 1963)

It appears clear that individuals who are iron deficient increase their absorption of iron, whereas those with iron overload absorb relatively little Iron that has entered the epithelial cell at the luminal pole has two possible fates It may be transported to the base of the epithelial cell, across the basement membrane and into the plasma where it is bound by plasma transferrin The other route appears to be conversion to ferritin and its loss into the gastrointestinal tract as the mucosal cells are sloughed off of the tips of the villi [3] It is now believed that the prime regulator of the amount of iron absorbed into the body via the rapid transport method to the plasma is the capability of the cell to synthesize ferritin, sequester the gut iron, and then reject it into the intestinal lumen as the cells slough off (Conrad et al, 1964) It is not exactly established what switches on and off the synthesis of apoferritin to sequester the iron Certainly if there is a low mucosal apoferritin content the probability of iron's making the transit across the epithelial cell to be picked up by transferrin in plasma is much greater

Iron is transported in the blood by a single plasma protein, transferrin Approximately 30 to 40 mg of iron each day is required in a normal individual to synthesize hemoglobin This is 6 to 10 times the total plasma iron As described in Chapter 1, transferrin can bind two atoms of ferric iron per molecule The normal plasma iron concentration is between 60 and 150 μg/100 ml, which is about one-third of the plasma total iron-binding capacity This means approximately one-third of the circulating transferrin is saturated with iron

It is probable that transferrin molecules with

[3] The gastrointestinal tract is a cell renewal system in which the cells are being continually formed and desquamated The transit time from formation in the crypts of Lieberkuhn to the tip of the villus and being sluffed off is between 1 and 3 days depending on the species and the area of the gut

iron attach to developing red cells, allowing the iron to be transferred into the erythroblast with release of the transferrin to return and deliver more iron (Jandl and Katz, 1963).

The rates of iron transport, turnover, and incorporation into red cells are useful observations as indirect measures of red cell production. They are clinically and experimentally useful. The student is referred to hematology and nuclear medicine tests for details of techniques and data interpretation of iron kinetics (Wintrobe, 1967; Wagner, 1968).

As mentioned earlier, the commonest disease of iron metabolism is a deficiency induced by chronic hemorrhage in the male, repeated pregnancies and menstruation in the female, and nutritional deficiency of iron. There is an exceptionally rare congenital absence of transferrin. In chronic infection there is an ample amount of iron in the reticuloendothelial cells of the bone marrow, liver and spleen; there is a low serum iron and a low total iron-binding capacity along with a normocytic normochromic anemia. The exact pathogenesis is not clear, but removal of the infection usually completely corrects the disorder.

There is also a rare disorder of iron loading called hemochromatosis. The pathogenesis of this disorder is not clear, but it is characterized by extensive deposits of iron in the liver, skin, pancreas; any organ may be involved. Diabetes mellitus may develop as the result of injury to the islets of Langerhans. When the disease is fully developed, iron absorption is normal but is believed to be high in the early stages. Presumably it is due to a defect in the normal mechanism that controls iron absorption. The treatment of this disease is simply bleeding in order to remove the excess iron. This strikingly decreases the mortality of the disease by mobilizing the harmful deposits of iron in the tissues for erythropoiesis. The synthesis of heme and globin are equally important to erythropoiesis. The student is referred to standard texts on biochemistry for consideration of this aspect of erythropoiesis.

4 / HEMOGLOBIN[1]

Hemoglobin the red matter of erythrocytes makes up about 95% of the dry weight of the red cell Hemoglobin functions primarily as a carrier of oxygen but it is also concerned with the transport of carbon dioxide and with the acid-base balance of the body Hemoglobin takes up a large volume of oxygen in the lungs and carries it to the tissues Water at body temperature and an oxygen pressure of 100 mm Hg absorbs 0 3 ml of oxygen per 100 ml whereas 100 ml of normal blood at the same temperature and pressure takes up about 20 ml of oxygen The difference is due to the reversible oxygen-binding capacity of hemoglobin (Harper, 1963, Harris, 1970)

The blood's capacity to absorb oxygen is called the *oxygen capacity* and it is proportional to the hemoglobin concentration The oxygen capacity of 1 g of completely oxygenated hemoglobin is 1 39 ml therefore, the oxygen capacity of 100 ml of normal blood (with 15 g of hemoglobin) is 20 8 ml (15 × 1 39) (Gambino, 1967)

Blood from a normal male contains about 15 g (14 to 16 g) of hemoglobin per 100 ml , all of which is within the red cells Hemoglobin is 0 347% iron by weight, thus, there is about 50 mg of iron/100 ml of blood and 2 5 g in the total blood volume of 5000 ml (Gambino 1967)

THE ESTIMATION OF HEMOGLOBIN IN BLOOD

Hemoglobin concentration in blood can be measured by colorimetric, spectrophotometric, gasometric, chemical, and physical techniques, including x-ray fluorescence and atomic absorption spectroscopy (Drabkin, 1950, Gambino, 1967, MacFate, 1964) Photoelectric colorimetry determines hemoglobin concentration by measuring color intensity in terms of the light-absorbing power of the solution at a specific region of the visible spectrum The estimation of cyanmethemoglobin gives a rapid precise measurement of all hemoglobin derivatives except sulfhemoglobin

Gasometric methods measure hemoglobin through its ability to combine stoichiometrically with oxygen In principle, a measured volume of blood is equilibrated with air under standard conditions of temperature and pressure and is then analyzed in the Van Slyke blood-gas apparatus for its content of oxygen The results of gasometric methods represent functional hemoglobin in the blood i e that portion capable of carrying oxygen therefore, the nonfunctional pigments like methemoglobin and carboxyhemoglobin are not measured

Structure and Metabolism

Hemoglobin is a conjugated protein with a molecular weight of 64,458 (Gambino 1967) It consists of an iron-containing pigment (metalloporphyrin) combined with a protein, *globin* This pigment belongs to a group of compounds called *porphyrins* which combine with metals *Heme* is the name given to the compound of iron and the particular porphyrin found in hemoglobin The iron-porphyrin-globin complex (hemoglobin) forms a loose complex with oxygen when the iron is in the *ferrous* (Fe^{++}) state

SYNTHESIS OF PORPHYRINS AND HEME

The basic framework upon which all porphyrins are built consists of four pyrrole rings linked together in a larger ring-like structure called *porphin* By substitution of the 8 hydrogen atoms about the edge of the porphin structure with various side chains—acetyl, methyl, vinyl, propionyl—the various porphyrins in nature are produced The positions of some substituents for a few related structures are summarized in Table 4 5 The particular compound found in heme is known as *protoporphyrin IX* (MacFate, 1964)

The complex molecule is entirely synthesized by a series of condensations, beginning with glycine and succinate. From these simple

[1] See also Regeneration of Blood, Chapter 2

Table 4 5
Porphyrin structure

Compound	Side Chains
Uroporphyrin I	Acetyl in 1, 3, 5, 7, propionyl in 2, 4, 6, 8
Uroporphyrin III	Acetyl in 1, 3, 5, 8, propionyl in 2, 4, 6, 7
Coproporphyrin I	Methyl in 1, 3, 5, 7, propionyl in 2, 4, 6, 8
Coproporphyrin III	Methyl in 1, 3, 5, 8, propionyl in 2, 4, 6, 7
Protoporphyrin IX	Methyl in 1, 3, 5, 8, propionyl in 6, 7, vinyl in 2, 4

structures Δ-aminolevulenic acid (ALA) is formed, after which 2 molecules of ALA condense to form porphobilinogen The precise mechanisms of the subsequent reactions whereby 4 molecules of porphobilinogen condense to form protoporphyrin IX are not yet completely understood The protoporphyrin IX is combined with iron and globin to form a complete hemoglobin molecule *Iron* enters the red cell precursors through the cell membrane and is transferred to the site of heme synthesis where it combines with the protoporphyrin under the influence of *heme synthetase*

The breakdown of heme, when it is released from the red cell in the course of its normal destruction, involves the oxidative splitting of the porphyrin ring to yield bilirubin-urobilinogen products The conversion of hemoglobin to bilirubin probably takes place in the entire reticuloendothelial system, but the extent of participation by various organs (spleen, liver, bone marrow, etc) is unknown It is not certain whether *1*) the iron-porphyrin complex is split from the globin to form hematin (a hydroxide of the trivalent iron derivative of (heme), at which time the porphyrin ring opens and the iron is released to form the straight-chain bilirubin compounds, or 2) oxidation of hemoglobin (as the initial step) opens the porphyrin ring to yield choleglobin, a green, bile pigment that is an iron-globin complex, which upon subsequent loss of the iron and globin forms bilirubin (Harper, 1963, Harris, 1970)

By either route, the opening of the porphyrin ring occurs at one of the α-methene bridges, and 1 mole of carbon monoxide is formed Because endogenous production of carboxyhemoglobin occurs via hemoglobin degradation, the measurement of carbon monoxide production has been used as an indication of red cell survival (Harris, 1970)

After bilirubin, the principal bile pigment, is formed it is excreted into the gut A small but unknown portion of the bilirubin may be excreted either as mono- or dipyrroles, but it has been technically difficult to detect or quantitate these In the gut, bacterial action progressively reduces the bilirubin to members of the urobilin-urobilinogen groups Measurements of bilirubin production and fecal urobilinogen excretion have also been used to estimate hemoglobin degradation The possible degradation of cellular hemoglobin through a nonbilirubin pathway has been described, the hemoglobin may be degraded to iron and a porphyrin compound (Veech et al , 1967)

THE STRUCTURE OF GLOBIN

The hemoglobin molecule consists of four subunits, and each subunit consists of a polypeptide chain and an associated heme molecule The tortuously coiled polypeptide chains fit together in the complete molecule in such a fashion that the heme portions are more or less at the corners of a tetrahedron, near the surface of the molecule, where there can be a prompt reaction with oxygen Attachment of the heme portion greatly modifies the properties of the globin molecule The conjugated protein is much more resistant to denaturing agents and to digestive enzymes than is the free protein

Differences in various human hemoglobins (see below) are due to changes in the amino acid sequence of the polypeptide chains, or to different combinations of polypeptide chains A functional hemoglobin must have two pairs of different polypeptide chains In the few instances when a hemoglobin has only a single chain, the molecule does not function normally (Huisman and Schroeder, 1970)

Normal adult hemoglobin (A) has two so-called α-chains and two so-called β-chains and may be represented symbolically as $\alpha_2\beta_2$ The differences between the α-chains and β-chains lie in their primary structure each α-chain contains 141 amino acid residues, whereas, each β-chain contains 146 amino acid residues Fetal hemoglobin (F) (that normally present during intrauterine life) has one pair of α-chains identical to that in adult hemoglobin and a second pair of γ-chains, hence, it is

shown as $\alpha_2\gamma_2$ A minor fraction (2%) of hemoglobin normally present in adult human blood termed hemoglobin A_2 is made of two α-chains and two δ (delta)-chains, so it is shown as $\alpha_2\delta_2$ Hemoglobin H, with the structure β_4 and hemoglobin Barts, with the structure γ_4, are two rare abnormal hemoglobins (Huisman and Schroeder, 1970 Ingram 1963, Jonxis and Delafresnaye 1959)

The Combination of Hemoglobin with Oxygen

Hemoglobin combines with oxygen by virtue of the iron it contains Each of the four iron atoms in the heme groups reacts directly with molecular oxygen For this reaction to occur the iron must be in the divalent (ferrous Fe^{++}) state Deoxygenated hemoglobin has been shown to distort a magnetic field presumably because of unshared electrons on the four iron atoms On combination with oxygen, the unshared electrons participate in formation of the iron-oxygen bond and the molecule loses its magnetic moment When the iron atom is oxidized to the trivalent (ferric, Fe^{+++}) state, as in methemoglobin, it does not react with oxygen, although it will bind certain ligands such as cyanide Under normal physiological conditions, in vivo, the methemoglobin reductase system of the red cell maintains the iron of hemoglobin in the divalent state

In the hemoglobin molecule the iron is in a hexacovalent state, with four of the bonds linking it with the planar porphyrin molecule (Fig 4 18) The resulting heme molecules (4 in number) are attached to the surface of the globin molecule by another of the covalent links of the iron atom The sixth covalent bond which protrudes from the plane of the heme is the point of attachment of molecular oxygen It is evident that globin is not merely an inert carrier of the heme groups, on the contrary it markedly influences the reactivity of the iron of heme with oxygen (Perutz et al, 1968, Perutz 1969)

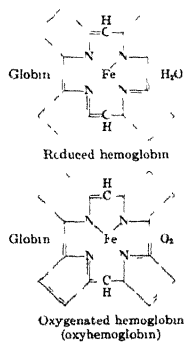

Fig 4 18

HEME-HEME INTERACTION

Since each hemoglobin molecule contains four iron atoms it can combine with four molecules of oxygen The oxygenation of one of the four hemes enhances the oxygen affinity of the remaining hemes This heme-heme interaction i e the effect of the oxygenation of one heme upon the ease of oxygenation of the other hemes results in a sigmoid curve that describes the percentage of oxyhemoglobin at a given oxygen tension This plot is called the oxyhemoglobin dissociation curve When there is no interaction such as in the case of the monomeric myoglobin, a similar plot will yield a curve in the form of a rectangular hyperbola (Antonini, 1965, Antonini and Brunori, 1970)

BOHR EFFECT

The reversible combination of hemoglobin and oxygen is dependent upon temperature, and on the ionic strength (electrolyte composition) of the reaction medium as well as on its P_{CO_2} and pH (Antonini, 1965, Antonini and Brunori, 1970) The interrelated P_{CO_2}-pH influence on the oxygen-hemoglobin equilibrium is known as the Bohr effect—i e , the higher the P_{CO_2} and thus the greater the hydrogen ion concentration (and the lower the pH), the lower is the affinity of the hemoglobin molecule for oxygen Figure 4 19 shows the effects of P_{CO_2} and pH on the red cell oxyhemoglobin dissociation curve The effect of one variable is shown when the others are constant The importance of the Bohr effect lies not only in its physiological role as a regulatory mechanism in the oxygen transport and gas exchange, but also in its use as a model for studying the effects of pH on the functional properties of proteins in general When hemoglobin is combined with oxygen, an imidazole group of the amino acid, histidine, in the α- and β-chains is influenced by the H^+ concentration, an increased H^+ concentration tends to promote dissociation of oxygen from hemoglobin

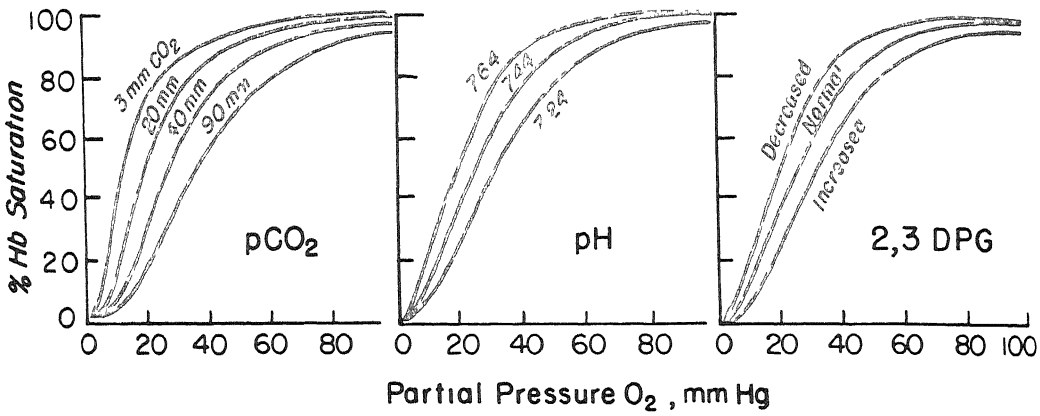

Fig 4 19 The influence of P_{CO_2} pH and 2 3 DPG on oxygen dissociation curves

THE BINDING OF ORGANIC PHOSPHATES TO HEMOGLOBIN

The oxyhemoglobin dissociation curve of extracorpuscular hemoglobin is different from that of cellular hemoglobin This difference may be explained by the existence of certain compounds with which hemoglobin is associated intracellularly

Organic phosphates bind to hemoglobin, and this binding is accompanied by a decrease in the hemoglobin molecule's affinity for oxygen Decreased hemoglobin-oxygen affinity is caused by many organic phosphates and by some inorganic phosphates, but the most dramatic results occur principally with the binding of 2,3-diphospho-D-glyceric acid (DPG), adenosine triphosphate (ATP), and inositol hexaphosphate (IHP) (Benesch and Benesch, 1969, Chanutin and Curnish, 1967) Because DPG and to a lesser extent ATP are present in significant amounts in human erythrocytes, their binding to hemoglobin is considered to be important to the function of the molecule in vivo Figure 4 19 shows also the effect of 2,3 DPG on the red cell oxyhemoglobin dissociation curve

The oxyhemoglobin dissociation curve of intact red cells is a resultant of oxygen-hemoglobin interaction influenced by a variety of intracellular substances -ionic concentration of hydrogen, sodium, potassium, and chloride, red cell levels of P_{CO_2}, 2,3 DPG, ATP, and glutathione, and the amount of carboxyhemoglobin and methemoglobin in the red cells (Antonini, 1965; Antonini and Brunori, 1970) Increased affinity of red cell hemoglobin for oxygen is associated with increased levels of red cell carboxyhemoglobin and methemoglobin, decreased concentration of hydrogen ion (increased pH), and decreased levels of red cell P_{CO_2}, 2,3 DPG, ATP, and glutathione Decreased affinity of the red cell hemoglobin for oxygen is associated with elevated red cell levels of 2,3 DPG, ATP, glutathione, and hydrogen ion (decreased pH) At a given P_{O_2} tension, decreased affinity for oxygen by red cells increases (facilitates) oxygen delivery to tissue, while increased affinity for oxygen decreases (reduces) oxygen delivery to tissue

Although the presence of DPG markedly reduces the oxygen affinity of hemoglobin, many variables determine the magnitude and nature of the effect The binding of DPG to hemoglobin is sensitive to a wide variety of factors There is a lower binding of DPG to hemoglobin F than to hemoglobin A DPG apparently controls the ease or difficulty with which hemoglobin releases oxygen to the tissues, thereby affecting the "position" of the oxyhemoglobin dissociation curve For example, in patients in whom defects in red cell glycolysis alter the DPG concentration in the red cell, there is abnormal oxygen affinity In a patient with hexokinase deficiency, the level of DPG is about two-thirds normal and the oxygen affinity is greater than normal, by contrast, in a patient with a deficiency of pyruvate kinase, DPG is more than double the normal level and the oxygen affinity is decreased

Tissue hypoxia plays an important part in regulating the red cell DPG level. Hypoxic hypoxia (pulmonary), stagnant hypoxia (cardiovascular), and anemic hypoxia (red cell mass deficit) all tend to raise red cell organic phosphates in patients with normal or elevated blood pH, a change that affects the oxyhemoglobin dissociation curve so as to favor unloading of oxygen to the tissues. Ascent of normal subjects to a height of 4500 m results in a reduction in oxygen affinity with a concomitant rise in red cell DPG level. The maximum effect is reached within 48 hr and values return to normal within 48 hr of descent to sea level. The mechanisms responsible for the changes in red cell DPG and ATP in vivo during hypoxic states are clearly linked to the red cell pH.

SIGNIFICANCE OF GLOBIN VARIANTS

Variations in the globin portion of the hemoglobin molecule influence the Bohr effect, the heme-heme interaction, and the hemoglobin molecule's affinity for oxygen in different ways. Globin variants in the α- and β-chains produce a large number of abnormal hemoglobins (hemoglobinopathies). The structural analyses of these abnormal hemoglobins yield important information about structural-functional relations in the hemoglobin molecule (Weatherall and Clegg, 1969). Some of the hemoglobin variants (Chesapeake, J Capetown, Yakima, Kempsey, Rainier, Yps., Hiroshima, and St. Mary's) are associated with increased oxygen affinity and usually with increased red cell volumes (familial polycythemia). Other hemoglobin variants (Seattle, Kansas, and the hemoglobins SA, SS, E, SO, and SC) are associated with decreased oxygen affinity and usually with reduced red cell volumes. Figure 4-20 schematically demonstrates the relation between hemoglobin mass and the oxyhemoglobin dissociation curve P50 value (partial pressure of oxygen in millimeters of mercury at which 50% of the hemoglobin is oxygenated) in patients with a variety of hemoglobinopathies.

Oxyhemoglobin dissociation function is an important factor in the regulation of oxygen transport to tissue. An increase in red cell 2,3 DPG in circulating red cells may tend to compensate for an impairment in oxygen supply to

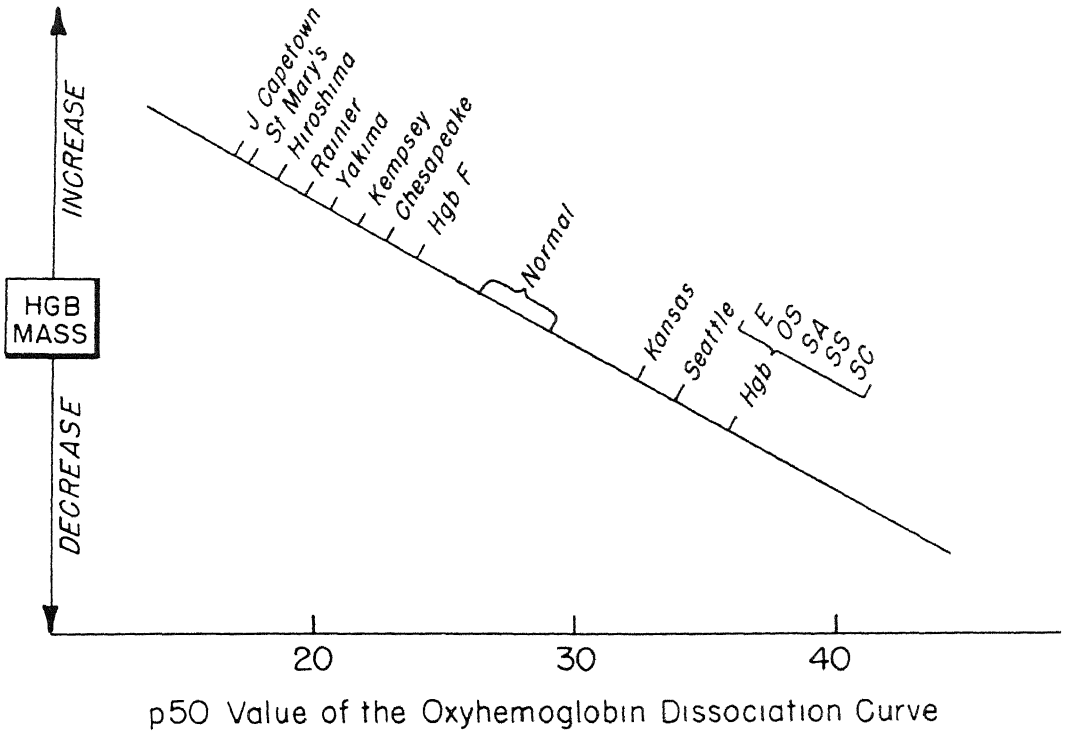

Fig 4-20 Relationship between hemoglobin mass and P50 of oxyhemoglobin dissociation curve for abnormal hemoglobins

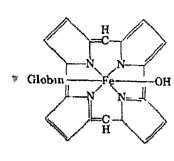
tissue The adaptive mechanisms possessed by the body to assure an adequate oxygen supply in patients with either decreased red cell mass, cardiac disease, or pulmonary insufficiency include not only increased releases of oxygen from hemoglobin but augmentation of cardiac output, greater flow to more important organs, and usually an increased rate of red cell production

Derivatives of Hemoglobin

The terms, *reduced hemoglobin, ferrohemoglobin, or deoxyhemoglobin,* are used as synonyms for the molecule that has given up its oxygen

Oxygenated hemoglobin or *oxyhemoglobin* is applied to the molecule that has oxygen molecules attached



Methemoglobin, or *ferrihemoglobin* results when, by the action of oxidizing agents, the ferrous iron in the heme is changed to ferric iron (Fig 4 21) Normal blood contains about 0 1% methemoglobin, but in cases of poisoning by drugs such as nitrites, chlorates, sulfanilamides, etc , the percentage is increased So-called "toxic" cyanosis occurs when the more darkly colored methemoglobin amounts to about 3 g /100 ml of blood Methylene blue, injected into the blood stream, causes the formation of methemoglobin

A *hemochromogen* of hemoglobin results when the heme containing the ferrous iron is combined with a denatured globin

Cathemoglobin is a compound of heme containing ferric iron with denatured globin

Each of the various heme pigments and derivatives of hemoglobin has a characteristic absorption spectrum, thus, they may be readily identified and measured by appropriate spectrophotometric techniques The major absorption bands of a few compounds are listed in Table 4 6

Carbon Dioxide. Hemoglobin is of considerable importance in the carriage of carbon dioxide By virtue of the Bohr effect (see above)

Methemoglobin

Fig 4 21

Table 4 6
Wavelengths at the points of maximum intensity of absorption bands of hemoglobin and its derivatives

Compound	No of Bands	Situation of Wave Lengths of Absorption Bands in Nanometer (nm)		
Oxyhemoglobin	2	578	542	
Reduced hemoglobin	1	565		
Carboxyhemoglobin	2	569	539	
Sulfhemoglobin	3	618	578	540
Reduced heme	2	607	582	
Cyanmethemoglobin	1	540		

oxygenation of the hemoglobin molecule causes the release of a proton This proton in turn reacts with bicarbonate to liberate CO_2 according to the reaction outlined below

$$HHB + O_2 \rightleftharpoons HbO_2 + H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

The reactions take place in the lungs in the direction indicated, in the peripheral tissues the reverse reaction takes place and allows more CO_2 to be carried in venous blood About 60 to 70% of the total CO_2 transport is accounted for by this mechanism Within the red cell a zinc-containing enzyme, carbonic anhydrase, greatly facilitates the transport of CO_2 from the tissue to the lungs by its action in the reversible formation of H_2CO_3

$$H_2O + CO_2 \rightleftharpoons H_2CO_3$$

A second way in which hemoglobin is important in the transport of carbon dioxide is through the formation of carbamino complexes

$$RNH_2 + CO_2 \rightarrow RNHCOOH$$

Deoxyhemoglobin binds more CO_2 as a carbamino compound than does oxyhemoglobin, and thus, the shuttle of the hemoglobin between oxyhemoglobin and reduced hemoglobin provides an additional mechanism for the transport of CO_2

Carbon Monoxide. Carbon monoxide unites with hemoglobin in the same proportions as does oxygen, competing successfully with the latter for hemoglobin and displacing oxygen volume for volume to form carboxyhemoglobin Unlike oxygen, however, the combination of carbon monoxide with hemoglobin results in a stable compound which can be disrupted only with the greatest difficulty The

much greater avidity (between 200 and 250 times) which hemoglobin shows for carbon monoxide renders the gas highly dangerous Nitric oxide gas also has a strong affinity for hemoglobin and forms a stable compound with it As with methemoglobin and carboxyhemoglobin, in the presence of nitric oxide-hemoglobin there is an increased affinity for oxygen by hemoglobin (Drabkin 1950)

Hydrogen Sulfide. Sulfhemoglobin a green compound resulting from the reaction of ferrohemoglobin with hydrogen sulfide, ordinarily occurs only when blood undergoes putrefaction Certain drugs, however, notably acetanilid and phenacetin, sensitize hemoglobin so that it combines more readily with hydrogen sulfide Small quantities of the gas that are absorbed from the alimentary canal may then cause sulfhemoglobin to reach a relatively high concentration in the circulation, resulting in a bluish or mauve tint to the skin So-called *enterogenous cyanosis* occurs when sulfhemoglobin amounts to 3 to 5 g /100 ml of blood

OTHER HEME COMPOUNDS

Cytochrome. Cytochromes are heme compounds that are widely distributed in the tissues of plants and animals, where they play a fundamental role in cellular respiration Oxidation of one of the cytochromes by molecular oxygen ultimately results, after a series of coupled oxidation-reduction reactions, in oxidation of a substrate thereby making energy available to the organism The function of hemoglobin by contrast is to deliver oxygen to the cells so that these reactions will take place

Myoglobin Myoglobin the pigment of muscle resembles hemoglobin in its function It is the simplest example of a respiratory heme protein, since the molecule consists of but one polypeptide chain and one heme group It has a molecular weight of about 17 000, the iron content is 0 32% It acts as an oxygen reservoir within the muscle fiber Since it has a higher capability for oxygen binding than does hemoglobin, it becomes oxygenated more rapidly than hemoglobin at any given Po_2 (Antonini, 1965)

Porphyria Disorders of porphyrin metabolism, in which abnormal porphyrins or large quantities of normal porphyrins are excreted, are collectively known as porphyrias The inherited (primary) abnormalities of porphyrin metabolism are customarily classified as erythropoietic porphyria, acute intermittent (hepatic) porphyria, porphyria cutanea tarda, and mixed (hepatic-cutaneous) porphyria The term porphyrinuria refers simply to the increased excretion of porphyrins in the urine, whether this be on a primary or secondary (acquired) basis Detailed descriptions of these disorders may be found in cited references (Harris, 1970)

5 / TRANSFUSIONS: THE BLOOD GROUPS

Blood transfusion is required to maintain adequate oxygen transport in anemia and to restore the blood volume after hemorrhage from trauma or disease Different fluids have been used for these purposes physiological saline, solutions containing compounds of high molecular weight such as polyvinylpyrrolidone and dextran, plasma fractions, concentrated red cells, whole blood, and washed red cells Of these, only adequately preserved red cells can restore oxygen transport Substances of small molecular weight maintain the blood volume for only a short time, whereas solutes of large molecular weight remain in the circulation for a longer time and may produce toxic reactions

CONSIDERATIONS FOR BLOOD TRANSFUSION

Transfusion techniques are relatively safe providing certain precautions are taken Careful selection of donors is important to avoid transmission of homologous serum jaundice, malaria, and syphilis (Blood is now tested for the presence of the Australian antigen, although its exact nature has not been established, its presence is closely associated with serum hepatitis) The blood must be sterile The blood transfusion is immunologically satisfactory when neither the recipient nor the donor blood cells are destroyed by antibodies in donor or recipient plasma, and when the transfused cells do not stimulate antibody formation in the recipient The major consideration in blood transfusion is the determination of blood groups of the donor and the recipient and selection of compatible donor blood Landsteiner (see 1936) at the turn of the century, described the ABO blood group system along with many of the basic facts regarding the immunological reactions of the erythrocytes. Usually, a blood transfusion will be clinically acceptable (successful) if ABO and Rh compatible blood is used However, there exists a potential for immunization from other blood group antigens (Mollison, 1967, Schmidt, 1969, Strumia et al , 1963)

Blood Groups

Lansteiner (1936) and others classified blood into four groups, A, B, AB, and O The classification is based on the antigenic nature of the red cells Other blood groups were later discovered, including M, N, P, and many more

Most erythrocyte antigens are not clinically significant except in rare cases In some instances, however, they may be responsible for transfusion reactions and hemolytic disease of the newborn (see below) Table 4 7 shows most of the human blood group systems and some of the related antigens within each system Table 4 8 shows the incidence of various antigens in the general American population Blood group antigens are in the cell membrane

Certain antigens are characteristic of ethnic groups—e g , the D (Rh_0) antigen is present in approximately 85% of the Caucasian population, but is present in 95% of the Negro and 100% of the Oriental and the American Indian population A complete discussion of all antigenic systems is beyond the scope of this chapter Emphasis will be placed on systems of greatest clinical importance

THE ABO SYSTEM

Determination of Groups When antigen A is present on cells, they react with serum that contains corresponding antibodies called anti-A, so that large numbers of cells clump together (agglutinate) This reaction is the same as that between any antigen and its antibody Similarly, cells with antigen B will react with anti-B antibodies Cells containing A and B antigens are agglutinated by either antibody, cells without A or B antigens (group O

Table 4 7
Blood group antigens in man

System	Antigens Detected by: Positive reaction with specific antibody	Antigens Detected by: Positive reaction with one antibody negative with another
A_1A_2BO	A_1B, H^b	A_2, A_3, A_x and other A and B variants
MNSs	M, N, S, s, U, M^g, M_1, Tm, M^k, Hu, He, $M1^a$, Vw(Gr), Mur, Hil, Vr, Ri^a, St^a, Mt^a Cl^a, Ny^a, Sul, Sj	M_2, N_2, M^c M^a M_3, S_2

cells) do not agglutinate with either antibody These findings led to the formulation of the so-called "Landsteiner's law," namely that in the plasma of persons with cell group A, anti-B antibodies are present, in the plasma of persons with cell group B, there are anti-A antibodies, group AB blood contains neither anti-A nor anti-B antibodies, and group O blood contains both anti-A and anti-B antibodies (Table 4 9) Obviously, if the serum from a person of group A is mixed with the cells of a person of group B, agglutination will occur If the same serum is added to group O cells, no agglutination will occur The antibodies of the ABO system are naturally present in human plasma (or serum) but the mechanism of their production is uncertain

Blood group antibodies (isoantibodies) are present in the γ globulin fraction of the plasma By using two antisera, one containing anti-A and the other containing anti-B, it is possible to determine to which of the four groups of the ABO system any sample of blood belongs Agglutination of the cells by only the anti-A serum shows that the cells are of group A, while agglutination only with anti-B serum

Table 4 9
Antigens and antibodies of major blood groups

Group	Cells Contain Antigens	Serum Contains Antibodies
O	O	Anti-A and anti-B
A	A	Anti-B
B	B	Anti-A
AB	A and B	Neither

indicates that the cells are of group B If agglutination occurs with both antisera, the cells are of group AB, and if agglutination does not occur with either antiserum, the cells are of group O

Blood Group Antibodies. Isoantibodies fall into two groups based on sedimentation constants The 19S globulins have a molecular weight of about 1,000,000 They usually agglutinate red cells suspended in saline The 7S globulins have a molecular weight of about 160,000 They agglutinate red cells only in a modified medium containing a high protein concentration or after treatment with certain enzymes Presence of the 7S globulin on the red cell surface can also be detected by the antiglobulin test of Coombs, Mourant, and Race (see next paragraph) The 7S globulins pass the placental barrier and may cause hemolytic disease of the newborn Agglutination or, in some cases when complement is present, hemolysis reveals the presence of antibodies on the red cell

Antiglobulin (Coombs) Test. The antiglobulin test has been of great practical importance in the field of blood transfusion and its application has enhanced our knowledge of blood group systems (Coombs et al , 1945, Bove, 1967, Mollison, 1967) Antihuman globulin serum (Coombs serum) contains antibodies against human γ globulin, and therefore, it reacts with all human antibodies Red cells coated with 7S γ globulin are not agglutinated because 7S γ globulin is an "incomplete" antibody However, upon the addition of Coombs serum to the reaction medium, agglutination occurs The action of the antiglobulin antibody may be visualized as a link that binds the blood group antibodies together, these in turn are bound to red cells which are thus agglutinated When the addition of antiglobulin serum to a sample of washed red cells causes agglutination, it indicates the presence of 7S γ globulin on the red cell surface (see Fig 4 22) When the test is properly conducted, the inference that the globulin is a specific antibody is permissible (Nonantibody-caused, Coombs serum-induced agglutination is possible) This test, called the *direct Coombs test*, is used to detect the presence of antibodies already bound to red blood cells, as in hemolytic disease of the newborn or "autoimmune" acquired hemolytic anemia In contrast, in the *indirect Coombs test*, the antibody coating of red cells is induced in vitro, using a known though incomplete antibody, to aid in blood typing or for purposes of antibody identification (using red cells of known antigenic composition) (see Fig 4 22)

Subgroups of A. The existence of subgroups of A, called A_1 and A_2, reflects differences both qualitative and quantitative in the expression of the A antigen on the surface of the red cells This terminology is somewhat confusing in that cells of group A_1 contain both A and A_1 antigens, and cells of group A_2 contain only A antigen The use of an antiserum specific for A_1 permits this distinction Group AB may be subdivided into A_1B and A_2B

Inheritance of ABO Blood Groups. The gene O is an amorph It has no recognizable specific gene product It is now believed that there are 4 alleles, A_1, A_2, B, and O, and that

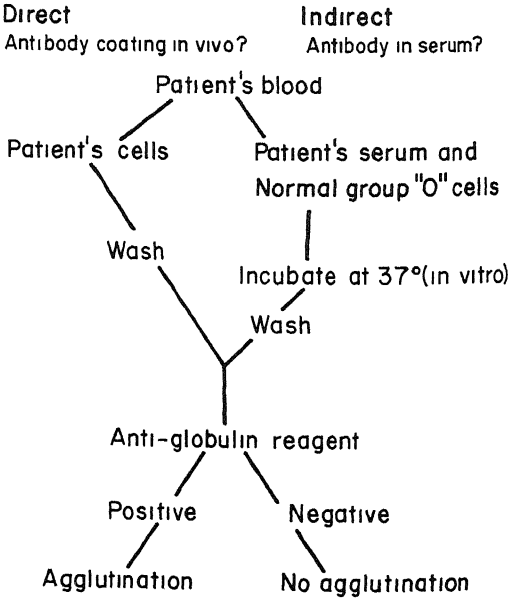

Fig 4 22 Direct and indirect Coombs test (From Bove 1967)

these yield 10 genotypes with 5 distinguishable phenotypes (Table 4 10)

Other Sources of Blood Group Antigens. The antigens are typically a part of the red cell membrane, but many other body tissues and fluids can usually but not always produce serological reactions with the A and B antigens The antigens on red cells have glycolipids, those in body fluids are polysaccharides The antigenic sites are probably chemically identical Persons whose saliva, gastric juices, etc contain appreciable amounts of ABO antigens are classified as *secretors* as opposed to *nonsecretors* *Secretors* of ABO do not have the Lewis antigen (Le^a), whereas most *nonsecretors* have this antigen on their erythrocytes and in their body fluids

The A and B substances present in body fluids have a low nitrogen content (compared with protein) and high concentrations of reducing sugar and hexosamines Antigenic specificity lies in the sugar component, e g group A specificity is associated with α-D-N-acetylgalactosamine, whereas B specificity is associated with α-D-galactose

M, N AND P ANTIGENS

Landsteiner and Levine (1928) demonstrated the existence of additional antigens, M, N, and P By using anti-M and anti-N sera, cells may be classified as either M, N, or MN M and N are poor antigens in man, and anti-M and anti-N are rarely found in human sera Antigen P is of little clinical importance

Table 4 10

THE RH BLOOD GROUP SYSTEM

Landsteiner and Wiener (1940, 1941) immunized rabbits and guinea pigs with the red cells of a Rhesus monkey The resulting antiserum produced agglutination in a large portion of the human red cells studied, the responsible human blood antigen was called Rh Individuals with the antigen are Rh-positive About 85% of Caucasians are positive and 15% are Rh-negative There are several Rh antigens "Rh-positive" and "Rh-negative" refer to the presence or absence of the most important, the D antigen

There is no known antigenic stimulus that accounts for the production of antibodies of the ABO system In contrast, antibodies to the Rh antigen are almost always produced by exposure to the "foreign" Rh antigen, but only by those individuals who lack the corresponding antigen Isoimmunization occurs in two ways *1)* a transfusion of Rh-positive red cells to an Rh-negative recipient, or *2)* the transplacental displacement of Rh-positive cells of the fetus into an Rh-negative mother

Hemolytic Disease of the Newborn (HDN). Hemolytic disease of the newborn or *erythroblastosis fetalis* is a serious complication of pregnancy affecting the fetus in utero The child may be born dead or with hemolytic anemia High concentrations of bilirubin, a degradation product of hemoglobin, may damage brain cells and produce a condition called kernicterus

The sequence of events causing hemolytic disease of the newborn is as follows an RH-negative mother conceives from an Rh-positive father, and an Rh-positive fetus results In some manner, Rh-positive fetal cells enter the maternal circulation and stimulate production of anti-Rh antibodies The antibodies return to the fetus attacking fetal red cells in proportion to their avidity and concentration HDN usually is not produced in first pregnancy, several Rh-positive pregnancies may take place before HDN develops During subsequent pregnancies the antibodies increase in potency and cross the placental barrier into the fetal circulation They react with the fetal Rh-positive cells and destroy them A transfusion of Rh-positive cells to an Rh-negative woman years prior to a pregnancy increases the probability of HDN with later pregnancies

Hemolytic disease of the newborn is treated by "exchange transfusion," i e , by slowly re-

moving blood from the affected infant and simultaneously replacing it with Rh-negative blood By this procedure, the anti-Rh antibodies are removed along with bilirubin Within a few weeks the transfused cells are removed from the circulation and are replaced by the infant's own Rh-positive cells Recently, in an attempt to reduce the number of stillbirths due to HDN, Rh-negative blood has been infused into the abdominal cavity of the fetus in utero The transfused cells are absorbed into the fetal circulation, where they circulate without being attacked by the anti-Rh antibodies

In addition to the various forms of therapy for the established disease, an approach to prophylaxis is now possible through the application of the principle of "antibody-mediated immunosuppression" Pollack et al (1969) have administered Rh-positive antibodies to previously nonimmunized Rh-negative women following delivery The passively administered Rh antibodies prevent Rh antibody formation (Pollack et al , 1969) This principle of prevention may be applicable in other conditions

Hemolytic disease may also result from ABO incompatibility between mother and fetus, but this is usually milder than that caused by Rh incompatibility In rare cases other antibodies are responsible

Nomenclature. Shortly after the discovery of the Rh antigen a number of related antigens were found Two systems of nomenclature, based on slightly different concepts of the genetics of the Rh antigen, have been widely used to describe them (Race and Sanger, 1968) In recent years as many variants of the Rh antigen have been found, the terminology to describe these variants has become increasingly complex (Wiener and Wexler, 1958) A third nomenclature, using numbers, has been proposed (Rosenfield et al , 1962) The reader is referred to the paper of Wiener and Wexler (1958) for a discussion of the Rh nomenclature, to the paper of Fisher (see Race and Sanger, 1968) for a discussion of the CDE nomenclature, and to publications by Rosenfield and collaborators (1962) for a discussion of numerical terminology

A complete discussion of all the Rh variants is not possible in this text, but a brief discussion of some of the more common ones follows Table 4 11 shows the reactions of the Rh antigens with the more commonly available antisera

According to Race and Sanger (1968) there are at least three sets of antigens C and c, D and d, E and e The corresponding antibodies are anti-C, anti-c, anti-D, anti-E, and anti-e Anti-d has not yet been found C antigen corresponds to Wiener's rh′, D antigen to Rh_0, and E antigen to rh″ The antigen combination CDe corresponds to Wiener's Rh_1 An Rh-negative type is shown as cde It should be noted that the use of lower case letters implies not only the absence of one of the Rh antigens, but also the presence of its reciprocal antigen

D, or Rh_0, is by far the strongest immunogenic antigen In European populations most Rh-positive cells are CDe, or Rh_1

Reciprocality and Absence of Rh Antigens. There seems to be a reciprocal relation between blood groups in the Rh system, i e , the absence of a certain antigen implies the presence of another (reciprocal) For example, if there is no C antigen, then the c antigen

Table 4 11
Reaction of Rh antigens with antisera

Cells		Antiserum				
Antigen combination (Wiener agglutinogen symbol)	Gene symbol	Anti-C (anti-rh′)	Anti-D (anti-Rh_0)	Anti-E (anti-rh″)	Anti-c (anti-hr′)	Anti-e (anti-hr″)
cDe (Rh_0)	R^o	−	+	−	+	+
Cde (Rh′)	r′	+	−	−	−	+
cdE (Rh″)	r″	−	−	+	+	−
CDe (Rh_1)	R^1	+	+	−	−	+
cDE (Rh_2)	R^2	−	+	+	+	−
CDE (Rh_z)	R^z	+	+	+	−	−
CdE (Rh_y)	r^y	+	−	+	−	−
cde (rh)	r	−	−	−	+	+

must be present, or the absence of rh' implies the presence of hr' The absence of the E (rh') antigen implies the presence of e (hr') Anti-c and anti-e sera may be used to demonstrate the existence of the alternative antigens One might expect that a d (Hr_0) antigen exists as an alternative to the D (Hr) antigen, however its existence has never been demonstrated

Very rarely are persons encountered in whom the Rh antigens are absent but several people who have no detectable representatives of any of the Rh antigens i e (- - -) have been reported This is called an *Rh null*

OTHER BLOOD GROUPS

Other blood groups include Kell (K) and Cellano (k) (which bear a reciprocal relationship) and Duffy (Fy^a, Fy^b), Diego (Di^a), Lewis (Le^a, Le^b), Lutheran (Lu^a, Lu^b), and Kidd (Jk^a, Jk^b) (Table 4 7) Some 'private" blood group antigens are infrequently seen in the general population, and positive reactions occur only in members of a particular family

Transfusion of Blood

EFFECTS OF INCOMPATIBLE TRANSFUSIONS

When blood from a person of group A is transfused into a recipient of group B, there are two possible ways by which agglutination of red cells may occur the anti-B antibodies of the donor may agglutinate the B cells of the recipient, or the anti-A antibodies of the recipient may agglutinate the A cells of the donor Generally the donor antibodies are so well diluted in the recipient's plasma that this type of agglutination is rare The antibodies in the recipient's plasma, on the other hand, are only slightly diluted by the small amount of blood usually given, and readily react with the cells of the donor (Mollison, 1967, Schmidt, 1969)

Reactions can ordinarily be avoided by transfusing group O blood, since these cells have neither A nor B antigens to be agglutinated by the recipient's anti-A or anti-B antibodies The anti-A and anti-B antibodies present in O blood usually are diluted enough so there is no effect on the recipient's cells, and the term "universal donor" has been applied therefore to persons with group O blood Persons with group AB blood are sometimes called "universal recipients " These terms are misleading because some people with group O blood have high concentrations of anti-A or anti-B antibodies of strong hemolytic nature which despite dilution may destroy recipient cells Such reactions can be avoided by using washed red cells

If blood of the "wrong (incompatible) ABO blood group is transfused a hemolytic transfusion reaction is probable Destruction of red cells produces hemoglobinemia and hemoglobinuria Chills fever, shock, renal insufficiency and death may ensue

Routine crossmatching is performed only for the ABO and Rh systems therefore, isosensitization may develop in recipients who receive donor red cells that contain antigens which the recipient lacks (Table 4 11)

STORED BLOOD AND BLOOD COMPONENTS

Fresh blood is rarely transfused today Blood is usually collected and stored in the liquid or frozen state Liquid whole blood contains many substances that may cause adverse reactions, therefore, its routine clinical use has been repeatedly criticized Often it is recommended that only the required blood component be used Today whole blood after collection can be fractionated into its various components concentrated red cells, platelet-rich plasma or platelet concentrates, fresh frozen plasma, antihemophilic globulin or cryoprecipitate, albumin, and various γ globulin fractions Liquid-preservation, the principal method of storing red cells, extends the shelf-life of whole blood only to 3 to 4 weeks Freeze-preservation extends the shelf-life of red cells many months and perhaps indefinitely (Bishop and Surgenor, 1964, Valeri, 1970)

Preservation Injury. Red cell preservation is satisfactory when the transfused red cells circulate and function immediately after transfusion Preservation procedures involve use of a liquid medium with storage at 4° C, a freeze-preservation technique using various cryoprotective agents and storage at either −80° C or −150° C, or a combination of the liquid- and freeze-preservation approaches Blood for freezing is collected in one of several liquid preservatives, acid-citrate-dextrose (ACD), citrate-phosphate-dextrose (CPD), ACD plus adenine, or CPD plus adenine with or without inosine, it is then frozen by one of a number of

procedures, stored at either −80° C or −150° C, thawed, and washed prior to transfusion Either previously frozen glycerolized red cells or nonfrozen red cells stored as concentrated red cells or as whole blood can be washed and resuspended in a nonplasma-crystalloid medium and stored at 4° C up to 24 hr prior to transfusion These manipulations, however, produce "preservation injury" which manifests itself in the form of severely and irreversibly damaged red cells that are removed from the recipient's circulation at an accelerated rate during the transfusion and the 24-hr post-transfusion period Figure 4 23 shows that "preservation injury" affects only the 24-hr post-transfusion survival of preserved red cells Preservation injury is a composite effect that reflects a combination of lesions produced by the following conditions collection, storage in the liquid state prior to freezing, storage in the frozen state, freeze-thaw per se, red cell washing, and storage after thawing in the liquid state with or without post-thaw washing or any other manipulation "Preservation injury" is to be distinguished from immunological incompatibility between the donor red cells and the recipient

With the in vitro compatibility tests currently in use (saline, albumin, and antiglobulin crossmatching), red cell incompatibility can, with rare exception, be ruled out as the cause of the rapid removal of nonviable red cells during the 24-hr post-transfusion period There is no in vitro measurement, however, that can predict the 24-hr post-transfusion survival value of preserved red cells The rapid removal (phagocytosis) of nonviable but compatible red cells suggests a defect in the red cell membrane recognized by the recipient's reticuloendothelial system The rate of removal of damaged red cells during transfusion is affected by the recipient's health seriously ill patients have an ineffective removal mechanism, whereas otherwise healthy recipients with accidental injuries promptly remove irreversibly damaged red cells Furthermore, the method of preservation is a determining factor in the mechanism of removal of the nonviable red cells Liquid-preservation procedures (i e , collection and storage in either acid-citrate-dextrose (ACD), National Institutes of Health, Formula A or citrate-phosphate-dextrose (CPD) produce nonviable compatible red cells that are removed by extravascular sequestration without intravascular liberation of extracorpuscular hemoglobin Some freeze-preservation procedures may produce compatible but nonviable red cells that are removed with the intravascular liberation of hemoglobin from the cells (Valeri, 1970)

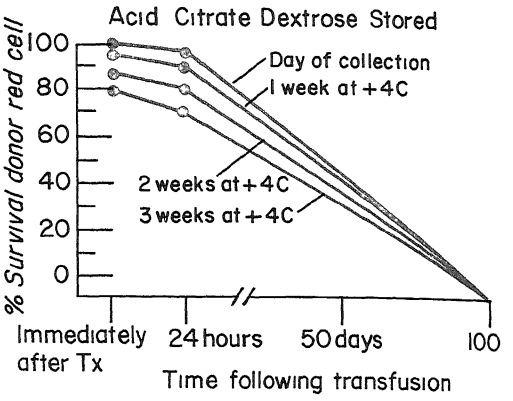

Fig 4 23 The relationship between the fraction of red cells surviving after transfusion to storage time in ACD

LIFESPAN OF PRESERVED RED CELLS

Nonviable red cells are removed during the 24 hr following transfusion Figure 4 23 shows that red cells that remain in the circulation have a *potential* for normal long-term survival In vivo restoration of reversibly damaged liquid-stored or previously frozen red cells has also been demonstrated A rapid decrease in donor red cell sodium level and slow increase in donor red cell potassium concentration, together with a change in red cell osmotic fragility towards normal indicate that preserved red cells are restored during circulation in the recipient A satisfactory preservation procedure maintains normal intracellular sodium and potassium levels and normal osmotic fragility until the time of transfusion Viable transfused red cells have a *potential* for normal lifespan, however, the lifespan may be adversely affected by the recipient's intravascular environment, e g , certain immunological, chemical, and mechanical factors Post-transfusion mean lifespan of those red cells that are viable is not related to the preservation technique nor to the length of storage in the liquid or frozen state

FUNCTION OF PRESERVED RED CELLS

"Preservation injury" may markedly affect oxygen transport by an increased affinity of

the hemoglobin for oxygen In blood collected in ACD the increased affinity for oxygen is correlated with a decrease in the 2 3-diphospho-D-glyceric acid (DPG) concentration of the red cells (see chap 4) A slight decrease in the red cell adenosine triphosphate (ATP) level also occurs After transfusion there is in vivo restoration of the oxyhemoglobin dissociation curve usually within 24 hr and an increased 2,3 DPG concentration The quantity and quality of the preserved red cells and the physical condition of the recipient determine the rate of in vivo restoration of the red cell oxygen dissociation curve towards normal

A relation has been observed between the oxyhemoglobin dissociation curve and the levels of red cell organic phosphate compounds (ATP and 2,3 DPG) in blood preserved in acid-citrate-dextrose (ACD), ACD plus adenine, citrate-phosphate-dextrose (CPD), or CPD plus adenine The addition of pyruvate, inosine, and phosphate to these media replenishes the levels of red cell 2,3 DPG and ATP and restores toward normal the oxyhemoglobin dissociation curve

After blood preserved for 15 days is transfused into anemic recipients there is progressive in vivo restoration towards normal of 2,3 DPG, ATP, potassium and sodium ion concentrations Within 8 hr of the transfusion a restoration of at least 25% of the final level of red cell 2,3 DPG occurs, and within 24 hr at least 50% of the final level is achieved Thereafter, the increase in donor red cell 2,3 DPG is curvilinear and reaches a plateau usually within 9 to 11 days after transfusion The ATP level of the transfused red cells rises rapidly during the first 24 hr , this rise is associated with a rapid fall in donor red cell sodium concentration Donor red cell potassium levels rise very slowly, and the increase in cellular potassium concentration appears to be related to the absolute level of red cell 2,3 DPG (Valeri, 1970)

Current methods of freeze-preservation of human red cells maintain normal levels of the organic phosphates It is now possible to combine liquid- and freeze-preservation methods to provide functioning red cells and help to resolve problems of imbalance of supply and demand for human red cells One can collect blood in CPD-adenine and store it for at least 2 weeks at 4° C If the blood is not used during this initial period, pyruvate, inosine, and phosphate can then be added to restore the 2,3 DPG and ATP pools, after which the red cells can be frozen using one of the glycerol procedures Current methods of freeze-preservation of human red cells use glycerol an intracellular cryoprotective substance therefore post-thaw washing is essential This reduces the amount of adenine and inosine that might otherwise produce untoward effects after multiple-unit transfusions However, freezing human red cells immediately upon collection obviates the need for purine nucleoside supplementation and permits separation of whole blood into its components Each blood component can then be stored separately using the appropriate technique for optimal preservation

Preservation and reconstitution techniques must also minimize the hemolysis that may occur Haptoglobin of plasma binds hemoglobin If, in the course of destruction of nonviable red cells in vivo, the haptoglobin-binding capacity of plasma is exceeded there will be free extracorpuscular hemoglobin Bound hemoglobin is cleared by the reticuloendothelial system Free extracorpuscular hemoglobin, either infused with the supernatant of the blood unit or liberated in vivo from the removed nonviable red cells, may saturate the hemoglobin-binding capacity of the recipient and then if the tubular reabsorptive capacity of the kidney is exceeded, the excess free plasma hemoglobin will be excreted in the urine Hemoglobinuria can be tolerated by normotensive, normovolemic subjects with normal renal function It may precipitate acute renal insufficiency, however if associated with hypotension, an increased secretion of the antidiuretic and renin-angiotensin hormones, dehydration, acidosis, or hemorrhage

If no intravascular hemolysis occurs, a limiting factor in the clinical acceptability of preserved red cells is the amount of infused free supernatant hemoglobin This does not mean necessarily that hemoglobin is toxic, the damage may be produced by red cell stroma liberated simultaneously with the hemoglobin during hemolysis

Some degree of in vitro hemolysis occurs with all types of preservation, resulting in the liberation of hemoglobin, potassium, enzymes, purine nucleotides, and the red cell membrane The presence of a significant amount of red cell stroma (ghosts and fragments) may precipitate renal insufficiency by sludging in the microcirculation or by activating dissemi-

nated intravascular clotting. Intravenous potassium is potentially myocardiotoxic; thus, the amounts of these substances present in the preserved blood must be kept within safe limits.

Washing frozen or nonfrozen red cells effectively removes in part *1*) white cells and platelets; *2*) isoagglutinins; *3*) the anticoagulant preservative and red cell metabolites; and *4*) plasma factors, protein and nonprotein (allergens, etc.). The clinical indications for the transfusion of washed red cells (liquid-preserved or previously frozen) are:

1) A history of febrile transfusion reaction, or urticarial and anaphylactoid transfusion reaction—attributable to recipient antibodies.

2) The need to avoid overloading the circulation—caused by vasoconstrictor plasma substances in preserved blood and excess sodium.

3) Preparation for allografting procedures—because removal of platelets and leukocytes will minimize probability of presensitization to donor organ.

4) Desire to reduce the probability of a graft vs. host reaction in recipients with immunological deficiency diseases.

5) Intention to decrease the probability of post-transfusion hepatitis by washing out the virus.

HEMOLYSIS AND SUSPENSION STABILITY OF THE BLOOD

Hemolysis in vitro results in escape of hemoglobin from the red cell into the surrounding medium whereas hemolysis in vivo results in a reduction of the lifespan of red cells There are two mechanisms by which red cells may be destroyed in vivo *1)* disruption or dissolution within the general circulation by the action of immune bacterial, or chemical lysis resulting in *intravascular hemolysis* and liberation of hemoglobin into plasma, and *2)* the more common sequestration of red cells in cells of the reticuloendothelial system particularly in the spleen and liver, where the cellular hemoglobin is degraded producing the clinical picture of *extravascular hemolysis* Two primary mechanisms for the red cell sequestration have been proposed *a)* by a surface adherence of the cells to the reticuloendothelial cells that line the blood vessels, followed by phagocytosis (essentially a chemical or electrostatic process), or *b)* by simple filtration (essentially a physical process) (Jandl et al , 1961, Rifkind, 1966) (See chap 3, spleen)

Hemolysis in Vitro

Hemolysis in vitro liberates red cell constituents (e g , hemoglobin potassium purine nucleotides, and the red cell membrane-stroma) into the supernatant fluid The erythrocyte membrane consisting of lipids, ions, proteins, and water is altered during hemolysis The membrane lipids include phospholipids, neutral lipids (free and esterified cholesterol), and glycolipids The erythrocyte membrane composition of cholesterol and the lysolecithin-lecithin ratio are influenced by the plasma enzyme levels of lecithin-cholesterol acyltransferase and phosphatidases (Cooper and Jandl, 1968, Ferber et al , 1970, Jeannet and Hassig, 1964) The protein composition of the red cell membrane, especially the membrane sulfhydryl activity, is related to hemolysis both in vitro and in vivo (Jacob and Jandl, 1962) In the autohemolysis test sterile defibrinated blood is incubated at 37° C for 24 and 48 hr and the amount of spontaneous hemolysis is determined The autohemolysis test is a nonspecific test and reflects the red cell metabolic and physical-structural states (Selwyn and Dacie 1954)

The permeability of the red cell membrane is quite different from that of the capillary membrane Under physiological conditions the membrane of human erythrocytes is impermeable to hemoglobin to the plasma proteins and to the organic phosphate compounds but it does permit the passage of water H^+ NH_4^+, Cl^- HCO_3^- and $PO_3^{\equiv}$ It is permeable also to the Na^+ and K^+ ions, these ions exchange across the membrane and for each there is a specific energy-dependent gradient between the red cells and the plasma Under conditions which injure the red cell membrane, potassium escapes from the cells and the potassium loss is closely related to the hemoglobin loss

OSMOTIC FRAGILITY

The osmotic fragility test, an in vitro test to determine the susceptibility of a red cell population to a hypotonic gradient, reflects the surface-to-volume ratio, intracellular osmotic pressure, and membrane permeability of the red cell population Osmotic fragility in vitro is influenced by *1)* the suspending medium whose pH and tonicity are controlled, *2)* the total number of intracellular osmotically active constituents which determine cell volume in any given external environment, and *3)* the critical hemolytic volume (the mean red cell volume for the population tolerated before total hemolysis occurs), which varies with quantitative and qualitative factors associated with the composition of membrane lipid and protein (Weed and Bowdler, 1966) Normal red cells swell when placed in 0 6% saline solution (osmolarity is 200 mosmole) with a controlled pH and temperature, although the mean red

cell volume increases, the intracellular hemoglobin does not escape (Normal plasma has an osmolarity of 300 mosmoles/liter, equivalent to a 0 9% NaCl solution) Hemolysis begins at a salt concentration of about 0 42% when the red cell volume increases to about 145% of normal At 0 35% saline solution, the red cells are fully hemolyzed, the red cell volume is about 165% of normal (the critical hemolytic volume) The osmotic fragility test detects red cells with increased fragility in patients with intrinsic red cell abnormality (i e , hereditary spherocytosis) and with acquired spherocytosis (antibody-coated red cells) Increased osmotic fragility may indicate a decreased surface-to-volume ratio of red cells (resulting from loss of red cell membrane cholesterol alone, or loss of red cell membrane fragments containing cholesterol and phospholipid) and an increase in membrane permeability to the sodium ion (hereditary spherocytosis) (Cooper and Jandl, 1969, Jacob and Jandl, 1964, Jacob and Karnovsky, 1967, Weed and Reed, 1966)

Decreased osmotic fragility of red cells is usually associated with iron deficiency anemia, hereditary hemolytic disorders of thalassemia and sickle cell anemia, and liver disease with obstructive jaundice There is an increased surface-to-volume ratio, with an increased membrane cholesterol content secondary to decreased plasma lecithin-cholesterol acyltransferase activity, in patients with elevated levels of bile salts, and there is a decreased intracellular osmotic pressure from a decrease in the amount of hemoglobin in the red cells of patients with iron deficiency anemia (Cooper and Jandl, 1968, Wintrobe, 1967) Osmotic hemolysis does not occur usually in vivo Nevertheless, the in vitro test of osmotic fragility has been helpful in the evaluation of red cell abnormalities

ACID HEMOLYSIS

Acid hemolysis is used in vitro to determine the susceptibility of red cells to a hydrogen ion gradient When the temperature and the osmotic pressure of the environment are maintained constant, this test can be used to diagnose an acquired defect of red cells called paroxysmal noctural hemoglobinuria The sensitivity of red cells to acid hemolysis can be detected by exposing them to an acid environment, to thrombin, or to a low ionic medium ("sugar-water test") (Hartmann and Jenkins, 1966)

IN VITRO CHEMICAL HEMOLYSIS

Ether, chloroform, benzene, and alcohol hemolyze by dissolving the lipid constituents of the red cell membrane Surfactant substances, such as bile salts, alkalis, and saponin, also cause hemolysis in vitro These phenomena, however, are of no clinical significance

MECHANICAL FRAGILITY FILTERABILITY REVERSIBLE DEFORMABILITY, AND AGGLUTINABILITY OF RED CELLS

Because red cells are subjected to mechanical trauma during normal circulation, in vitro tests capable of simulating the in vivo state are important A simple test of limited value has been developed to quantitate the mechanical fragility of red cells by standardized rotation of blood in a flask with glass beads Teitel (1965) has studied the disc-sphere transformation and plasticity alteration of red blood cells by observing the filterability of washed red cells through filter paper under controlled conditions, in a variety of hematological conditions the results with this in vitro test correlate with the in vivo survival data In addition, reversible deformability of red cells has been determined from the mean pressure required to deform the cells sufficiently to cause them to enter and traverse a micropipette analogue of the microcirculation (LaCelle, 1969, Weed, 1970) The normal biconcave disc-shape of red cells with relatively higher surface area to volume ratio is more deformable than the spherical form of red cells The mean deformability of preserved red cells at specific time intervals correlates with their post-transfusion survival values (Haradin et al , 1969) Thus, shape and deformability of red cells largely determine their post-transfusion survival (Haradin et al , 1969, Teitel, 1965)

Positively charged polyelectrolytes (polybases) induce agglutination of erythrocytes at very low concentrations (Markikovsky et al , 1966) For example, positively charged polylysine attaches to N-acetylneuraminic acid, the major negatively charged component of the red cell membrane, thus, linking cells and producing agglutination The observation that "old red cells" have a reduced negative charge and are agglutinated more easily with polylysine than are "young red cells," indicates a correlation between agglutination and the surface charge of the red cells

Hemolysis in Vivo

Hemolysis in vivo is best defined as shortening of the lifespan of erythrocytes With the exception of incompatible transfusions and some rare disorders, intravascular hemolysis with hemoglobinuria is uncommon Clearance of senescent or defective red cells from the blood is usually performed by the macrophages in the reticuloendothelial system (RES) (See chap 3) It is now apparent that RES-mediated erythrocyte destruction involves the sequential operation of at least three component processes *1) Injury*—the development of a critical, prehemolytic red cell lesion mediated by normal red cell aging, by an intracorpuscular biochemical defect, or by an extracorpuscular agent *2) Sequestration*—the selective filtration of injured red cells from the general circulation and their concentration within the vascular spaces of the RES *3)* Red cell *degradation* by enzymatic digestion within the lysosomal vasuoles of the reticuloendothelial macrophages (Rifkind, 1966; Weed and Reed, 1966)

INTRAVASCULAR HEMOLYSIS

When the rate of hemolysis is excessive, as in blood transfusion reactions, in drug-induced hemolysis, and in malaria (blackwater fever), the plasma extracorpuscular hemoglobin cannot be converted into bilirubin as rapidly as it is liberated, and hemoglobinuria may occur Extracorpuscular hemoglobin in plasma combines stoichiometrically with plasma haptoglobin, a specific α_2 globulin to form a hemoglobin-haptoglobin complex which is cleared from the circulation by the reticuloendothelial system When the concentration of plasma extracorpuscular hemoglobin exceeds the hemoglobin-binding capacity and the tubular reabsorption capacity of the kidney, the excess "free" plasma hemoglobin will be filtered and excreted in the urine A port wine, dark brown, or black colored hemoglobin pigment may be produced by acid urine where hemoglobin may be converted into acid hematin and methemoglobin

Paroxysmal (Cold) Hemoglobinuria. The Donath-Landsteiner hemolysis test is pathognomonic for this disease The unique hemolysin responsible for this reaction is effective against all normal erythrocytes (a panhemolysin) and requires the following conditions in the reaction mixture for its full activity *1)* complement, *2)* chilling to fix the antibody to the red cell and *3)* subsequent warming to induce hemolysis (Harris, 1970)

The Donath-Landsteiner hemolysin is usually but not always associated with a positive reaction to the Wassermann test resulting from congenital or acquired syphilis It may be present only transiently but it usually persists for long periods of time It may or may not disappear following antiluetic therapy, and it has been shown to be separate from the Wassermann factors responsible for the various biological tests for syphilis In a few instances, it has been demonstrated for short periods following infectious diseases (measles) The reason for the development of the peculiar antibody in any of the situations in which it has appeared is not known In many instances hemolytic episodes have been produced by the controlled chilling and warming of an extremity in a susceptible patient with the Donath-Landsteiner hemolysin

Paroxysmal Cold Hemoglobinuria Associated with Cold Agglutinin. A second type of paroxysmal cold hemoglobinuria is distinguishable by the presence of an abnormal amount of cold agglutinin Curiously enough, except under special conditions the agglutinin exhibits little or no lytic activity

The clinical picture and the hematological changes noted may follow very closely those described for the Donath-Landsteiner factor The patients are more apt to develop dermal manifestations, Raynaud's phenomenon, frostbite, and even gangrene of the extremities They are less likely to experience hemoglobinuria with each paroxysm and are more likely to develop a chronically depressed hematocrit and hemoglobin concentration associated with reticulocytosis and hemosiderinuria The chronicity is obviously related to exposure and to climate In the Northern Hemisphere the changes may be noted only during the cold winter months Extraordinarily high titers of the agglutinin are associated with the syndrome With the exception of type I-negative erythrocytes all red cells are agglutinated by the cold antibody Since this blood type occurs in less than 1 in 10,000 individuals, this antibody can be considered a panagglutinin (Harris, 1970)

March Hemoglobinuria. Hemolysis in vivo and hemoglobinuria may occur even in healthy persons after strenuous walking or running In certain persons hemoglobinuria may follow relatively mild exercise The pigment in the

blood and urine is hemoglobin and not myoglobin No red cell abnormalities, hemolysins, or autoagglutinins have been demonstrated Hemoglobinuria occurs after hand trauma, as in the karate chop, suggesting that the disorder is related to mechanical trauma On the other hand, hemoglobinuria decreases during training in marathon runners and is aggravated by sway-back posture This hemolytic mechanism is not simple (Gilligan and Blumgart, 1941)

Nocturnal Hemoglobinuria of Marchiafava In this third type of paroxysmal hemoglobinuria, hemoglobin or hemosiderin is passed almost continuously in the urine, but in greatest amounts at night It is accompanied by a severe hemolytic anemia The hemolysis is caused by the susceptibility of red cells to acid, the greater destruction at night is attributed to the accumulation of carbon dioxide during sleep The abnormal cells are hemolyzed when incubated in slightly acidified normal serum or patient's serum (Ham test), but the normal red cells are not destroyed by the patient's serum The defect in the patient's red cells is unknown This syndrome may produce severe renal damage

INFECTION AND HEMOLYSIS

Three distinct uncommon hemolytic syndromes in patients with infection have been described *1*) an acute, often lethal, intravascular hemolysis during blood-stream invasion by hemolysin-producing organisms such as *Clostridium welchii*, *2*) direct infection of red cells by the red-cell-adherent organism *Bartonella bacilliformis*, causing red cell trapping in the spleen and acute hemolytic anemia; and *3*) an acute or chronic hemolytic anemia developing during the convalescent or postconvalescent phase of certain viral or bacterial infections that stimulate autoantibodies against red cells Such hemolysis is usually attributable to cold agglutinins or to cold hemolysins

The venom of certain poisonous snakes, such as the cobra, and the poisons of various stinging insects and spiders cause destruction of red cells Cobra snake venom liberates an enzyme phosphatidase A, which converts lecithin to lysolecithin, a powerful hemolytic and cytolytic substance Since lecithin is present in erythrocytes, plasma, and all cells, the entrance of snake venom into the body stimulates production of this hemolytic substance (Ferber et al., 1970).

Suspension Stability of Blood

IN VITRO

Sedimentation of freshly collected anticoagulated whole blood is governed by the hematocrit, the viscosity, and the composition of the plasma protein (primarily the fibrinogen and the α and β globulin levels) Whereas, albumin inhibits red cell sedimentation, large asymmetric molecules (fibrinogen and high molecular weight dextran) increase the sedimentation rate

There are various methods of measuring the erythrocyte sedimentation rate (ESR) (Dawson, 1960, Hardwicke and Squire, 1952, Wintrobe, 1967) Because the relative quantities of plasma and red cells influence the sedimentation rate, various methods to correct for the anemic state have been devised These methods may give misleading results since aggregation of the red corpuscles and size of the aggregated particles are far more important factors in rapid and slow sedimentation than the degree of anemia Furthermore, differences in the size and hemoglobin content of the red corpuscles also effect the sedimentation rate, and these have been found to be as important as the plasma factors Variations in red cell size (anisocytosis) may interfere with rouleaux formation (pseudoagglutination, normal red cell tendency to cling together in chains), and variations in red cell shape (poikilocytosis) such as are encountered in sickle cell anemia actually prevent the formation of rouleaux Therefore, in sickle cell anemia sedimentation is very slow even when there is marked anemia The ESR is faster in normal females than in normal males It is a nonspecific reaction which may be compared with the body temperature, pulse rate, and leukocyte count for diagnostic purposes (Wintrobe, 1967)

The conventional capillary tube method of measuring blood viscosity yields information applicable only to the circulatory dynamics in arteries and large arterioles The method detects changes in the concentration of red blood cells, and changes in the concentration and nature of the plasma proteins It does not detect aggregation of the blood elements, unless these aggregates approach in size the diameter of the capillary tube (usually 300 μm) used for testing flow characteristics of the blood It seems likely that aggregates of blood elements, if sufficiently large and held together by sufficiently strong force, would occlude the smaller

arterioles, venules, and capillaries These same aggregates would not interfere with passage of blood through larger blood vessels Aggregates which appear to meet these criteria have been observed in vitro in blood that has been stored for transfusions, during hypotensive endotoxin, and anaphylactic shock, after the ingestion of large amounts of fatty foods and after the addition to blood of large molecular weight substances (dextrans gelatins and the biogenic serotonin and adenosine diphosphate A screen filtration pressure method has been designed to measure the adhesiveness and aggregation of blood cells in an attempt to simulate the flow of blood through the microcirculation (Swank et al., 1964)

The stability of preserved red cells (nonfrozen or previously frozen) after washing and storage at 4° C, for 24 hr is influenced by the composition of the resuspension medium Plasma is not a satisfactory medium because of the possible transmission of homologous serum jaundice Although an artificial medium having a pH of about 7 2 and containing albumin, glucose, phosphate, and sodium chloride adequately maintains the stability of the red cells, it is far from ideal as evidenced by the above described in vitro measurements and their post-transfusion survival

IN VIVO

Normal erythrocytes possess remarkable deformability This is a subject of great interest to those interested in the microcirculation, because deformability is important in determining lifespan in vivo Knowledge of cellular deformability also provides insight into the pathophysiology of shortened red cell lifespan in many hemolytic anemias Alterations in the intrinsic physical properties of erythrocytes may also interfere with blood flow through the microcirculation (Merrill, 1969, Wells, 1964)

Within the microcirculation, where the vital exchanges of oxygen and carbon dioxide take place, there are several factors in addition to the intrinsic properties of the red cells themselves which may influence these physiological functions Circulatory dynamics vessel wall integrity and plasma proteins which may alter the flow properties of whole blood must be normal. Whole blood is non-Newtonian in its fluid and flow characteristics When hematocrit is normal, the high viscosity of blood at low shear rates can be attributed primarily to fibrinogen dependent rouleaux formation which is a common occurrence under conditions of stagnation and can be disrupted by increased shearing forces Rouleaux formation is enhanced by fibrinogen and γ globulin and is inhibited by albumin Certain pathological plasma proteins, such as those found in macroglobulinemia or cryoglobulinemia, may increase the blood viscosity and may help occlude the microcirculation

Prosthetic heart valves may produce a hemolytic anemia

In addition, gram-negative sepsis and posttraumatic states may initiate disseminated intravascular coagulation (DIC) with fibrin deposition in the microcirculation particularly of the lung and the kidney This syndrome of microangiopathic hemolytic anemia often appears very suddenly and is recognized by a distinct appearance of erythrocytes which seem to be contracted, distorted, and sometimes triangular ("helmet cells" or "burr cells") (Brain et al., 1962) It is encountered in a number of conditions characterized by necrotic lesions of the small vessels (arteries and capillaries), particularly in the kidneys Microscopic examination reveals aggregated red cells ("sludged blood") in the small vessels Platelet destruction, intravascular coagulation, and defibrination may occur

Circulation through the microvasculature is critically related to rheological properties of the blood (Merrill, 1969, Wells, 1964) The administration of low molecular weight dextran or albumin has been suggested to improve in vivo the stability of red cells and the other constituents of blood

7 / GRANULOCYTES

Their Production and Role In Defense Against Bacterial Infection

Introduction

In this chapter attention will be devoted to the neutrophilic granulocyte which plays such a central role in the defense against bacterial infection Clinical experience demonstrates the increased susceptibility to infection of individuals in whom the neutrophilic granulocyte count is depressed below 1000/mm ^{3} This is particularly evident following whole body irradiation of man or animals For example, one of the major causes of death in the Japanese exposed to ionizing radiation from the nuclear bombs at Hiroshima and Nagasaki was bacterial infection that followed aplasia of the bone marrow and marked depression in the granulocyte counts in the peripheral blood (Bond et al , 1965) There are also valuable drugs in the physician's armamentarium that unfortunately produce bone marrow aplasia with granulocytopenia The role of the neutrophil in defense against infection has long been known Its role in inflammation and defense was enunciated by Metchnikoff (1887) and emphasized by the ubiquitous presence of granulocytes in pus from all sources

The nucleus of an adult granulocyte is composed of two or more lobes connected by strands of chromatin The cytoplasm contains granules that stain in a characteristic fashion They are of three types *1)* The *eosinophils* constitute only about 2 to 4% of the total white cell count normally, their granules are oval, coarse, and stain bright red with acid dyes such as eosin These leukocytes increase in number during allergies, parasitic infections and idiopathic diseases *2)* The basophils are present to the extent of only 0 15% or less, their granules are large and coarse and stain deeply with basic dyes, e g , methylene blue Their significance is not clear, although they appear to be related to heparin and histamine metabolism Eosinophils and basophils will not be discussed further here *3)* The *neutrophils* are by far the most numerous leukocyte in the blood of human beings. Blood leukocytes of a normal individual are 65 to 70% neutrophils (the remaining being mononuclear leukocytes, that will be discussed in Chapter 9) The neutrophil granules are fine and stain a violet tint with neutral dyes The neutrophils are actively ameboid, are capable of locomotion, and have very active phagocytosis They measure about 10 to 14 μm in diameter Their nuclei show a variable number of lobes The number of lobes is called the Arneth count—the greater the number supposedly the older the cell This is an archaic concept and not useful

GRANULOCYTE STRUCTURE

Structurally the nuclei of all mature peripheral blood granulocytes are similar by light and electron microscopy Nuclear pores are seen, but they are not as prevalent as in the more mature of those cells that are still capable of mitotic division There is no clearcut evidence of transport between the cytoplasm and the nucleus There is no well-defined nucleolus Since in other cells the nucleolus is the origin of much of the cytoplasmic ribonucleic acid (RNA), it is probable that in neutrophils most major biosynthetic processes have ceased (Zucker-Franklin, 1968) Similarly, the Golgi body and centrioles are elementary and found with great difficulty

Granules are membrane-bounded structures containing hydrolytic and oxidative enzymes characteristic of lysosomes (Cohn and Hirsch, 1960) The neutrophil is a mature, motile cell laden with potent enzymes awaiting the opportunity to perform its one obvious function of phagocytosis, a process discovered by Metchnikoff (1887) During phagocytosis an orderly sequence of events takes place The granulocyte surrounds the particle to be phagocytized with pseudopods which fuse, engulfing the particle into a vacuole limited by cell membrane Thus, the particle still occupies extracellular space although inside of the cytoplasm The neutrophilic granules (lysosomes) fuse to the membrane and inject their content of hydro-

lytic and oxidative enzymes into the phagocytic vacuole This process is paralleled by degranulation (Zucker-Franklin, 1968)

During the process of phagocytosis there is a burst of both aerobic and anerobic metabolism, although glycolysis is believed to provide the energy necessary for this phagocytic activity (Karnovsky 1962) The hexosemonophosphate shunt is rapidly activated Hydrogen peroxide is generated Oxygenases that use molecular oxygen are present within the leukocyte and may be important in bacterial killing After the phagocytosis and burst of enzymatic and respiratory activity, the hydrolytic enzymes are activated by a fall in the pH

Phagocytosis of a single bacterium causes a limited amount of degranulation Phagocytosis of 50 bacteria may produce complete degranulation and death of the phagocytic granulocyte that releases the lysosomal enzyme and histamine, and contributes to the various extracellular mediators of inflammation (Cline, 1970) A large number of granulocytes disappear from the blood daily and are destroyed without producing any detectable physiological or harmful effects Actually, the average number of granulocytes destroyed per day in standard man (70 kg) is about $1\,14 \times 10^{11}$ This represents 1600/mg /day or 66/mg /hr averaged out through the body Krogh (1922) estimates the filtration bed of the capillaries to be 6300 m^{-2} If granulocytes leave through the capillary bed and die in the tissues this represents 18/day/mm^{-2} of capillary bed The capillaries of the alveolae of the lungs are estimated to have a surface area of 140 m^{-2}. If granulocytes normally proceed through capillaries in proportion to the area of capillary bed about 4 5% of these granulocytes stray into the alveoli The lungs, however, are only 1 4% of body weight, and the alveoli represent a small fraction of lung weight Hence the alveoli are richly endowed normally with a large supply of granulocytes for a first line of defense against airborne bacteria

Under some circumstances it is believed that the powerful enzymes of the neutrophil may be released and produce undesirable or severe painful pathological episodes For example in gout, urate crystals are deposited in joints and joint capsules producing mechanical irritation Neutrophils migrate into the area and phagocytize the crystals In the absence of an enzyme, uricase, the neutrophil is injured, empties its enzymes and humoral inducers of inflammation into and around the joints and produces a violent painful inflammatory response (Malawista 1965) It is also believed that chemotactic influences e g antigen-antibody reactions may attract neutrophils into tissues (joints in rheumatoid arthritis, arteries in periarteritis nodosa kidney in glomerulonephritis, etc) resulting in death of the neutrophil Subsequent release of their enzymes (including collagenases and elastases) may be the cause of the necrotizing and severe inflammatory lesions that typify these diseases (Janoff, 1960)

The tissue release of these enzymes nevertheless serves a useful purpose at times Neutrophils accumulate in areas of tissue destruction following burns and trauma Through the release of collagenases and other enzymes they accomplish a debridement of necrotic tissues

CHEMOTAXIS OF LEUKOCYTES

Chemotaxis is a term that has been used to describe the directional locomotion of cells towards chemical substances or particles in their environment The chemotaxis of phagocytic cells can be looked upon as a phenomenon of recognizing harmful foreign material such as bacteria or their products The ensuing directional migration of phagocytes towards the inducing agent probably serves as a first stage in the response of phagocytic cells to bacteria When in contact with the material, phagocytosis occurs There are many techniques for the measurement of chemotaxis in vitro and in vivo (Sorkin et al , 1970) Many substances are not chemotactic per se but exert their effect by inducing formation of chemotactic mediators in fresh serum (Keller and Sorkin, 1965) It is believed that antigen antibody complexes and several fractions of complement interact to result in chemotaxis Cationic polypeptides from granules of polymorphonuclear cells increase the vascular permeability, cell adhesion to the vascular walls and infiltration of leukocytes into an inflamed area (Golub and Spitznagel, 1966) One can imagine that the initiation of the inflammatory response by a few granulocytes results in a local killing of a few granulocytes and release of material from their granules, which in turn serves as a multiplication factor comparable to a chain reaction that attracts more

cells into the inflammatory area Chemotactic factors are specific for neutrophil and macrophages, respectively

THE INFLAMMATORY RESPONSE

For centuries medical students have been taught the cardinal signs of inflammation—rubor, tumor, calore, and dolore (Celsus) Inflammation may progress to loss of function Histologically, one sees necrosis of cells, vasodilation locally, edema and accumulation of leukocytes The inflammatory reaction is one of the mechanisms of host defense against attack by bacterial and other agents As alluded to earlier, however, the inflammatory reaction may develop under other circumstances and become harmful to the host The inflammatory reaction is induced not only by cells but also by humoral agents released from cells, and produced by the leakage of specific plasma proteins into the area Classically the cellular events consist of margination and sticking of leukocytes to the vessels, their transit through the vessel walls and migration into the inflammatory area In general pathology, the acute inflammatory process commences with the terminal arterioles, capillaries, and venules The circulation at first is characterized by vasodilation with increased capillary permeability and the leakage of plasma proteins *Histamine* release probably plays an early transient role in the inflammatory process by inducing increased capillary permeability In a later stage, during which leukocytes are infiltrating into the tissues, the blood flow is slowed and hemorrhage may occur *Serotonin* may also be released from platelets during their breakdown within tissue, and also could influence blood flow and leakage of plasma from the capillaries by a combination of arteriolar dilation and venular constriction (Majno and Palade, 1961)

An exceptionally important humoral system in the inflammatory response is the production of *bradykinin*, a linear nonapeptide with a molecular weight of 1060 (Rocha e Silva, et al, 1949, Elliott et al, 1961, Pierce and Webster, 1961) Bradykinin is accepted as the most powerful pain producing agent known (Armstrong et al, 1957) It is exceptionally potent in producing arterial and venular dilatation by direct action on smooth muscle It thus participates in the inflammatory response in a manner similar to histamine and serotonin but is much more potent All three induce separation of intercellular junctions of the venular endothelium, causing endothelial cells to contract and swell into the lumen of the vessel and pulling endothelial cells away from each other and exposing subendothelial tissue (Majno et al, 1969) Bradykinin is a prototype of several low molecular weight polypeptides (*kinins*) which are released from an inactive plasma αglobulin substrate called kininogen by a number of enzymes that exist in the plasm and tissues called kallikreins The kallikreins in themselves must be activated in vivo al though this mechanism is not well-known The intricate interrelations of these systems have been analyzed (Donaldson, 1970, Miller and Melmon, 1970) The activation of the kalli krein-kinin-kininase system is related to a key blood coagulation factor, the Hageman factor (Margolis, 1958, Webster and Ratnoff, 1961) This is shown schematically in Figure 4 24

Granulocytopoiesis

THE BONE MARROW PRODUCTION OF GRANULOCYTES

Approaches to the study of cell proliferation in the bone marrow were described in Chap ters 2 and 3 The characteristics of granulo poiesis as a cell renewal system are shown in Table 4 12 The stem cell pool has been en dowed by the fountain of youth with immortality, and continually replenishes itself and provided cells for all differentiated hemopoietic cell lines by the action of feedback signals that starts the stem cell down an irreversible pathway In contract to the infinate capability of stem cells to divide upon need, the differentiated cell lines have the capability of dividing only a finite number of times before some cytoplasmic nuclear interaction causes them to

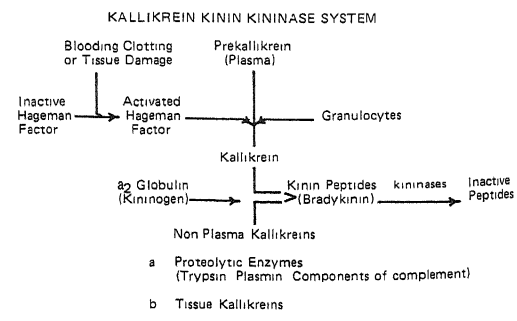

Fig 4 24 Kallikrein-kininase system (From Miller and Melmon 1970)

Table 4 12
Scheme of a cell renewal system and structure of granulopoiesis in parallel indicating function and capabilities

Cellular Pool	Granulopoiesis	Characteristics	Mitotic Capability
Stem cell	Stem cell		Self-perpetuating
Multiplicative	Myeloblast (M_1)	Amplification of input	Finite number of
	Promyelocyte (M_2)	and maturation	mitoses allowed
	Myelocyte ($M_3 + M_4$)		
Maturation	Metamyelocyte (M_5)	Maturation	None
	Band (M_6)		
	Segmented (M_7)		
Functional	Segmented in blood (M_7)	Function fight infection	None
Cell death	Random loss and pyknotic segmented granulocytes	Random or senescent death	

From Cronkite and Vincent, 1969

cease cycling Two important transitions in the flow of cells from the stem cell to the blood granulocyte are shown The first is the invisible but definite flow from the stem cell to the granulopoietic compartment Second, the myelocyte-metamyelocyte transition represents the flow from the multiplicative compartment into the first part of the nondividing maturation compartment This transition is clearly defined by the movement of labeled cells, from the proliferative compartment into the first stage of the nonproliferative compartment The statistical variability of this rate has not been established A single in vivo observation in man was 3 3%/hr (Cronkite et al , 1960), probably faster than normal because of infection The third transition is the emergence of neutrophils into the blood, which can be measured by the radioautographic appearance of labeled granulocytes in the blood The transitions from myeloblast to the promyelocyte and thence to the myelocyte cannot be observed directly, since pulse labeling with tritiated thymidine (^{3}HTdR) simultaneously tags each of these stages The behavior of the stem cell pool and its regulation were discussed in Chapter 2 Recent observations suggest that granulopoiesis at stem cell level is controlled in a manner similar to erythropoiesis with a committed and pluripotent stem cell, the former in cycle and the latter primarily in G_0 (Rickard et al , 1971) The fine details on granulocytopoiesis have been reviewed (Cronkite and Vincent, 1969)

The observations required for a quantitative discussion of granulocytopoiesis are *1*) the proportional distribution of cells within the bone marrow obtained by a marrow differential count of sufficient cells to attain reproducibility in defining the ratio among the cytological compartments, *2*) the absolute cellularity of bone marrow providing the number of dividing and nondividing granulocytic cells of the marrow per kilogram, data essential for computation of absolute production rates in the marrow (Donohue et al , 1958), *3*) the mitotic and/or ^{3}H thymidine labeling index with the respective mitotic and deoxyribonucleic acid (DNA) synthesis times (Strychkmans et al , 1966)

With these data one can estimate the fluxes into, the birth rate within, and the fluxes out of sequential cell compartments relative to the number of the most immature identifiable cell, the myeloblast as described in Chapter 2 In Table 4 13 the proportional distribution of cells in granulocytopoiesis within the bone marrow is tabulated along with the in vitro labeling index, the number in synthesis (N_s), the fluxes into and out of each compartment and the birth rate (K_b) within the compartments In earlier studies the smaller myelocyte M_4 was considered to be a more mature myelocyte than M_3 Present thinking places this cell as primarily a G_1 myelocyte (Cronkite and Vincent, 1969) Accordingly, in the estimation of the relative production M_3 and M_4 are pooled Since the stem cell cannot be identified its flux is omitted, hence, the relative production rates are underestimates Later the stem cell influx will be estimated indirectly The number of cells appearing in M_5 and those exiting M_4 are close There may be a small loss of cells in the production line particularly when the stem cell influx is considered In fact it has been postulated that granulocyte pro-

Table 4 13

[c] 2 5/hr the turnover rate required to equal the absolute granulocyte turnover rate in the blood

duction may in part be regulated by a controlled death function in such a way that turning off the death function-increases the output This notion suggests that cells die at the myelocyte level unless needed (Patt and Maloney, 1964)

The relationship among flux out (K_{out}), flux through DNA synthesis (K_s) and stem cell flux into (K_{in}) in a system in which there are multiple mitoses can be expressed thus

$$K_{out} = 2^n K_s = 2^n K_{in} \quad (1)$$

$$K_{out} = [\Sigma (2^{n-1} + 2^{n-2} \quad + 2^0] + K_{in} \quad (2)$$

The first term is equal to

$$\Sigma N_s/T_s = K_B \quad (3)$$

and

$$K_{out} = K_B + K_{in} \quad (4)$$

where

T_s = DNA synthesis time

n = number of mitoses

It follows that K_{in} is also equal to the rate of entry of cells into, through, and out of any phase of the generative cycle. If not, then cells will pile up in a phase, and a steady state will not exist Aberrations in which cells pile up are characteristic of some abnormalities

Equation (3) allows calculation of production rate without knowledge of the number of mitoses because it requires only labeling of cells in DNA synthesis by the specific precursor, tritiated thymidine, and knowledge of DNA synthesis time However, as will be shown later, one can estimate the average number of mitoses utilizing the preceding equations

The preceding concept and the data in Table 4 13 for the ratio of cells in DNA synthesis for myeloblast, promyelocytes, and myelocytes of 85 190 1100, or 1 2 2 13 indicates that this ratio is best fitted by assigning approximately one mitosis to myeloblast and promyelocyte and two sequential mitoses in the myelocyte If each cell were to divide accordingly, there would be an amplification factor of 16 from the stem cell However, there is no direct evidence that each cell committed to granulopoiesis actually divides four times before maturation and entering the first compartment of the nonproliferating pool M_5, the metamyelocyte

The blood granulocyte turnover rate (GTR) is $6\,79 \times 10^7$/kg /hr If there is no loss between the myelocyte and the peripheral blood granulocyte the marrow must make at least $6\,79 \times 10^7$ granulocytes/kg /hr The marrow myelocyte mass is 260×10^7/kg (Donohue et al, 1958) From Table 4 13 it is seen that 0 22 of the myelocytes are in DNA synthesis, hence, the

$$K_B = \Sigma N_s/T_s = (260 \times 10^7 \times 0\,22)/12$$

$$= 4\,76 \times 10^7/\text{kg /hr}$$

The flux into the myelocyte pool must be

$$K_{in} = K_{out} - K_B = 2\,03 \times 10^7/\text{kg /hr}$$

Rearranging equation (1) and substituting,

$$n = \frac{\log_e (K_{out}/K_{in})}{\log_e 2} = \frac{\log_e (6\,79/2\,03)}{\log_e 2} = 1\,74$$

the average number of mitoses at the myelocyte level as derived from the values presently available for GTR The average transit time through the myelocyte compartment will be 91 hr Cronkite and Vincent (1969) deduced that the generation time of myelocyte is about 52 hr Of this the DNA synthesis time is 12 hr, and G_2 + M is 3 hr, leaving 37 hr for G_1 The ratio of DNA synthesis time to generation time is 0 23, close to the observed labeling index of 0 22 given in Table 4 13 These are current estimates not rigorously proved by human data and subject to revision as more information becomes available The examples are used to illustrate the principles involved

In producing 6 79 × 10^7 granulocytes/kg /hr (assuming no loss between the metamyelocyte and the emergence of granulocytes into the peripheral blood and using the absolute marrow cellularity of 270 × 10^7/kg for M_5, 360 × 10^7/kg for M_6 and 250 × 10^7/kg for M_7,) the respective turnover rates must be 2 5%/hr, 1 9%/hr, and 2 7%/hr and the respective turnover times are 40, 53, and 37 hr This is illustrated in Figure 4 25

A major discrepancy exists between the relative data on distribution of nondividing granulocytes in the marrow and the absolute number used in the calculations of the preceding paragraph and shown in Figure 4 25 When similar computations are made on a basis of relative numbers in Table 4 13, the following times are obtained 40, 66, and 94 hr, respectively for M_5, M_6, and M_7 with turnover rates of 2 5%, 1 5 and 1 06%/hr There is no obvious explanation to date for this discrepancy, except that one or another observation is in error

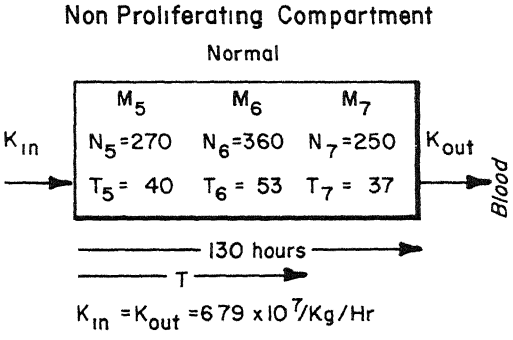

Fig 4 25 Compartment size (N) and transit time (T) for the nonproliferating granulopoietic compartment based on absolute cellularity in cell per Kilogram body weight

The number of segmented granulocytes stored in the marrow is about four times the number in the blood The total number of stored granulocytes in the entire nonproliferating compartment (M_5 + M_6 + M_7) is about 12 5 times the number in the blood Upon demand a physiological mechanism exists which releases the mature granulocytes quickly into the blood and accelerates the maturation of the rest of the storage compartment, with a resulting shortening of the emergence time of cells labeled at the myelocyte level (Fliedner et al 1964b) The chemical factor responsible for the rapid release has been termed the *leukocytosis inducing factor* (Gordon et al, 1960a) A sustained granulocyte turnover rate requires accelerated cell production and release (Lapin et al, 1969)

THE BLOOD GRANULOCYTE

Knowledge of the behavior of the blood granulocyte has accrued primarily from the use of diisopropylflurophosphate ($DF^{32}P$) labeling of granulocytes followed by autotransfusion of the labeled cells and observation of their dilution and disappearance rate (Cartwright et al, 1964) The flow of ^{3}HTdR labeled cells from the marrow into the blood (Fliedner et al, 1964a,b, Cronkite and Vincent, 1969) has also given considerable insight into the behavior of the blood granulocyte The rapid granulocytosis produced by exercise or adrenalin has long been thought to be due to the rapid mobilization of a pool of readily available mature granulocytes in the blood The "margination" of granulocytes in areas of the circulation where the blood flow is relatively slow is an old observation (Vejlens, 1938) From the $DF^{32}P$ labeling of an individual's granulocytes followed by autotransfusion, it has been directly shown by dilution that the blood contains a circulating granulocyte pool (CGP) and a marginal granulocyte pool (MGP), and that the sum of these equals the total blood granulocyte pool (TBGP) The ratio of the CGP to the TBGP is 0 44 with a range of 0 16 to 0 99 An equilibrium between the CGP and MGP is attained rapidly after introduction of labeled granulocytes into the circulation. The disappearance of autotransfused $DF^{32}P$ labeled cells is random with a half-time ($T_{1/2}$) of 6 7 hr (Athens et al, 1961). The notion that the loss of granulocytes of the blood is random is di-

Table 4 14
The total blood granulocyte pool (TBGP) circulating granulocyte pool (CGP) marginal granulocyte pool (MGP) half time disappearance ($T\frac{1}{2}$) and granulocyte turnover rate (GTR) in normal subjects

Determination	No of subjects	Mean	95% limits
TBGP $\times 10^7$ cells/kg	100	70	14–160
CGP $\times 10^7$ cells/kg	109	31	11–46
MGP $\times 10^7$ cells/kg	109	39	0–85
$T\frac{1}{2}$ in hours	56	6 7	4–10
GTR $\times 10^7$ cells/kg /day	56	163	50–340

From Cartwright et al , 1964

rectly supported by the observation that ^{3}HTdR labeled granulocytes appear in the blood and extravascular sites such as saliva simultaneously (Fliedner et al , 1964b) Blood granulocytes also die by a process of senescence This was demonstrated by the appearance of labeled pyknotic (dying) forms seen in the peripheral blood 30 hr after labeled granulocytes first appeared in the blood Thus, the random loss of granulocytes from the blood is truncated by senescent loss about 30 hr after the entrance of the cells into the blood (Fliedner et al , 1964b) In Table 4 14 the values on measurement of the various compartments of the blood granulocyte pool are tabulated The fractional turnover rate per hour (λ) for a compartment from which there is random loss is $\log_e - T\frac{1}{2}$ The reciprocal of λ is the average time spent in the compartment The granulocyte turnover rate (GTR) is therefore,

$$GTR = TBGP \times \lambda = 6\,79 \times 10^7/kg\ /hr$$

$$\lambda = 0\,103/hr$$

$$1/\lambda = 9\,7\ hr$$

The GTR is $6\,7 \times 10^7$/kg /hr or 163×10^7/kg /day

It has always been tacitly assumed that the instantaneous marrow production rate (MPR) equals the marrow release rate (MRP) equals the granulocyte turnover rate (GTR) in the blood The notion of such a steady state where instantaneous production and turnover rates are equal is incompatible with the observation of a long term oscillation of the granulocyte count in the blood of normal men (Morley, 1966). From peak to peak the granulocyte oscillation in the peripheral blood varies from 14 to 23 days This cycling is considered as being compatible with a system that has a negative feedback circuit acting on the marrow stem cell (self perpetuating level) with a time delay corresponding to the time from induction of the stem cell into granulopoiesis until it appears in the blood as a granulocyte The time delay would approximate half of the cycle time Intuitively one might expect a normal cycling of the blood granulocyte concentration since many tissues are in a state of flux, the size varying with changes in rate of production on one hand or in the rates of disappearance on the other hand, and regulated by need and use With the reasonable establishment of a granulocyte cycle in the blood, steady-state calculations of granulocyte kinetics should be based on the average production and granulocyte turnover rate through an entire cycle rather than at any single point in time MPR will equal GTR at some time later when the cells produced at time (t_1) are being destroyed in the blood The periodic state is shown in Figure 4 26 Although the actual curve of the variation of the granulocyte concentration with time (solid line) does not conform to a sine wave it is shown thus for simplicity The reciprocal of this curve, the dotted line, represents the strength of the signal that drives stem cells down the granulopoietic pathway This signal presumably initiates a complex sequence of

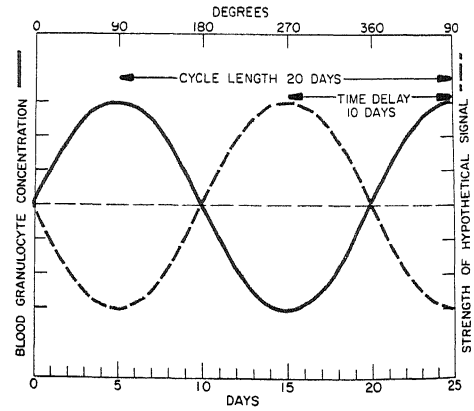

Fig 4 26 Diagram of concept of cyclic variations in the blood granulocyte concentration based on the observations of Morley Granulocyte concentration is shown as a solid line and the strength of a hypothetical signal stimulating granulopoiesis is shown as a broken line Sine waves have been used in this model although in fact the shape of the curves is probably more complex than this The cycle length is 20 days and the time delay from maximum signal to maximum response is 10 days

biochemical events that constitute the process of differentiation into a cell type characterized by the numerous specific proteins enzymes granules, and organelles as described in the earlier part of this chapter In keeping with contemporary knowledge on transfer of biochemical codes, the signal is almost certainly chemical and initiates the derepression of transcription sites for m-RNA coded for the enzymes and proteins that are characteristic of the cell line Since many specific proteins and enzymes are going to be synthesized it is conceivable that the chemical signal derepresses the transcription sites for a single protein, and that the subsequent cascade of derepression of transcription sites for different proteins is related to repression of other sites by successive protein products These, in turn, after attaining a specific concentration may suppress their own transcription sites by product ' inhibition, analogous to that suggested for mean corpuscular hemoglobin concentration in turning off cell cycling in erythropoiesis (Chap 3)

Several factors influence the TBGP, CGP, MGP, and GTR Adrenal corticosteroids increase the total granulocyte count apparently by a combination of increase in MRR and a decreased efflux from the blood (Bishop et al 1968) Bacterial endotoxin produces a granulocytosis preceded by a fleeting granulocytopenia with shift in cells from the CGP to MGP This is followed by an absolute increase in TBGP with a decrease in granulocytic specific activity of the labeled cells, indicating an increased MRR of unlabeled cells (Athens et al , 1961) The TBGP is increased in infection where the half-time in the blood is usually prolonged, and GTR is always increased This increased GTR demands an increase in MRR and MPR as described earlier

When there is a sustained granulocytosis the mean age of the granulocyte in the blood measured from the last myelocyte mitosis is younger Probably these cells have not reached the degree of effeteness described in the first section on the granulocyte structure, and thus, may have a longer life that perhaps explains the longer half-time of granulocytes in the blood during infection

The reserve granulocytes available to be drawn on in time of need are the mature granulocytes in the marrow, the number of which is about four times the number present in the peripheral blood The total nonproliferating pool of marrow cells is about 12 5 times the number present in the blood Cells leave the marrow more or less by a "pipeline ' process the older cells being released first (Maloney and Patt, 1968) The time needed for a cell labeled with tritiated thymidine as a myelocyte to appear in the peripheral blood is defined as the emergence time it varies between 96 and 144 hr normally It can be shortened to 48 hr under the stress of bacterial infection (Fliedner et al 1964a)

FACTORS RELATED TO REGULATION OF GRANULOPOIESIS

In Figure 4 27 an idealized scheme of granulopoiesis is presented The ordinate shows the flux of cells as 10^7/kg /hr and the abscissa the time from entry of a stem cell into granulopoiesis From the stem cell to the metamyelocyte the transit time is 138 hr During the normal periodic state the stem cell influx will vary as described earlier, and will give rise about 288 hr later to a rising or falling input into the peripheral blood, which in turn determines the concentration of granulocytes in the blood The rigid scheme shows a 16-fold amplification of the stem cell input if each cell that enters granulopoiesis shows four mitoses and divides four times Some cells may divide fewer times as suggested in earlier discussion As mentioned earlier, the myelocyte is believed to have a G_1 period of 37 hr A theoretical mechanism of increasing production rate in the same time interval from stem cell to metamyelocyte would be a shortening of G_1 Sufficient time would be provided for an additional mitosis and thus, a doubling of the production rate within the 138 hr transit from the stem cell to the metamyelocyte Whereas, the transit from the last myelocyte mitosis (emergence time) normally ranges from 96 to 144 hr , during the stress of infection the emergence time can be decreased to as little as 48 hr (Cronkite et al , 1960) Thus, with a shortening of the generation time, an additional mitosis and a shortened transit through the nonproliferating pool an increased input into the blood could be experienced within a few days These three mechanisms constitute an attractive hypothesis but one not yet experimentally verified

If the entire increase in production were to

come from an increased input from the stem cell level without changes in generation time, it would take about 12 days to be seen in the peripheral blood Inasmuch as sustained granulocytosis is seen much faster than this, an increased stem cell input does not appear to be the sole mechanism of increasing granulocyte production Prolonged increased GTR requiring more than twice the normal production will demand an expansion in the mass of the granulopoietic marrow

In Figure 4 28 the notions discussed are in-

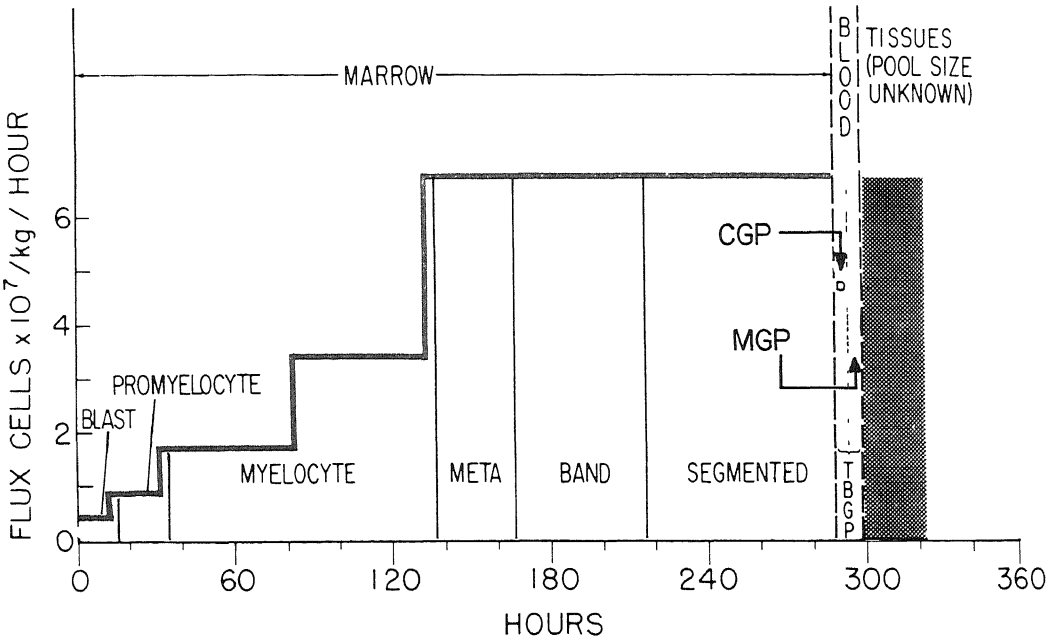

Fig 4 27 Sequential flow of cells through granulopoiesis The ordinate shows the flux through each compartment relative to the GTR and the abcissa shows the time in each compartment The area of each of the nondividing compartments gives the number of cells in that compartment In the case of the proliferating compartments large and small myelocytes have been combined The stepwise increase in cell numbers through the dividing compartments represents serial divisions The size of TBGP is in scale but the relationship between CGP and MGP does not necessarily imply flow through MGP to the tissues The size and existence of the tissue pool are unknown (From Cronkite and Vincent 1969)

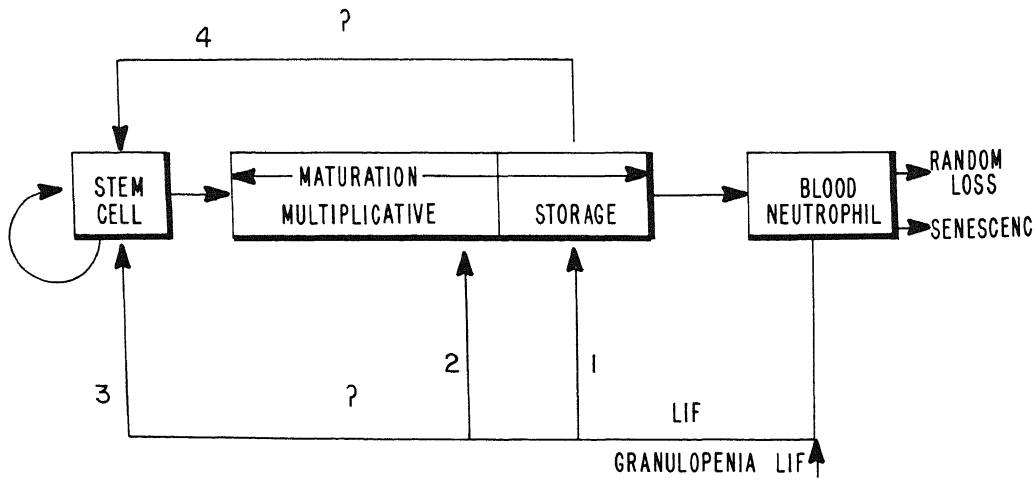

Fig. 4.28 Concept of regulation of granulopoiesis by several possible feedback loops *1)* LIF releases stored marrow granulocytes *2)* Myelocyte generation time decreases with more mitoses *3)* A peripheral signal differentiates more stem cells and triggers more cycling to restore size *4)* Possible intramedullary signal from storage to stem cell pool induces differentiation and cycling

corporated into a general operational concept of regulation of normal granulopoiesis and its response to stress Granulocytes are being lost from the blood by a random and senescent process As the granulocyte count falls from any reason the leukocytosis inducing factor (LIF) increases in concentration (Lapin et al 1969) The LIF through a fast feedback loop causes the marrow to release the storage granulocytes quickly Then either due to the action of LIF or other factors, it is believed that the myelocyte generation time decreases with an additional mitosis that doubles the output The transit through storage compartment is shortened Then through a feedback loop to the committed or possibly pluripotent stem cell, there is an increased rate of differentiation followed by increased rate of proliferation to rebuild the stem cell pool size Whether this results from an intramarrow sensing device that determines the diminution in size of the storage compartment or is a direct action of LIF or other peripheral factor on the stem cell pool is obscure

CLINICAL ASPECTS OF GRANULOPOIESIS

Dangers of Chemotherapy For a computer analysis a model for granulopoiesis can be based on the following concepts a periodic cycle of blood granulocyte concentration, regulated by two feedback loops—a fast loop that controls the release of stored granulocytes in the bone marrow (LIF), and a slow loop that controls the entrance of stem cells into the granulopoietic pathway, the time constant observed for lifespan of cells in the peripheral blood, and the transit time through the bone marrow This computer model reproduces the low amplitude oscillations observed in normal males (Morley et al, 1970) In addition, it yielded an important prediction to the effect that mild marrow failure might produce a cyclic neutropenia with a large amplitude This has been experimentally confirmed With a decreasing store of marrow granulocytes the fast feedback loop becomes less capable of modulating the inherent tendency of a system with long time delay to oscillate, and one can therefore detect swings of larger amplitude With further reduction in size of the proliferative compartment of the marrow, the production rate of granulocytes will fall further, and as the size of the marrow granulocyte reserve approaches zero, the extreme oscillations will flatten out into a noncyclical neutropenia of severe and dangerous degree Such has been frequently observed after prolonged heavy dosage of marrow depressant drugs or radiation Clinically the early detection of marrow depression before it is irreversible is of utmost importance in radio or chemotherapy of metastatic disease in procedures for immunosuppression, or in evaluation of possible marrow toxicity of new drugs To safeguard the patient an adequate number of granulocyte counts should be performed at intervals sufficiently frequent to reveal any increase in the amplitude of any granulocyte cycle that might precede the development of a severe noncyclical neutropenia Isolated counts can be misleading if they are made by chance at the peak or the bottom of a cycle

Chronic Granulocytic Leukemia. Chronic granulocytic leukemia is clearly an aberration of granulocytopoiesis There is an increase in the blood concentration of leukocytes at all levels of maturation, and proliferation from the marrow into the peripheral blood with cells' being seeded out in the spleen and elsewhere where they proliferate This disease could be due to an increased input of stem cells that enlarges the entire system and expands the marrow compartment to the point that it 'leaks'' and cells metastasize to the body at large There is also an enzyme defect of granulocytes in chronic granulocytic leukemia with the absence of alkaline phosphatase In many cases, the abnormal Philadelphia chromosome described in Chapter 2 is present

Marrow Suppression by Drugs and Radiation. Following exposure to whole body irradiation there is a decrease in the stem cell input into granulocytopoiesis that is followed by a progressive depletion in the maturation and multiplicative compartment and is finally reflected in the blood as a marked neutropenia If the irradiation has been sufficiently heavy and blood cell production has decreased to near zero levels the individuals are markedly susceptible to infection and may die of this cause before regeneration of the bone marrow can occur (Bond, et al, 1965)

Drugs can also interfere with blood cell production Butazolidin is an example of a drug that occasionally produces a very severe granulopenia, apparently because of interference in the transit of cells from the myelocyte to the metamyelocyte Examination of the bone marrow will show a striking depletion of the

nonproliferating compartment with an active myelopoiesis. Upon withdrawl of the drug, one can observe an orderly flow of cells through the nonproliferative pool and the reappearance of granulocytes in the blood.

Chronic Granulomatous Disease of Childhood. This is a fatal genetically determined disorder effecting male children with an onset of manifestations early in life (Good et al., 1968). The abnormality involves enzymatic deficiencies in the lysosome phagocytic vacuole system that prevent the effective killing of phagocytotized pathogenic bacteria. The fundamental metabolic lesion in this disease is deficient production of hydrogen peroxide during phagacytosis (Baehner et al., 1970).

Congenital Neutropenia. This relatively benign disorder is characterized by an inability of immature myeloid cells to proliferate and mature to normal numbers of granulocytes (Vriedt, et al., 1970). If the production rate is so low that there is no, or little, storage pool in the marrow a noncyclical neutropenia would be predicted on the basis of the discussion outlined above under dangers of chemotherapy.

THROMBOPOIESIS, HEMOSTASIS, COAGULATION, AND THROMBOSIS

Thrombocytes

The platelet is a non-nucleated cell yet, it has a complex structure The surface limiting plasma membrane is 70 to 90 A in thickness it is interpreted to consist of one lipid bimolecular layer and two protein layers Mitochondria are always present in the cell There are electron dense granules (α granules) that are believed to contain platelet factor 3 and enzymes Vacuoles and vesicles are present, and remnants of Golgi bodies are seen Microtubules can be identified and separated, their function is obscure but appears to be related to maintaining the shape of the platelet Possibly the microtubules represent a retractile element of the platelet cytoplasm called *thrombosthenin* There are abnormalities in platelet structure in various hemorrhagic diseases The ultrastructure of the platelet and its relationship to function has been extensively reviewed (Hovig, 1968)

HEMOSTASIS

Hemostasis is the business of platelets This may be defined as the arrest of blood flow from a break in a vessel wall and the prevention of spontaneous bleeding This function probably requires three properties of platelets *1*) an endothelial supporting function of platelets measured by capillary resistance tests, *2*) a capability of forming hemostatic plugs, which can be measured by the bleeding time in human beings or by the enumeration of red blood cells in the lymph in animals with cannulated thoracic ducts, and *3*) the release of a lipoprotein material called *platelet factor 3* that activates plasma prothrombin to thrombin in the coagulation mechanisms, and can be measured by prothrombin consumption time and other in vitro tests Platelet factor 3 will be discussed later under blood coagulation

The platelets occupy a central role in the staunching of blood loss from small and large blood vessels Following injury to a blood vessel the following sequence of events is observed Blood oozes out through the hole or severed vessel the vessel constricts the endothelium everts, and platelets adhere to the collagen in the underlying connective tissue exposed to the flowing blood by the injury Platelets also migrate into spaces which appear between endothelial cells (Ashford and Freiman, 1967 French et al , 1964) Platelets continue to accumulate on top of the first platelets already adhering to the collagen and injured endothelial cells probably as a result of the release of adenosine diphosphate (ADP) from the platelets themselves or possibly from damaged vascular tissue (Gaarder et al , 1961, Born and Cross, 1964) Platelets continue to accumulate and initiate coagulation in the area By a combination of constriction of blood vessels formation of the hemostatic plug of platelets, and fibrin clot the outflow of blood is decreased and usually stopped Retraction of the clot holds the edges of vessels and wound together and so prevents further loss of blood For greater detail on the hemostatic process see the extensive review on blood coagulation (Donaldson, 1970)

The relationship of the platelets to vascular integrity is inferred, from the fact that spontaneous hemorrhage develops when the blood platelet count falls below 20,000/mm ^{3} (Gaydos et al 1962) At 50,000/mm ^{3} or more a reasonable hemostasis is possible during surgical procedures The exact mechanism whereby platelets prevent hemorrhage and maintain capillary strength is not completely understood but has been reviewed extensively (Johnson et al , 1966) Data obtained by utilizing radiosulfate labeled platelets suggests that the platelets directly contribute something to the capillary endothelium (Cronkite et al , 1960) Platelets

have been observed by electron microscopy to enter endothelial cells in thrombopenic states (Johnson et al , 1964)

Freshly separated platelets transfused into the fatally irradiated dog will prevent hemorrhage (Cronkite et al , 1952) Platelet transfusions have been shown to be efficacious in control of thrombopenic bleeding in man (Hirsch and Gardner, 1952)

MEGAKARYOCYTOPOIESIS AND THROMBOPOIESIS

A model for megakaryocytopoiesis is presented in Figure 4 29 From the studies of Whang et al , (1963) it is clear that the common stem cell feeds the megakaryocytic pool upon need There is also good evidence for existence of a committed stem cell pool as described earlier under erythropoiesis and granulocytopoiesis Megakaryocytes have been divided into three stages depending upon their maturity Tritiated thymidine initially labels stage I megakaryocytes The label can be seen to appear successively in stages II and III As the label progresses through the more mature stages, the percentage labeling in stage I increases, this indicates an influx of cells from an earlier, labeled, unknown precursor, possibly from a committed stem cell compartment As the megakaryocytes mature they produce platelets and die For details of megakaryocyte proliferation, kinetics of their maturation and platelet production see Ebbe (1968)

Platelets are formed when the mature, granular megakaryocytes shed their cytoplasm The normal human platelet has an average volume of 5 8 μm^3 New platelets are probably larger than platelets that have aged Platelet counts are remarkably stable over long periods of time, signifying that production and destruction under normal conditions do not vary significantly (Brecher et al , 1953)

Platelet *turnover* rate must be measured indirectly from measurements of platelet *survival* and platelet *count* The most commonly used method for measuring platelet survival is based on a chromium-51 labeling with auto transfusion The normal platelet turnover is in the vicinity of 40,000/mm ^{3}/day (Davey, 1966) There appears to be some random loss of platelets in addition to the senescence that sets an upper limit on lifespan The mean platelet life is in the vicinity of 9 to 11 days in normal individuals Random removal of platelets appears to be in the vicinity of 5 to 15%/day This apparent random loss may be due to elution of the label

Platelets can be counted by electronic methods, but the most practical laboratory and clinical method remains enumeration with phase microscopy (Brecher et al , 1953)

The peripheral blood platelets appear to be distributed between the blood and a splenic pool It has been estimated that about one-third of the total platelet mass is concentrated in the spleen in equilibrium with the remaining two-thirds distributed throughout the rest of the vascular system (Aster, 1966)

The regulation of platelet production has been studied by hypertransfusion of platelets and the transfusion of plasma from markedly thrombocytopenic animals and human beings These and other studies on regulation were critically reviewed by Ebbe (1968) It can be concluded that there is a feedback regulatory system, in which the level of the circulating platelets influences the rate of megakaryocytopoiesis and platelet production Although it is not conclusively proved, there is evidence suggesting that a thrombopoietin exists which

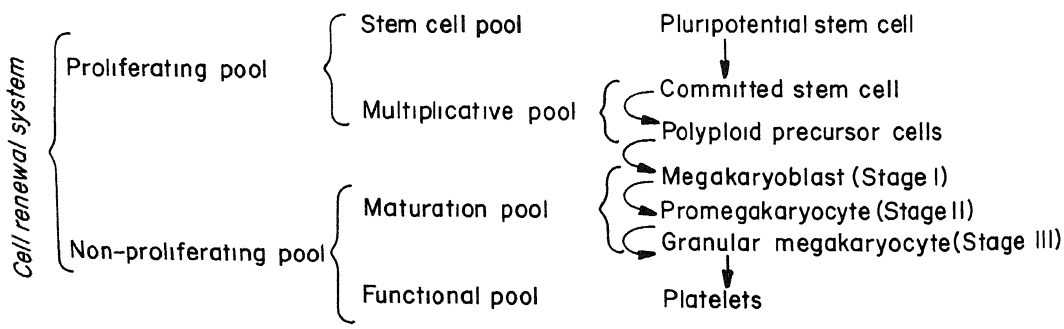

Fig 4 29 Model of megakaryocytopoiesis (From Ebbe)

stimulates platelet production The inhibition of platelet production by increasing concentration of platelets in the blood remains a possibility Because the compartment of recognizable megakaryocytes is a nondividing compartment (Ebbe and Stohlman, 1965) there are two possible mechanisms for increasing the output of platelets 1) each megakaryocyte may make more platelets, or 2) an increased input of cells into the megakaryocytopoietic compartment from the precursor pool may yield more platelet-producing cells It appears that the latter is the mechanism by which increased platelet production is accomplished in acute thrombocytopenia

Coagulation of Blood

GENERAL DESCRIPTION

Clot Formation If blood is collected into a test tube, at the end of a few minutes it will have lost its fluidity and set into a jelly Microscopically this clot is made up of a mesh of very delicate fibrils among which are entangled, as in a net, the red and white cells and many fragmented platelets The fibrils are composed of fibrin that is formed by the alteration and polymerization of fibrinogen molecules If the clot is allowed to stand for an hour or so, it shrinks and expresses from its interstices a clear faint straw-colored fluid This is the *serum*

In this retraction of the clot or *syneresis*, as it is termed, the platelets play an essential role They attach themselves to the fibrin threads which then contract, draw the fibrin compactly together, and thus, squeeze out the serum Clots formed in blood deficient in platelets are soft and friable and easily loosened from the injured vessel The importance of these small particles of protoplasm in hemostasis will be dealt with later

The Clotting Mechanism. No field of physiology is more complex or has been so confused by contradictory results, differences of interpretation, and diversity of opinion as that of blood coagulation Blood coagulation is essentially a series of enzymatic reactions involving a number of plasma proteins Many of these are present only in traces Within an intact healthy circulatory system these enzymes, for the most part, are in an inactive form However, when blood is shed or placed in contact with a "wettable surface," such as glass, a series of autocatalytic enzymatic reactions is initiated In the effort of various investigators to understand the order in which the numerous factors enter into the process of coagulation, the results of an enormous number of 'mixing' experiments have been reported This has resulted in a confusion not only of terminology but also between what is a separate enzyme entity and what is merely a resultant activity To make some order out of chaos an international system of numbering has been introduced for the identification of those factors accepted by a majority of authorities in the field In Table 4 15 the international numbering system for the accepted coagulation factors is shown No numbers have been suggested for the physiological anticoagulants

DEVELOPMENT OF THROMBOPLASTIN ACTIVITY

By the end of the 19th century, it was established that extracts of tissues free of blood accelerate the clotting of whole blood or plasma but have no effect on solutions of *fibrinogen* According to the hypothesis put forward at that time, this tissue extract (called *thromboplastin*), in conjunction with calcium acts by converting *prothrombin* to its active form *thrombin* During the early 1940's it was shown that thromboplastin requires both lipid and protein constituents for full activity Also, at about the same time, work in a number of laboratories indicated that factors other than

Table 4 15
Synonymous terms for clotting factors

International Committee Nomenclature	Synonymous and Descriptive Terms
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Thromboplastin
Factor IV	Calcium
Factor V	AC-globulin, proaccelerin labile factor
Factor VII	Proconvertin, SPCA
Factor VIII	Antihemophilic factor
Factor IX	Plasma thromboplastin component (PTC), Christmas factor
Factor X	Stuart-Prower factor
Factor XI	Plasma thromboplastin antecedant (PTA)
Factor XII	Hageman factor, contact factor
Factor XIII	Fibrin stabilizing factor, fibrinase

thromboplastin are involved in the normal conversion of prothrombin to thrombin (Biggs and Macfarlane, 1962)

With the introduction of silicone, a new phase in the study of blood clotting began With proper solutions of silicone, test tubes, syringes, and needles can be covered with a smooth "nonwettable" surface This makes it possible to withdraw blood and prepare plasma for study without causing changes due to surface action Using siliconed glassware it is possible to show that blood itself contains all the factors needed for thromboplastin generation (Biggs and Douglas, 1953), it requires only a change in surface contact to trigger the mechanism Thus, there are two sources of thromboplastin activity, one from tissue extracts sometimes called the *extrinsic source*, and the other from the interactions of a number of trace plasma proteins, calcium ions, and platelets called the *intrinsic source*

The factors that are involved in the formation of intrinsic, or plasma thromboplastic activity are illustrated in Figure 4 30*A* It is now generally accepted that factor XII when activated by surface contact initiates the reaction Then, in the presence of calcium ions, other trace proteins, factors XI, IX, and VIII (possibly in this order), are in turn activated Factor VIII (antihemophilic factor) is present in normal fresh plasma but is absent or inactive in normal serum and rapidly disappears from stored blood, it is relatively stable however, in plasma stored at −20° C, it is not readily absorbed on the usual prothrombin-absorbing reagents such as aluminum hydroxide or tricalcium phosphate Factor IX (Christmas factor) is present in both plasma and serum and is readily absorbed on prothrombin-absorbing agents, it is present in stored blood Deficiencies in factor VIII or factor IX result in a bleeding condition known as parahemophilia, this is an hereditary condition linked with a defect of the X chromosome Factor XI (plasma thromboplastin antecedent) has some of the characteristics of both factors VIII and IX, it is not readily adsorbed on prothrombin-adsorbing reagents but is stable and is found in serum Bleeding defects due to lack of factor XI activity are quite rare In addition to these, and possibly other as yet unidentified proteins, a phospholipid is required for development of optimum thromboplastin activity. During normal coagulation

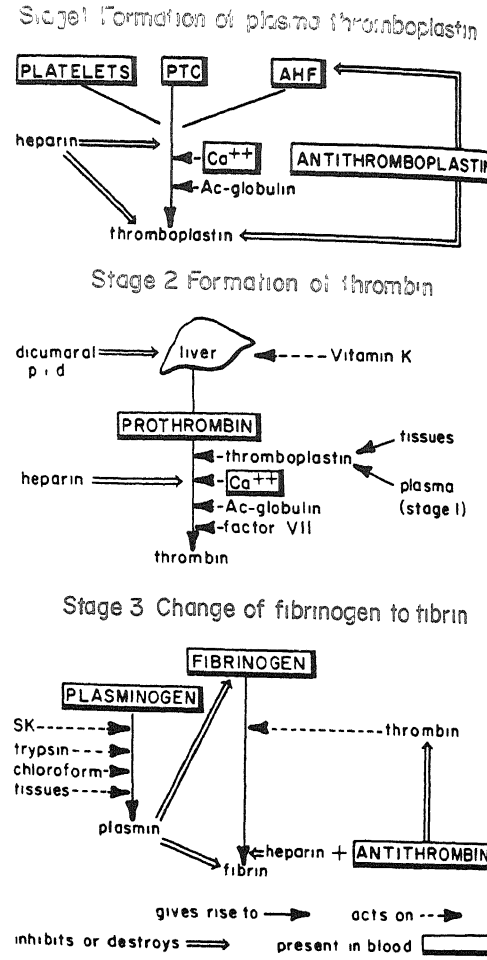

Fig 4 30 Sequence of reactions in clotting mechanism Stage I Formation of plasma thrombo + plastin Stage II Formation of Thrombin Stage III Change of fibrinogen to fibrin

this is supplied through platelet breakdown For in vitro coagulation the platelet phospholipid moiety can be replaced by phospholipid from brain tissue or soy bean (Macfarlane et al , 1964, Owren, 1947)

Agents such as citrate, oxalate, or ethylenediamine-tetra-acetic acid (EDTA) by binding calcium ions will completely inhibit the development of thromboplastin activity Heparin, which is not present in normal blood in measurable amounts, is probably of no importance in preventing normal blood coagulation When added as a therapeutic agent, however, it acts at a number of sites along the chain of reaction There is good evidence that its initial action is to prevent the development of thromboplastin activity It probably does this by com-

bining with the reactive sites on the tract proteins and by preventing platelet disintegration and release of phospholipids. Heparin is a mucopolysaccharide prepared from beef lung or beef and hog intestinal mucosa. A number of similar mucopolysaccharides have been synthesized (Howell and Holt 1935, Best et al. 1938, Jorpes 1949, Monkhouse and Clarke 1957).

ACTIVATION OF PROTHROMBIN

Recent studies have favored the hypothesis that both the thromboplastin formed from the interaction of plasma proteins and the thromboplastin in tissue extracts need an additional factor for full activity. This is factor X (Stuart-Prower factor). In addition to factor X, tissue thromboplastin requires factor VII (convertin). The exact order in which these proteins enter into the reaction is not yet established, but results obtained by Macfarlane and his colleagues (1964) support the order suggested in Figure 4-30*B*. Calcium ions are also required for prothrombin conversion, and factor V (AC-globulin) increases the rate of the conversion. It is known that heparin when added to a physiological system will inhibit the conversion of prothrombin, but much, if not all, of this inhibitory activity may be through the action via thromboplastin. In common with most other plasma proteins, prothrombin, factor X and factor VII are formed in the liver. The ability of the liver to maintain normal blood levels of these protein fractions, however, depends on the presence in the liver of sufficient amounts of vitamin K. Dicumarol, and other similarly acting drugs, antagonize vitamin K and depress the rate of production of prothrombin, factor VII, and factor X (Quick, 1945, Link, 1944).

CONVERSION OF FIBRINOGEN TO FIBRIN

Once thrombin is formed it acts enzymatically to convert the soluble fibrinogen into insoluble fibrin. It has been established that thrombin is a proteolytic enzyme having the same sequence of amino acids at its active site as digestive enzymes such as pepsin and trypsin. Most proteolytic enzymes break down fibrinogen completely, but thrombin splits off only a few terminal peptides. Two of these known as fibrin peptides A and B are the result of selective action of thrombin at terminal arginine-glycine bonds. The splitting off of the peptides causes a change in charge at the ends of the molecules of fibrinogen and allows them to polymerize end-to-end in long insoluble strands (Laki, 1962). When purified fibrinogen is clotted by purified thrombin, the clot is found to be soluble in urea, but the clot formed in plasma is not soluble in urea. A factor has been isolated from human and animal plasma which will render the clot formed from purified fibrinogen insoluble in urea. This factor has been named fibrin stabilizing factor or factor XIII. It greatly facilitates the healing of wounds, yet is missing from the blood in some persons.

Many authorities in the field of coagulation adhere to the view that fibrin is being continually formed and destroyed and that the integrity of the endothelium depends on the presence of a physiological mechanism for the constant removal of fibrin. Such a mechanism does indeed exist. It depends on the presence in blood of an inactive proteolytic precursor called *plasminogen* which has been identified as a β-globulin with a molecular weight in the region of 150 000. During clotting or purification of fibrinogen it is associated closely with the fibrinogen molecule. It is extremely difficult to prepare fibrinogen free of plasminogen and a normal clot usually contains sufficient amounts of plasminogen to insure clot dissolution if circumstances permit its activation. Activators that convert plasminogen to plasmin are of two different types. Activators from tissues and urine act directly on both human and bovine plasminogen. Activators such as streptokinase (prepared from streptococcal cultures) and lysokinases from tissues and blood must act first on a globulin fraction called proactivator. This proactivator is present in large amounts in human plasma, but is virtually absent from the blood of cattle and other animal species. There is usually an excess of plasmin inhibitor in normal blood. However, when large amounts of plasminogen are activated (this can occur during surgery, childbirth, or prostatic cancer), fibrinogen as well as fibrin is destroyed by the enzyme and serious hemorrhage can result. Small increases in the fibrinolytic activity of plasma have been reported following exercise, anoxia, or the injection of adrenalin or serotonin. On the other hand, high levels of lipoproteins tend to

inhibit fibrinolysis (Sherry et al, 1959, MacMillan and Mustard, 1961)

It has been known for decades that normal plasma can neutralize large amounts of thrombin Morawitz (1904) proposed the name *antithrombin* for this activity in plasma The neutralization of thrombin in plasma, however, is a complex action and is not due to a single effect Thrombin can be neutralized without being destroyed Breakdown products of fibrin digestion can do this by blocking the thrombin-fibrinogen reaction Heparin in combination with a plasma factor (heparin-cofactor) acts in a somewhat similar manner There is, however, an enzyme in plasma (true plasma antithrombin) which destroys thrombin, this has been shown to be an α globulin Relatively large quantities of this are present in normal plasma In fact the amount of antithrombin available far exceeds the amount of thrombin formed during coagulation

TESTS EMPLOYED IN THE INVESTIGATION OF DEFECTS IN THE CLOTTING MECHANISM

Coagulation Time. This is the time taken for blood to clot after it is withdrawn from the body Decreased coagulability of the blood is manifested by lengthening of the coagulation time and vice versa A number of methods have been developed to measure the precise moment in which clotting occurs The clotting time of normal blood will depend upon the size of the tube, the number of tubes employed, the temperature at which the blood is kept during the test, and the amount of tilting and agitation of the tube It is important to do the clotting test in exactly the same manner each time If the method is standardized, serial determinations of the clotting time will provide useful information

A modification of the Lee-White method for whole blood clotting time is widely used One-milliliter quantities of blood drawn by clean venipuncture are placed in each of three small test tubes (11-mm internal diameter) placed in a water bath A stop watch is started at the time of venipuncture After 3 min, the first tube is tilted at 15-sec intervals When the blood clots in this tube, the next tube is tilted until clotted and then the third tube is treated similarly. The clotting time is taken as the time of clotting of the blood in the third tube The coagulation time by this method varies between 9 and 11 min for normal individuals By using three tubes, variations in clotting time due to variation in rate and degree of tilting (surface effect) are reduced

In small children venipuncture may be difficult and the clotting time can be measured on capillary blood With a sharp lancet, a drop of blood is obtained from the finger, ear lobe, or heel and allowed to run into a capillary tube The ends of the tube are sealed with plasticine and then the tube is immersed in a water bath at 37° C At 15-sec intervals small fragments of that tube are broken off and the end point is taken when a string of clot is observed The normal coagulation time by this method is between 3 and 5 min, it is shorter than clotting time by the Lee-White method because of the relatively greater surface area of glass in contact with the blood

Prothrombin Time. In the one-stage method developed by Quick, excess of tissue thromboplastin and optimal calcium are added to citrated or oxalated plasma The tubes are placed in a water bath at 37° C and the time for clotting to occur is recorded A standard value for the day is determined using a sample of normal plasma This standard time will vary between 14 and 16 sec A dilution curve may be prepared with normal plasma diluted with adsorbed plasma (prothrombin free) to relate clotting times to prothrombin concentration in per cent of standard This is done in an attempt to reduce the variability caused by the tissue thromboplastin, the activity of which differs from day-to-day It is doubtful, however, whether the dilution curve is worth the effort in the practical management of patients taking oral anticoagulants (Quick, 1945)

Clot Retraction Time. In this test 2 to 3 ml of venous blood are placed in a test tube kept at a 37° C in a water bath After clotting has occurred the clot is freed from the sides of the tube by means of a wooden applicator stick Normally in a couple of hours the clot contracts to a firm mass expressing serum from its interstices Clot retraction is normal in hemophilia but abnormal in thrombocytopenia

Bleeding Time. Bleeding time is determined by nicking the skin with a pointed scalpel blade, the ear lobe being a convenient site. Drops of blood are wiped away every few seconds with filter paper The end point is taken as the moment when bleeding ceases

The normal bleeding time is about 2 to 7 minutes The ability to seal the wound depends on the platelets and on the state of the small blood vessels The bleeding time is normal in hemophilia This at first seems to be a paradox until it is realized that the platelets and blood vessels are normal in this condition In hemophilic patients manipulation of the small wound later causes renewal of bleeding which may be extremely troublesome to control It is believed that this is due to failure of an effective clot to back up the platelet plug (Tocantins, 1936)

Thromboplastin Generation Test. This test resembles the one-stage prothrombin time, but instead of saline extracts from acetone-treated brain as a source of thromboplastin activity, plasma components and platelets are first incubated together to produce plasma thromboplastic activity Normal thromboplastic activity requires factor VIII and factor IX from plasma, cephalin obtained from platelets, and calcium The generation mixture is kept at 37° C and at 1-min intervals thromboplastic activity is tested by adding samples to a substrate of normal platelet-poor citrated plasma and calcium The time of clotting of the substrate reflects the thromboplastic activity of the generation mixture In the test 0 2-ml quantities of normal alumina plasma diluted 1·5 (factor VIII), normal serum diluted 1 10 (factor IX), cephalin or platelets and M/40 calcium chloride solution are placed in a test tube At intervals of 1 min, 0 1 ml of the mixture is withdrawn into a Pasteur pipette and discharged simultaneously with 0 1 ml of M/40 calcium chloride solution into a tube containing 0 1 ml of normal platelet-poor citrated plasma A convenient substitute for platelets is cephalin prepared from brain or soy bean The clotting times of the substrate samples may be plotted as a curve showing normal thromboplastin generation Having prepared a normal thromboplastin generation curve, aluminium plasma or serum from a test subject may be substituted for one of the normal components and the resulting curve compared with the normal If the subject lacks a component necessary for thromboplastin generation, decreased thromboplastic activity will be detected (Biggs and Douglas, 1953)

Partial Thromboplastin Time. This test is widely used and has the advantage of being a one-stage test that is simpler to perform than the thromboplastin generation test It also resembles the Quick one-stage test for prothrombin time Instead of adding acetone-treated brain to plasma cephalin is used in this test If normal amounts of factors VIII and IX are present in the plasma a short clotting time will be observed If one of these factors is lacking, the time will be prolonged Since the early stages of clotting are influenced by surface contact it is customary to add kaolin to the plasma while doing the test to provide maximum activation of contact factors The test may be used for both the diagnosis and control of treatment of hemophilia

Abnormalities of Clotting Process

HEMORRHAGIC DISEASES

Hemophilia. In this condition the coagulation time (but not the bleeding time) is usually prolonged In some cases the blood may not clot for several hours Fatal hemorrhage may follow a minor wound or a simple operation such as a tooth extraction It is important to realize, however, that certain hemophiliacs have a clotting time which is normal or only slightly prolonged In these patients it is necessary to confirm the diagnosis with the thromboplastin generation tests or partial thromboplastin time Hemophilia is transmitted as a sex-linked recessive character On a statistical basis, females carrying the abnormal X chromosome transmit the disease to half their sons while half their daughters will be carriers A hemophilic father will have normal sons but carrier daughters If a hemophilic man marries a hemophilic carrier, it is possible to have a female hemophilic This occurrence is very rare Even hemophilic patients with normal or slightly prolonged clotting times may bleed to death following procedures such as tonsillectomy or tooth extraction. There is, therefore, really no such thing as mild hemophilia Since the disease carries an increased mortality it would eventually disappear were it not for the appearance of fresh mutations Approximately 30% of patients with the disease do not have a previous family history

Two distinct types of hemophilia may be recognized by laboratory testing Certain patients lack factor VIII while others lack factor

IX From the practical standpoint it is important to distinguish between the two types of hemophilia Factor VIII deficient patients require fresh blood or plasma since this activity disappears rapidly on storage Both human and animal factor VIII concentrates are now available Their use has saved many lives and major surgery has been made possible In factor IX deficiency it is not necessary to use fresh plasma since the factor is more stable on storage Satisfactory concentrates of factor IX are not generally available

Afibrinogenemia. The lack of fibrinogen may be either inherited or acquired Because fibrinogen is formed in the liver, in the end stages of serious liver disease the level in the blood may fall It may also temporarily disappear due to destruction by fibrinolysins This may occur following surgery on prostatic cancer, presumably due to release of fibrinolytic enzymes into the blood stream It also may occur in abruptio placentae when sudden and abrupt separation of the placenta may also result in release of fibrinolytic and thromboplastic material into the blood stream and thus, cause a rapid destruction of fibrinogen with bleeding

Purpura. Purpura is hemorrhage into the skin and mucous membranes It may be due to an abnormality of the platelets or of the blood vessels Thrombocytopenic purpura may be either idiopathic or secondary to a toxic agent, the former variety frequently responds very well to splenectomy The mechanism of vascular purpura is not well understood and the diagnosis is made very often by excluding other causes Damage to the blood vessel wall may occur in scurvy, in uremia and in severe infections An important type of vascular purpura is associated with hypersensitivity or allergy

Hypoprothrombinemia. Depression of the prothrombin level in the blood (hypoprothrombinemia) may be found in severe liver damage and in conditions where there is malabsorption of vitamin K, such as obstructive jaundice and steatorrhea Hemorrhagic disease of the newborn results from lack of vitamin K in the mother It may be prevented by giving the mother vitamin K before the baby is born Administration of coumarin drugs results in lowering of the plasma level of prothrombin and clotting factors VII and X

INTRAVASCULAR CLOTTING—THROMBOSIS

Coagulation of blood within vessels may be brought about experimentally by the injection of thrombin or thromboplastin into the blood stream There is an immediate reduction in the number of platelets and the level of fibrinogen After a short time the platelet count returns to normal suggesting that the platelets were not destroyed but were merely sequestered somewhere in the vascular system Return of the fibrinogen level takes longer and is not complete for 24 hr, indicating that fibrinogen was destroyed and was replaced by newly formed fibrinogen

Injury to the vessel wall results in a deposition of platelets from the flowing blood at the site of injury The platelets stick to the injured area and also to each other forming a platelet plug On top of the platelet, nidus fibrin threads are formed which enmesh red and white blood cells This is known as a *thrombus*, and it is important to distinguish this from a simple blood clot formed in a stagnant pool of blood A thrombus may either partially or completely plug the lumen of a vessel The "head" of a thrombus at its point of attachment consists mainly of platelets and fibrin The "tail" of the thrombus frequently lies within the lumen of a vessel and consists of fibrin and red cells

A thrombus or a portion of it may break free and being carried away in the blood stream may lodge in some remote area The portion of the thrombus that travels is known as an *embolus* Emboli from the leg veins lodge in the lung, producing an area of consolidation in the lung known as a pulmonary *infarct* If an embolus originates in the left side of the heart it will be carried to a peripheral artery, for example, a cerebral artery giving rise to a cerebral infarct

Causes of Thrombosis in Man. The causes of thrombosis in man may be considered under the following headings

Injury to a Blood Vessel Injury to a blood vessel by trauma, or the application of an irritating substance leads to thrombosis, but the basic mechanism underlying its development remains obscure It is possible that a damaged endothelial lining causes the release or activation of substances that initiate the clotting process

Deposition of Platelets Dietrich (1919) some years ago made an experimental study of postoperative thrombosis He described the deposition of the platelets and compared them with sand which is kept in suspension in a rapid stream Just as sand is deposited in a ribbed pattern upon the seashore or at a river's mouth where the current is slowed, so platelet deposited in a thrombus form characteristic ridges The identification of platelet strands or ridges enables the pathologist to distinguish a thrombus from a postmortem clot In vitro the addition of adenosine diphosphate (ADP) to a platelet suspension causes rapid clumping of the platelets It is possible that damaged endothelium releases substances similar to ADP which alter the platelet membrane causing them to adhere to each other and to the endothelium The platelet mass sometimes completely obstructs the vessel Occasionally it breaks away and forms a small embolus When this happens, another plug of platelets forms at the site of injury (Wright, 1942, Gaarder et al, 1961, Moolten et al, 1949)

Slowing of the Blood Stream After major surgery or childbirth, there is an increased risk of developing thrombosis and embolism This may be due to the fact that the flow of blood in the veins becomes sluggish, with a resulting platelet deposition and clotting Early ambulation after surgery and childbirth has been accompanied by a lowered incidence of thrombosis

Changes in the Blood After operation and childbirth, both the number of platelets and the level of fibrinogen are increased Many investigators have carried out tests of clotting factors in an attempt to demonstrate a prethrombotic state All such studies have been inconclusive, while some workers have reported changes, these have not been confirmed by other investigators An important factor leading to thrombosis is probably an alteration in platelet stickiness, associated with alterations in the endothelium and slowing of blood flow

Summary. The first event in the development of a thrombus is probably an alteration in the endothelial lining Platelets adhere to this area and to each other forming a white thrombus The growth of the thrombus occurs by the deposition of further platelets and the formation of fibrin, which enmeshes red and white cells The accumulation is favored by a sluggish blood flow The clot that has been formed may remain fixed and either completely or partially occlude the blood vessel The tail of the thrombus may be free in the flowing stream of blood The thrombus may grow by the fresh deposition of platelets and fibrin The thrombus may have a precarious hold on the lining of the vessel and break loose from its point of attachment, or a piece of the tail may become detached When this occurs an embolus is carried in the blood stream to lodge in a distant part Once the thrombotic process is recognized in leg veins, treatment consists of moderately active exercise, e g, walking to increase venous return from the part and to lessen the change of a clot's forming in stagnant blood Secondly, anticoagulant therapy with heparin or dicumarol may be given with the hope of lessening the buildup of a thrombus by fresh clot Anticoagulant therapy might be expected as well to allow the natural fibrinolytic process to proceed without hindrance

PREVENTION OF CLOTTING

The Means Used to Prevent or Retard Coagulation—Anticoagulants. *Cold* Since the clotting mechanism consists of a series of chemical and enzymatic reactions, it is to be expected that coagulation will be retarded by lowering the temperature Keeping blood at a temperature of from 5 to 10° C postpones coagulation but does not absolutely prevent its occurrence Cold, e g, ice, etc, applied to the surface of the body as a means of arresting hemorrhage has, however, no effect in retarding the coagulation process Actually a hemostatic action is exerted in such instances as a result of the vasoconstriction reflexly induced

Avoidance of Contact of the Blood with Foreign Materials or Injured Tissues Drawing the blood directly from an artery or vein (in order to prevent contact with the tissues—a source of thromboplastin), and collecting it into a receptical whose walls have been made smooth and *unwettable* by a coating of paraffin, or preferably of *silicone*, will slow greatly the coagulation process Silicone is the most effective substance known for this purpose, it acts like the vascular endothelium in inhibiting the breakdown of platelets (Jaques and associates,

1946) and the formation of thromboplastin activity Plasma, after it is collected in siliconelined apparatus and centrifuged at high speed in order to remove the platelets as completely as possible, will remain fluid for 3 or 4 days even at room temperature The importance of a smooth surface in maintaining the fluidity of blood is also shown clearly in the classical experiment of the "living test tube " If a section of the jugular vein of an animal, e g , the horse, be isolated between ligatures and carefully removed with its contained blood, this will not clot for a long period, not until changes occur in the lining of the vessel wall and the necessary thromboplastin is thereby provided

Decalcification The addition of oxalate (sodium, potassium, or ammonium) or a fluoride to blood to the extent of 0 1% or more, completely destroys its power to clot spontaneously In the former instance the calcium is precipitated as calcium oxalate Oxalated blood recovers its ability to clot if shaken with chloroform, but the fibrin which forms redissolves after the blood has stood for a time Fluoride does not precipitate the calcium but forms a weakly dissociated calcium compound Sodium citrate also prevents coagulation, in this instance a double salt—calcium sodium citrate—is formed, which again is only slightly dissociated

Neutral Salts Magnesium sulfate solution in a strength of 27% mixed in the proportion of 1 4 of blood postpones coagulation for some time, but does not prevent it indefinitely Sodium sulfate in half-saturated solution added to an equal quantity of blood has a similar effect, as has also a 10% solution of sodium chloride in the same proportion The manner in which these substances act is not clear They do not decalcify the blood

Anticoagulants Used Therapeutically. At the present time there are two types of anticoagulants used for therapeutic purposes The anticoagulant heparin has an immediate direct action on the coagulation system, whereas, a group of drugs represented by dicumarol has an indirect effect on the coagulation system through their action on the liver

Heparin is a naturally occurring sulfonated polysaccharide with strong anticoagulant action It can be prepared from bovine lung on porcine or bovine intestinal mucosa It requires a plasma fraction for its antithrombic activity but can inhibit at a number of points during the coagulation process (Fig 4 30) Heparin must be given parenterally since it is not absorbed from the alimentary tract Because it is rapidly inactivated and removed from the circulation, it is difficult to maintain a therapeutic level in the blood while avoiding the danger from bleeding Prolonged action can be obtained by intramuscular injections of concentrated solutions of heparin Heparin readily combines with basic peptides and proteins and can be inactivated by protamine

Dicumarol (4-hydroxycoumarin), which was originally extracted from spoiled sweet clover, lowers the level of prothrombin and associated coagulant factors by acting as an antagonist to vitamin K (Link, 1944) There is now a large number of analogues of dicumarol and phenolindane-dione compounds which are more potent than dicumarol but act similarly The effect of these drugs can be prevented or overcome by the administration of vitamin K These drugs have no effect on coagulation when added directly to blood

The whole problem of anticoagulant therapy is undergoing a great deal of study and there are many physicians who question the therapeutic value of anticoagulants This problem, however, is beyond the scope of this chapter

SUBSTANCES WHICH HASTEN THE CLOTTING PROCESS (HEMOSTATICS)

It has been widely accepted that epinephrine hastens coagulation, but such an effect has not been proved The effects of thrombin and thromboplastin have been discussed Tissue extracts, especially those of lung and thymus which are rich in thromboplastin, are powerfully coagulant, as are also the venoms of some species of snakes The coagulant property of such venoms depends upon their containing a proteolytic enzyme that converts prothrombin to thrombin, the conversion occurs in the absence of ionized calcium

Thrombin sprayed upon the bleeding surface in conjunction with fibrinogen forms a covering film or foam of fibrin, and is an effective means of arresting bleeding, especially from numerous small vessels. Among other hemostatic agents used to hasten the clotting process are sodium alginate, derived from seaweed, and a gauze made of oxidized cellulose, which swells when soaked with blood When sodium alginate comes into contact with the blood and serum of the wound, it is converted to calcium alginate, which "clots" to form a tenacious layer

4. THE LYMPHATICS, LYMPH, AND TISSUE FLUIDS

General Considerations

STRUCTURE OF THE LYMPHATIC SYSTEM

The lymphatics can not be discussed without reference to blood capillaries (sect. 3, chap. 1). Their very close interrelation is shown in Figure 4-31. The part of a capillary nearest to the arteriole is called an arteriole capillary and that part nearest to the venule is designated as venous capillary. There are "through" capillaries in which blood flows continually, and there are branched capillaries in which the blood flow is regulated by vasoconstriction and vasodilatation mediated through the precapillary sphincters. The wall of the capillary consists of a single layer of flat endothelial cells resting on a basement membrane and surrounded by a thin adventitia of fibers and cells. The capillary endothelium, when appropriately stained, looks like pavement blocks.

The endothelial cells of blood capillaries have two distinct ultrastructural characteristics. *a*) The process of pinocytosis[1] takes place. This can be considered to be microphagocytosis. One can observe tiny pinocytic vesicules that appear by invagination of cell membranes and enclose fluid and sometimes particulate material. The direction of transport across capillaries is primarily into tissue at the arterial capillaries and into the capillaries at the venous end. *b*) In addition the capillaries in some anatomic areas appear to have pores varying in diameter from 300 to 500 Å, usually with a diaphragm overlying them. The pores play a role in the movement of fluid and solutes through the capillaries, and are particularly prominent in the glomerular capillaries. The role of osmotic pressure and hydrostatic pressure in controlling the flow of fluids out of the vascular system is discussed elsewhere (sect. 3, chap. 1). In Figure 4-31 the knoblike ends of lymphatic capillaries are shown almost in contact with blood capillaries. The direction of flow of fluids and solutes out of the arterial capillary and into tissue spaces and back into the venous capillaries and into lymphatic capillaries is shown by the arrows.

By combining the injection of colloidal materials and electron microscopy fundamental observations have been made upon the structure and function of the lymphatic capillary (Leak and Burke, 1966, 1968; and Cliff and Nicoll, 1970). The endothelium of the lymphatic capillaries is similar to that of the blood capillaries. There is no basement membrane. The diameters of the lymphatic capillaries vary widely from dilated terminal capillary bulbs to structures that are either very narrow and slitlike, or dilated capillaries, depending upon their state of function. Pinocytosis has been clearly demonstrated, it is one method of transportation of material from the tissue spaces into the lymph capillaries. The electron micrographic studies of the lymphatic endothelium show that in some areas away from the nucleus the endothelium is very attenuated, being in some places little more than the two membranes in width. The cytoplasm of the endothelial cells is either interdigitated or overlapping, although in some instances there appear to be wide gaps between the cells. In addition, there are collagenous anchoring filaments attached to lymphatic endothelium and then extending out to unite with collagenous bundles in the adjoining tissue. The detail of this structure is shown in Figure 4-32. When fluid accumulates in the interstitial spaces by transudation (or is injected, one can visualize that this fluid will occupy space between the lymphatic capillary and tissue collagenous fibers. Since the fibers attached to the lymphatic endothelium and the tissue collagen are inelastic one would expect the over-

[1] The absorption of liquids and tiny particulates by cells—"to drink."

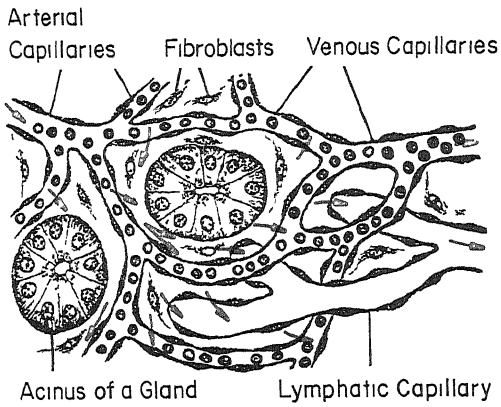

Fig 4 31 Diagram showing the relationship of lymphatic capillaries to blood capillaries and to the tissue fluids around the acini of a gland Similar relationships exist in most of the organs of the body Arrows indicate the direction of flow of fluid leaving the arterial capillaries permeating the connective tissue spaces as tissue fluid and re-entering the blood capillaries on the venous side The lymphatic capillaries supplement the venous capillaries in the drainage of fluid from the tissues to the circulatory system (From Copenhaver 1967)

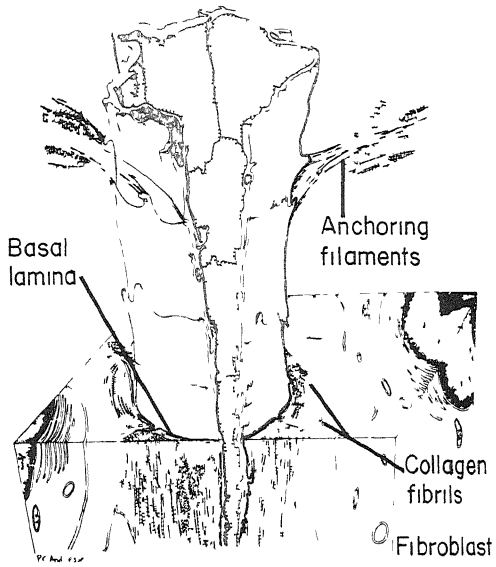

Fig 4 32 A three-dimensional interpretative diagram of lymphatic capillary that was reconstructed from collated electron micrographs The three-dimensional relation of the lymphatic capillary to the surrounding connective tissue area is illustrated The lymphatic anchoring filaments appear to originate from the endothelial cells, and extend among collagen bundles elastic fibers and cells of the adjoining tissue area thus providing a firm connection between the lymphatic capillary wall and the surrounding connective tissue Irregular basal lamina and collagen fibers are as marked (From Leak and Burke 1968)

lapping endothelium to be pulled apart so as to provide large pores through which the edema fluid under greater pressure can flow into the lumen of the lymphatic capillary The combination of a mechanism to open up the spaces between endothelial cells and an active process of pinocytosis gives two mechanisms by which fluid and its solutes can be rapidly transported from blood capillaries through the interstitial spaces and then into the lymph capillaries In the bat wing Cliff and Nicoll (1970) have shown that the terminal lymphatic capillary bulbs enter into collecting ducts that possess a contractile wall and valves These emerge into transport lymphatic channels with very active contractility and valves The transport lymphatics combine into larger and larger lymphatic vessels propelling the lymph to and through lymph nodes and toward the great veins Ultimately major lymphatic vessels are formed in the extremities and within the viscera, and then merge into the large right lymphatic and thoracic ducts From these lymph pours into the blood stream by way of the right and left subclavian veins, respectively

In the course of flowing from the periphery to the entrance in the blood vessels, the lymph flows through one or more lymph nodes As the lymphatics approach the node, they break up into finer channels called the afferent lymphatics, These penetrate into the sinuses of the cortex of the lymph node, then through the cortex and the medullary sinuses which are lined by phagocytic cells One or more large efferent lymphatics formed by confluence of the numerous medullary lymphatics emerge from the hilum of the lymph node, and progress onwards to join the major lymphatic vessels

In the walls of the abdominal cavity the lymphatics are most abundant on the under surface of the diaphragm, where the greatest lymphatic absorption takes place from the peritoneal cavity There is also substantial absorption into the lymphatics of the omentum Lymphatic systems exist in all organs with the exception of the central nervous system, cornea and the alveoli of the lungs Protein is not readily absorbed from the interior of the alveoli into the lymph capillaries because of the poor lymphatic supply, or possibly because it cannot readily penetrate the alveolar wall Water passes readily into the lung capillaries, however, because of the low hydrostatic pressure within them

THE FLOW OF WATER ELECTROLYTES SMALL MOLECULES AND PROTEINS BETWEEN THE BLOOD AND LYMPH

The rapid flow of oxygen and nutrients to cells and the return of carbon dioxide and metabolic waste products is accomplished because the blood capillary membrane is freely permeable to water and crystalloids There is a rapid and continual change between the intravascular and extravascular compartments by diffusion The transcapillary exchange takes place on an exceptionally large scale without any perturbation to the circulating blood volume or the electrolyte balance The magnitude of this flow is astonishing Once every minute a quantity equivalent to the total plasma sodium chloride and water are exchanged across the blood capillary membrane (Flexner et al , 1942, Merrell et al 1944, Chinard et al , 1955) This bulk movement of fluid into and out of the blood capillaries depends on the balance of hydrostatic and osmotic pressures acting across the capillary endothelium The essential characteristic of a capillary wall that regulates the net movement of fluid is its relative impermeability to plasma protein molecules The osmotic force exerted by the circulating plasma protein molecules within the blood capillaries counterbalances the hydrostatic pressure in the capillaries The capillary wall, however, is not completely impermeable to plasma proteins, and all protein molecules leak through to a certain extent Nevertheless, they are found in the interstitial fluid and lymph in significantly lower concentration than in plasma (Wasserman and Mayerson, 1952, Yoffey and Courtice, 1956) The accumulation of proteins in the interstitial fluid, with an increasing osmotic pressure that would disrupt the balance of forces controlling the exchange of fluid across the capillary membrane, is precluded by the rapid flow of protein molecules directly into the lymphatics, presumably by a combination of pinocytosis and flow through the gaps in the lymphatic capillary endothelium

The escape of plasma proteins into interstitial tissues varies with the tissue, it is greatest in the liver Factors that control the escape of protein into the interstitial space are not easily described by any simple concept It has been shown that a quantity roughly 50 to 100% of the circulating plasma proteins escapes across the blood capillary membrane and re-enters the blood through the lymphatics each day (Yoffey and Courtice 1956)

Composition and Flow of Lymph

The *protein concentration* of lymph is always lower than that of plasma, even though there is considerable variation between lymphatics depending upon the organ As oral or intravenous fluid intake is increased the protein concentration of lymph decreases

Lymph contains all of the *coagulation factors*, and clots although less readily than blood plasma There is a much higher concentration of some coagulation factors in the hepatic lymph in contrast to peripheral lymph because these factors are made within the liver Antibodies are found in the lymph and will be discussed in more detail in Chapter 10 Almost all of the enzymes that are found in plasma are also found in lymph to a lesser extent

The *electrolyte* concentration in lymph is not essentially different from that of plasma The total cation is slightly lower in the lymph than in the plasma and chloride and bicarbonate levels tend to be higher The direction of these differences in concentration is consistent with the Gibbs-Donnan equilibrium operating on two phases whose concentrations of nondiffusible ions (proteins) differ

Of the plasma *lipids*, cholesterol and phospholipid, being mainly associated with protein as lipoprotein, are present in the lymph in concentrations which vary with the level of protein in the lymph (Yoffey and Courtice, 1956) Neutral fat in the form of chylomicrons depends on the degree of fat absorption from the alimentary tract In the postprandial state one finds large quantities of lipoproteins and fats in the lymph coming from the gastrointestinal tract Between meals, the fat in the thoracic duct drops to low levels

The *other constituents* of the plasma that are readily diffusible, nonprotein and nonelectrolytes are present in the lymph in concentrations approximately the same as in the plasma After a carbohydrate meal when the blood sugar rises rapidly or after intravenous injection of glucose, the lymph sugar lags behind but soon an equilibrium is established between the plasma and lymph The nonprotein nitrogen, urea, amino acid, and creatinine levels are nearly the same in plasma and

lymph Small differences observed probably arise from errors of the techniques

The lymph contains *cells* Lymphocytes of all sizes and degree of maturity are the most numerous A very rare monocyte and macrophage is found Platelets are not observed Red cells, when present, indicate the degree of bleeding into the tissues as a result of injury, or when found in the thoracic duct suggest the presence of intestinal parasites Granulocytes are found in the lymph draining areas of infection Plasma cells are also found in very small numbers The concentration of lymphocytes in efferent lymph leaving a lymph node is always much greater than that in afferent lymph The circulation of the lymphocyte, its proliferation and factors that influence this will be considered in Chapter 10, along with the structure of lymph nodes and their role in immunity and defense against infection

THE FORMATION PRESSURE, AND FLOW OF LYMPH

Any condition that increases the outpouring of fluid from the capillaries into the tissues will increase the flow of lymph if there is no obstruction The factors influencing the flow are the contractility of the lymph vessels, activity of the skeletal muscles, peristalsis, and a differential pressure between interstitial spaces and lymphatics The average tissue pressure is about 1 9 cm of water, whereas, the pressure in the lumen of the lymphatic capillary is 1 2 cm of water (McMaster, 1947) Tissue fluid, therefore, enters lymphatic capillaries because of the gradient of pressure and through the gaps in the lymphatic capillary endothelium described earlier Presumably, the retention of fluid inside of the lymph capillary is in part due to the higher pressure of the interstitial fluid outside Propulsion of lymph from one region to another is brought about by the extrinsic and intrinsic forces described earlier The lymph pressure in the vessels will rise and the lymph will move centripetally to a region where the pressure is lower The numerous valves within the lymphatics prevent a retrograde flow of the lymph Since lymph flows centripetally along a duct there must be a gradient in pressure. During skeletal muscular contraction the lymphatics empty as tissue pressure increases, and during relaxation the vessels fill again.

FUNCTIONS OF THE LYMPHATIC SYSTEM

A most important function is obviously the return of protein, water and electrolytes from tissue spaces to the blood The lymphatics are exceptionally important in the absorption of nutrients, particularly fats from the gastrointestinal tract

The lymphatics serve also as a transport mechanism to remove red blood cells that have been lost into the tissues as the result of hemorrhage, or bacteria that may have invaded the tissues When there is an infection in a distant part of the body, the regional lymph node becomes inflamed as a result of the localization of bacteria or toxins carried in the lymph to the gland The lymph nodes contain a very efficient filtration system in the cortical and medullary sinuses, these are lined with phago cytic cells that engulf bacteria and red cells or other particulate material The efficiency of the filtration system can be demonstrated by the direct perfusion of pathogenic bacteria into lymphatics that are afferent to a lymph node Simultaneous culturing of the efferent lymphatic will show it to be sterile The capability of the lymph node to filter out pathogenic bacteria can be overcome, however, and bacteria escaping through the efferent lymphatics into the blood may produce a septicemia

CONDITIONS THAT INCREASE THE LYMPH FLOW

1) Increase in Capillary Pressure Landis and Gibbon (1935) found that filtration from the capillaries shows a definite increase when the venous pressure rises above 12 to 15 cm of water The rate of filtration from the capillaries is directly proportional to the increase in venous pressure (Fig 4 33) In their experiments, when the venous pressure was increased to any given level the filtration rate increased rapidly at first, but gradually slowed and finally ceased This falling off in the filtration rate they ascribed to a rise in extracapillary pressure due to the fluid accumulation, which opposed the hydrostatic pressure within the blood capillary The accumulation of extracellular fluid may be expected therefore to be greater in regions that are loose in texture and where the skin is readily stretched In persons with firm, resistant skin, edema, for the same reasons, is later in appearing and less pronounced

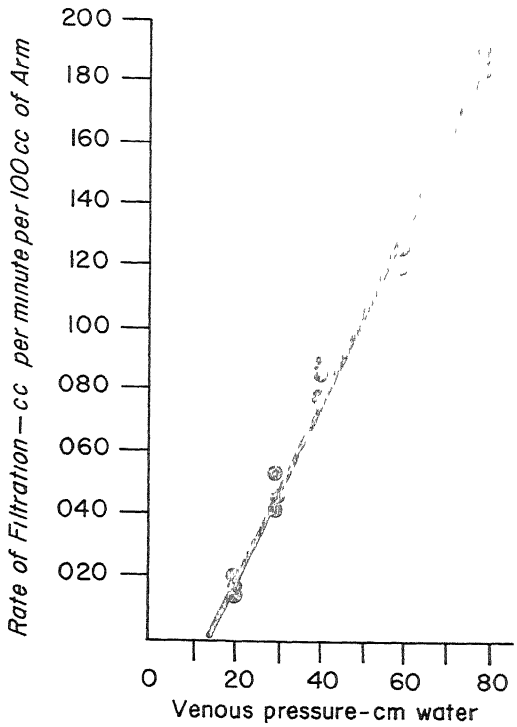

Fig 4 33 Rates of filtration produced during 30 min by venous pressures between 20 and 80 cm of water (After Landis and Gibbon 1933)

Increased pressure in the portal vein or in the hepatic veins, produced for example by obstruction, causes increased filtration into the tissues of the abdominal viscera and a great increase in the volume of lymph flowing through the thoracic duct Increase in arterial pressure, on the other hand, does not increase filtration in animals until the pressure reaches around 300 mm Hg

2) Increase in Capillary Surface area. This increases the leakage of protein and fluid It may follow any change that causes distension of the capillary vessels, e g., *a)* increase in capillary pressure, b) increase in the local temperature, or c) infusion of fluid

3) Increase in Capillary Permeability.

a) Rise in temperature locally may increase capillary permeability

b) Capillary poisons such as peptone increase the flow of lymph from the thoracic duct, probably as a result of its injurious effect upon the abdominal capillaries The increased flow occurs after removal of the liver, so injury to the hepatic vessels is not essential Other substances that increase lymph flow in this way are extracts to strawberries crayfish mussels leeches, histamine, and foreign proteins To what extent this is due to a change in permeability and to what extent it is a consequence of capillary dilation is not known

c) Reduced oxygen supply to the tissues increases lymph flow, probably because of dilation of blood vessels but possibly also through damage to the capillary endothelium

4) Hypertonic Solutions The intravenous injection of a concentrated solution of glucose sodium sulfate, or sodium chloride causes an increased flow of lymph from the thoracic duct These substances in concentrated solution may increase permeability of the capillary wall but also exert an osmotic effect that alters the normal equilibrium between the extravascular and intravascular fluids Water at first enters the plasma from the tissue spaces, particularly of the muscles and subcutaneous tissues of the limbs, which in consequence show a fall in volume, the brain shrinks Thus removal of fluid may actually extend to the fluids within the cells which undergo shrinkage, general desiccation of the tissues may result The blood volume for the time is greatly augmented, the excess fluid for the most part being accommodated in the capacious capillary and venous areas of the abdomen As the electrolyte injected moves out of the plasma and into the interstitial fluid it carries water with it The viscera—liver, kidneys, spleen, and intestines—then increase in volume, due not only to the distention of their vascular beds, but more importantly to the great outpouring of fluid as well as of protein that occurs through the capillary walls This fluid then swells the volume of lymph in the thoracic duct In this way these substances produce a redistribution of fluid

The injection of isotonic saline will also increase the passage of protein and fluid from the capillaries and increase lymph flow This too is probably a consequence of the changes in osmotic and hydrostatic pressures in the capillaries

5) Increased Function Activity. When a gland or muscle enters into activity an increase in lymph flow occurs which starts a little after the commencement of the secretory or contractile response, but is nearly synchronous with the increased metabolism resulting from the activity The increased flow is as-

cribed to *a*) formation of metabolites that increase the osmotic effect of the tissue fluids and cause more fluid to leave the vessels, *b*) vasodilation, with increased capillary pressure and increased fluid and protein leakage

During rest the flow along the lymph vessels of the muscles and subcutaneous tissues is slight, and the protein content of the lymph is high During activity the protein concentrations fall since less transuded water undergoes reabsorption into the blood and more is carried away by the lymph channels This may occur even though the leakage of protein from the vessels is greater The contracting muscles exert a pumping effect upon the lymph driving it along the vessels

6) Massage and Passive Movement. These act to a certain extent like muscular activity They augment the blood flow, capillary pressure, and capillary surface and so increase lymph formation The manipulations and movements of the muscles serve to propel the lymph along the lymphatic channels

Edema

Edema is a term applied to an excessive accumulation of fluids in the tissue spaces, and is due to a disturbance in the mechanisms of fluid interchange, which have been considered in the preceding pages Instead of there being a perfect balance between the inward and outward flow of fluid through the capillary membrane, absorption is exceeded by transudation The particular factor or factors of the mechanism that are disordered are not always clear, and a satisfactory explanation of all forms of edema cannot be given But from previous discussions it is evident that the following factors will tend to increase the volume of interstitial fluid *a*) reduction in the protein concentration of plasma, (edema commences when the albumin fraction has fallen to between 2 5 and 3%), *b*) a general or a local rise in capillary blood pressure, *c*) increased permeability of the capillary membrane, *d*) increase in the filtering surface as when the capillaries dilate, and *e*) obstruction of the lymph channels

There is a tendency for the accumulation of edema fluid to progress so far and then become stationary, provided that the conditions producing it remain constant, for when the tissue fluid pressure reaches a critical level its opposition to the force driving fluid from the vessels prevents further transudation It should be appreciated too that as a source of edema fluid the plasma has definite limitations in a quantitative sense, and unless the total extra cellular fluid is increased a generalized edema cannot be very severe

Since edema is only a symptom of some primary condition it may have a variety of causes, according to the particular disease with which it is associated

1) Cardiac Edema. In congestive heart failure there is both an increase in extracel lular fluid and a salt retention The volume of this extracellular fluid can be reduced by re striction of the salt intake or by the administration of diuretics that remove both water and salt Or it can be discharged by improving cardiac action by digitalis

2) Mechanical Obstruction of Veins When the main veins leading from a part are obstructed by any mechanism, as in cirrhosis of the liver, thrombosis, etc , an increased transudation of fluid occurs This is due in part to the rise in intracapillary pressure and an increase in the filtering surface, but the permeability of the capillary wall may also be increased as a result of the impaired blood supply or, as in the case of tumors, probably by the production of toxic substances as well

3) Edema Due to Renal Disease In chronic nephritis edema is not usually pronounced unless the heart is failing, however, in the nephrotic syndrome it is an outstanding feature In this condition a reduction in plasma protein as a consequence of the loss of protein in the urine leads to the passage of an abnormally large volume of fluid from the capillaries throughout the body This in turn is probably responsible in some way for renal retention of salt and as a consequence of this, retention of water

4) Inflammatory Edema. In this type sev eral factors combine to produce the fluid infiltration of the tissues Increased capillary pressure occurs, due to dilation of the vessels and local slowing of the blood stream as well as to thrombosis and obstruction of the returning veins There is an increase in the filtering surface too, and the lymphatics for a variable distance from the inflammatory area are obstructed as well The capillary walls are also seriously damaged by the bacterial toxin or other injurious agent, so that a fluid with a high protein content escapes from the vessels The edema is localized to an area of varying

extent surrounding the injured site Certain analgesics, e g , aspirin, morphine and Demerol, tend to reduce the edema of simple inflammation

5) **Giant Edema** This is a localized noninflammatory edema that comes on with great rapidity and involves the loose areolar tissue in regions such as the hands face, external genitalia or larynx It has a familial trend Little is known definitely regarding the mode of its production A histamine-like substance liberated at the site of the edema is apparently the immediate cause The remote exciting cause is frequently a foreign protein consumed in the diet, which apparently gains access to the blood stream in a more or less unchanged state, for the attack often follows a particular food to which the subject is susceptible, and is sometimes accompanied by gastrointestinal disturbances The effects are therefore of an anaphylactoid nature and constitute one type of allergy

6) **Edema Caused by Malnutrition or Toxic Substances** Edema may occur in the anemias or in conditions in which the general nutrition of the body suffers When the diet is deficient in vitamins, or there is too little fat or protein in the diet edema may occur, as in beriberi, scurvy, "war edema," or in the faulty nutrition of infants In animals edematous conditions have actually been induced by general underfeeding, or by a diet deficient in fat and soluble vitamins, or by one deficient in protein alone The factors responsible for the increased transudation in these cases are not always clear, but in others there is a marked lowering of plasma protein (more particularly the albumin), which alone is sufficient to account for the edema

Certain chemical substances such as arsenic, salts of heavy metals, and the toxins of certain infectious diseases, such as diphtheria, acute nephritis, etc , are known to act as capillary poisons and apparently cause edema in this way An interesting type of toxic edema is that which may be produced in animals by the injection of hematoporphyrin This substance sensitizes the tissues to ultraviolet rays, and the edema occurs only after the exposure Histamine causes local edema at the point of injection by inducing capillary dilation and increased permeability of the membrane.

7) **Chronic Lymphatic Obstruction.** Widespread obstruction of the lymph vessels may result from congenital or familial disorders of the lymph vessels Lymphedema of the familial type is called Milroy's disease Acquired lymphedema results from obstruction of the lymph channels by neoplasm, scars operative removal of lymph nodes and fibrosis caused by x ray therapy It may also follow a low grade lymphangitis from filariasis from lymphogranuloma venereum or from repeated streptococcal infections The filarial parasite finds its way into the lymph vessels of the limbs and blocks their lumens with the production of the condition known as elephantiasis

Severe edema may occur in the foot and ankle after fracture dislocations, and extensive hemorrhage due to injury to lymphatic capillaries It may be months particularly in older persons, before lymphatic drainage is reestablished Compression bandages enhance lymphatic drainage

For the absorption of fluid the pleural cavities depend upon the lymph channels, the accumulations of fluid may occur here as a result of lymphatic obstruction The edema associated with carcinoma is due chiefly to the filling of the lymphatic channels with cords of cancer cells, as well as to venous obstruction caused by the pressure of the growth The "milk leg" of the puerperium is in part due to lymphatic obstruction The tissue fluid in these types of edema has a relatively high concentration of protein

In the early stages, lymphedema cannot be distinguished from any other form of soft pitting edema On examination of the fluid, the high protein concentration separates it from cardiac and nephritic edema but not from the fluid of myxedema Ultimately, lymphedema causes fibrosis in the tissues, and in time the tissues become hard and brawny The skin may be thick and folded with indulent ulcers

8) **Heat Edema.** The effect of heat upon capillary permeability has been mentioned Excessive heat may actually lead to edema in man It occurs in the tropics and occasionally in so-called temperate zones during intense heat wave It is usually greater in dependent portions of the body Increase in blood volume, enlargement of the filtering surface as a result of the opening up of fresh capillaries, and the rise in capillary pressure incident to the dilation of capillaries previously patent are also factors in the production of this type of edema

10 / LYMPHORETICULAR SYSTEM AND THE LYMPHOCYTE

The lymphoreticular system includes the thymus, lymph nodes, spleen, lymphoid tissue of the alimentary tract, blood and tissue lymphocytes, the bone marrow lymphocytes, and the ceaseless traffic proceeding among these tissues through the blood and lymphatics Rich (1936) stated that ignorance about function of the lymphocyte was disgraceful because pathologists had known for over a century about the presence of lymphocytes in the sites of chronic infections, the large size of lymph nodes during immunization and in the presence of local infections The vast number of lymphocytes in the body indicated a vital albeit unknown function Yet precise knowledge was lacking, and speculation was based on concepts such as possible association of lymphocytes with immunological processes In the interval since Rich's comment, a plethora of techniques has developed for the study of lymphocytes and their relationship to immunity, with the result that knowledge is increasing exponentially Before proceeding to the cellular events connected with immunological processes a discussion of immunological responses and theories of immunity is required

Immunological Responses

TYPES OF RESPONSE

Two general types of immunological responses are recognized

1) The first produces humoral antibodies (immunoglobulins) Classically this type of response has been divided into the *primary response* in which a low but detectible titer of antibody is produced, and the *secondary response* which comes from introduction of the same antigen 2 to 3 weeks later At this time the antigen produces an exponential rise in the serum antibody concentration, and at the cellular level is accompanied by rapid development of germinal centers in lymph nodes and spleen, with intense cellular proliferation (Cottier et al , 1964a) The notion that a primary response represents a first contact with an antigen must be questioned In fact, the idea of a "virgin" immune response is questionable and difficult to rationalize with current thinking Nevertheless, the existence of phenomena called primary and secondary responses is not questioned These phenomena are probably best explained as a result of antigen dosage and timing that determine the number of cells recruited into antibody synthesis

Antibody can be found free in the serum (as well as within cells of all stages of maturation from small lymphocyte to the fully developed plasma cell) Although the appearance of antibodies in high concentration in plasma during the course of an infection had been considered beneficial, the use of antibody-containing antisera in patients with overwhelming infection was disappointing For example, in preantibiotic days it was quite evident that blood cultures became gratifyingly negative after large quantities of antipneumoccocal sera were given intravenously to patients with lobar pneumonia Alas, the patients frequently died This lack of therapeutic benefit has been attributed to the fact that in pneumonia large areas of the lung are "consolidated," with relatively little circulation through the affected region In addition, the immunoglobulins are large molecules and will not diffuse through the capillary endothelium unless there is a marked inflammatory response When they are released directly into the tissues, by contrast, the diffusion distances will be short It has been proposed that a major function of those cells that contain antibodies is the transport of specific antibody by migration of cells to anatomic sites where antibody is needed and to which it can not diffuse readily as a large molecule (Hall, 1969)

2) The second type of immunological response is mediated by cells, serum antibody is apparently incidental In these reactions, cells

of a lymphocytic family develop as part of an immunological reaction, later make direct contact with the antigenic material and then in various ways lead to its destruction or rejection. Examples are delayed hypersensitivity, allograft rejection and immunological surveillance for mutant cells (cancer, autoimmune clones, etc.) harmful to the host.

Humoral and all types of cellular immunity involve recognition of antigen by cells, followed by cellular differentiation and proliferation to amplify the reaction. The lymphocytes are unquestionally involved and in the center of immune responses. An understanding of the migration pathways, lifespan, proliferation rates, pool sizes and fluxes of lymphocytes between blood and the diverse tissues and the factors regulating the population size of these pools is crucial to an understanding of humoral and cellular immunity.

THEORIES OF THE CELLULAR BASIS OF IMMUNE RESPONSE

The instructive theory of antibody formation assumes that there are cells capable of responding to a huge variety of antigenic substances by differentiation and proliferation that produce a family of cells that synthesize the antibody complementary to the antigen. This view is called "instructive" because it postulates that the antigen is providing the cells with information and instructs them to produce the particular antibody. The concept can be presented, not in terms of a "template" idea (Pauling, 1940), but rather in molecular biological parlance. Thus, the antigen may be derepressing the genomes carrying the code for the immunoglobulin complementary to the antigen. The code is transcribed. The messenger-ribonucleic acid (m-RNA) passes into the cytoplasm and its message is translated into the antibody by the protein synthesizing machinery. This concept requires that all lymphocytes be able to respond to any antigen, this, however, does not appear to be compatible with the present information.

A second theory of antibody production is the *clonal selection theory* (Burnet, 1959). This theory envisions that during cell replication there develops a population of progenitor cells heterogeneous in respect to their capacity to respond to various antigens. This heterogeneity is believed to arise from somatic mutations, which affect the cellular genomes so that each member of the clone can respond to a specific antigen. This heterogeneity is assumed to develop by mutation without the intervention of a specific antigen.

A conservative but not established system to explain immunological behavior might embrace the following features. The antigen must be recognized. The simplest method for cellular recognition of antigen seems to be the possession of a coating of complementary antibody to trap the antigen as it passes by the cell, or to trap the cell as it passes by the antigen deposit. Immunoglobulin coating of some lymphocytes from splenic, lymph nodes, bone marrow, and blood (but not thymic lymphocytes) has been shown (Ratt et al., 1970; Rabellino et al., 1970). Since all proteins and other molecular constituents of cells except deoxyribonucleic acid (DNA) are in a steady state of molecular turnover, it follows that these cells must be synthesizing antibody albeit very slowly. Therefore, it is only necessary to amplify the rate of synthesis of antibody at the cell level. To do so this cell must synthesize more protein for which more mitochondria, m-RNA, transfer (t)-RNA and ribosomes are needed. Their rate of energy exchange becomes greater. The cells hypertrophy (differentiate and transform) which in accordance with the "critical mass" concept[1] (Mazia, 1956, Johnson, 1969) leads to mitosis and amplification by increased cell numbers.

In terms of the preceding notions one can visualize the primary antibody response as follows. A few cells with little antibody trap a little antigen and their protein machinery is stimulated a little. Although there is short term proliferation of cells the process does not continue so as to yield a steep exponential increase. Only a low titer of antibody results. While the preceding continues, antigen is being degraded. Such a mechanism would appear to have a threshold, such that tiny amounts of antigen would not produce a detectible effect.

When the second antigenic stimulus is applied the amount of antibody per cell and the number of cells are greater. More antigen is trapped, and thus, the stimulus for antibody

[1] This concept says cells divide when they become too large and inefficient machines and implies that regulation of cell division is controlled by an internal cell feedback loop and not through feedback loops external to the cell.

synthesis and the concomitant proliferation is greater The stimulated cells expand exponentially now on the steep part of the curve Germinal centers "blow up" Exponential increases in antibody titer are observed with a steeper slope A natural concomitant of such a system must be a built in negative feedback mechanism that somehow turns off the multiplication processes A large number of cells do migrate into the gut, as will be discussed later

The modified instructive theory described above predicts that cells could respond to separate antigens and produce more than one antibody, whereas, the clonal selection theory predicts that the antibody produced by each clone should have a specificity for its antigen Some cells have been found producing two different kinds of antibody It appears, therefore, that neither the clonal selection theory nor the modified instructive concept is exclusively correct, and that some combination of the two will prove to be needed

IMMUNOLOGICAL UNRESPONSIVENESS, PARALYSIS, TOLERANCE

Although antigen is accepted as one of the prime regulators of antibody synthesis, the usual response of transformation and proliferation of cells producing the specific antibody does not always occur A second type of response is possible in which no immunological reaction is observed, at least for a period of time after introduction of the antigen there is no antibody production This *immunological paralysis* is achieved only under special circumstances by the use of very large doses of antigen (Felton, 1949)

In newborn animals and the fetus the failure to respond has been observed following the administration of many different kinds of antigen, including homologous cells and foreign proteins This is called *actively acquired immunological tolerance* (Billingham et al , 1954)

A potentially clinically important aspect is the induction of tolerance to tissues with histocompatibility differences If tolerance is induced in a newborn mouse by the injection of spleen cells from a different strain of animal, the injected animal becomes tolerant When it becomes an adult it will accept skin grafts from animals of the strain from which the cells were originally obtained The tolerance to these skin grafts is specific, because the recipient animal rejects grafts obtained from mice of a third, unrelated, strain A thorough understanding of tolerance might lead to mechanisms by which transplantation of organs could be accomplished with impunity

THE THYMUS IN IMMUNITY

Current thinking relates the thymus to the development of the cellular immunity shown in allograft rejection and antibody formation via the concept that its cells are derived from the mammalian equivalent of the lymphoid bursa in birds (Meuwissen et al , 1969) Although this is an attractive hypothesis there is no clearcut evidence for the existence in mammals of an equivalent of the bursa of Fabricius in birds For the time being an open mind on the subject is required

Thymectomy of the newborn mouse originally led to the notion that the thymus is essential for the development of immune responses, since in initial studies the mouse thymectomized at birth accepted skin grafts from unrelated mice and often failed to respond to antigen with the production of circulating antibody (Miller et al, 1962) However, in repetition of these studies on pathogen-free animals (Hess et al , 1963) or the germ-free animal (Miller 1967), removal of the thymus did not suppress humoral or cellular immunity, and the animals responded normally to antigens and rejected the skin grafts (Hess et al , 1963) No one questions the fact that the thymus is related to immunity, but its precise role is not yet clearly established Thymectomy in the adult diminishes the lymphocyte count in the blood and output of thoracic duct lymphocytes, but has little influence on immune process Perhaps the sole function of the thymus is the production of vast numbers of lymphocytes

Lymphocytes

The lymphocytes occupy a central position in humoral and cellular immunity and as such their characteristics and behavior are essential to an understanding of these phenomena

HETEROGENEITY OF LYMPHOCYTES

The lymphocytes constitute a family of cells of different tissue origins, migration patterns, size, staining characteristics, ultrastructure, lifespan, and function Thoracic duct lymphocytes consist of two overlapping populations on the basis of volume (Sipe et al , 1966) The

smaller cell has a median volume of 270 μm³ and the larger median volume of 645 μm³. Morphologically the *small lymphocytes* are relatively featureless, consisting of a compact nucleus with a nucleolus and cytoplasm containing a Golgi apparatus, a few mitochondria, ribosomes and a poorly developed endoplasmic reticulum. The small lymphocytes appear to be metabolically relatively inactive. The *larger lymphocytes* have more numerous ribosomes and in some instances have polyribosomes with a rapidly developing endoplasmic reticulum. There are all gradations between these cells and mature *plasma cells* that contain an exceptionally well-organized endoplasmic reticulum to which are attached innumerable ribosomes (Fig. 4-34). The plasma cells thus possess the full efficient apparatus for protein synthesis. All stages of lymphocytes ranging from the small featureless cell to the characteristic plasma cell synthesize protein and specific antibodies.

The lifespan of lymphocytes varies from a few hours to years. By continuous infusion of tritiated thymidine into animals to label each lymphocyte as it is born, it has been shown in rats that the class of smaller lymphocytes has a median survival time of about 1 month while 5 to 8% had lifespans greater than 9 months (Robinson et al., 1965). The larger lymphocytes also are divided into cells with lifespans of the order of 1 to 2 days and others with a maximum lifespan of about 60 days (Little et al., 1962). It has been suggested that lymphocytes in human females have a mean lifespan of 530 ± 64 days (Norman et al., 1965). The long lived lymphocytes are believed to be immunologically committed and to serve as a basis for immunological memory (Fitzgerald 1964, Gowans and Uhr, 1966). The long lived cells are produced at a rate proportional to body growth, and recirculate from the blood to lymph (Everett et al., 1964). Heterogeneity of function will be discussed later.

THE GENERATIVE CYCLE OF LYMPHOCYTES

Methods described in Chapter 2, using tritiated thymidine labeling of DNA and observation of the flow of cells through mitosis, have revealed many parameters of the cell cycle of lymphocytes. In the rat spleen, the lymphatic nodules exhibit a DNA synthesis time of 5 hr, a minimum [illegible] hr, with a maximum of 2 hr, and a generation time of 10 hr. It appears that almost [illegible] of the germinal center cells are in cycle although only 1 to 2% of the cells in the mantle zone surrounding the germinal center are in cycle. About 45% of the mantle cells probably are in G₀ state (Fliedner et al., 1964c). Using lymphocytes from the thoracic duct of rodents a systematic study has shown that the generation time is about 5 to 6 hr, with a DNA synthesis time of 4 hr and a mitotic time of about 15 min (Sainer et al., 1967). Lymphocytes have the shortest cell cycle of mammalian cells.

During antigenic stimulus the time that it takes for a population of cells to double in number is about 24 hr (Cabalbo and Makinodan, 1964). Since this doubling time is substantially longer, than the generation time described above it appears that there is some death of lymphocytes during antigenic stimulation since the doubling time and the generation time are equal only if all of the labeled cells divide and there is no death of the progeny.

Studies on lymphocyte production shows that 0.5 to 2.7% of the DNA of rodent lymphoid tissue is renewed per hour in lymph nodes and the thymus (Schooley, 1964). It is easy to measure by DNA labeling the number of cells emerging from the thoracic duct and the fraction of these that are newly produced. It is still very difficult, however, to get any realistic estimate of the absolute production rate of new lymphocytes in all of the different lymphocytic organs. There are too many uncertainties in determining the migration pattern, the fraction of cells that are recycling from blood to lymph, the reutilization of DNA labeling materials, and the possibility of death of cells from antigenic or other stimuli.

Under normal conditions the mass of the adult lymphoreticular system is relatively constant, implying that there is a balance between the production and death of cells produced in response to some small constant input of antigens absorbed from the gastrointestinal tract, from the skin or elsewhere. One can determine the number of newly produced lymphocytes that leave a single lymph node by combining efferent duct cannulation with arterial perfusion using tritiated thymidine in order to label the DNA of all new cells. The absolute production can be determined from the replacement

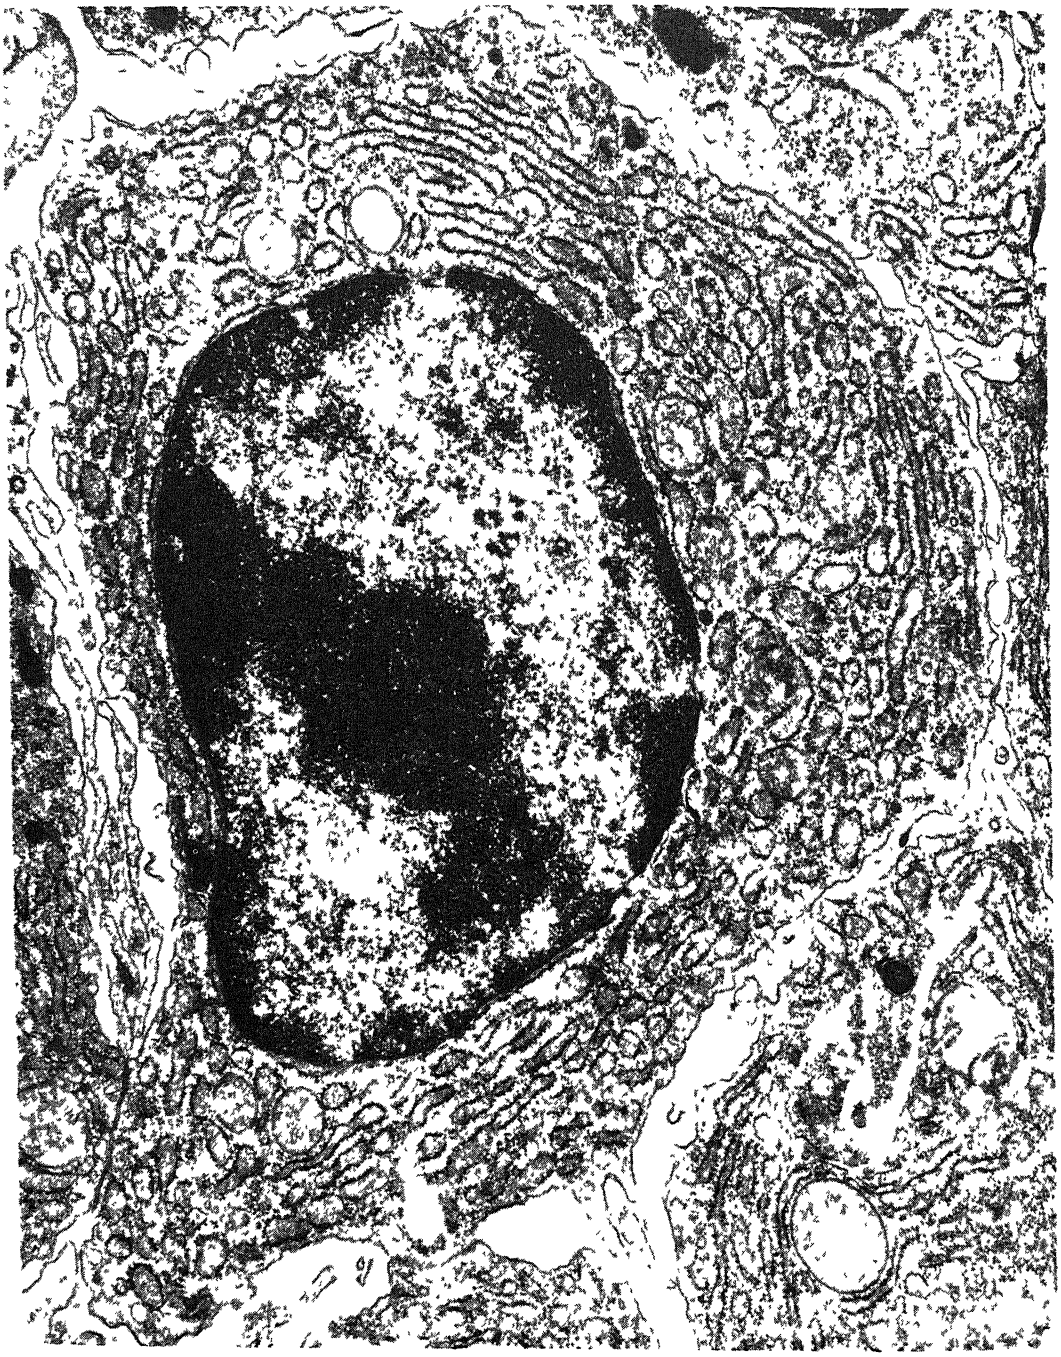

Fig 4.34 This is an electronmicrograph of a human plasma cell obtained by marrow aspiration The cytoplasm contains a well developed endoplasmic reticulum to which are attached ribosomes Magnification × 24 000 (Picture courtesy of Dr A F Howatson Preparation by Miss M Nagai)

of unlabeled by labeled DNA per unit time divided by the average DNA per cell, plus the number of labeled cells leaving the node The replacement of unlabeled by labeled DNA in the steady state represents the intranodal cellular death rate of cells produced in the node Imperfect knowledge of lymphopoiesis, however, prevents an accurate assessment of the

absolute production rates that can be determined for erythropoiesis and granulopoiesis

RECIRCULATION OF LYMPHOCYTES AND MIGRATION PATHWAYS

Examination of lymph from the thoracic duct in several mammalian species has shown that the output of lymphocytes is sufficient to replace all of those in the circulating blood several times daily (Drinker and Yoffey, 1941) The actual number of cells that enter the blood from the thoracic duct each day is very large, of the order of 10^9 in the rat and proportionately more in larger animals In the steady state whatever number of cells enters the blood must either be destroyed, migrate elsewhere, or recycle from the blood to the lymph and back again Two techniques have made possible the solution of this problem First, a technique for collecting lymph from the thoracic duct of unanesthetized rats over long periods was developed (Bollman et al, 1948) Second, tritiated thymidine and other pyrimidines were introduced into the study of cell kinetics in mammals (Hughes et al, 1958) and into the study of lymphopoietic tissue (Cronkite et al, 1959) The combination of these two procedures provided the answer that most of the turnover of lymphocytes is more apparent than real, since the same lymphocytes continuously recycle from blood to lymph through the postcapillary venule[2] of the lymph node, and then are swept back into the lymph as it filters through the sinuses of lymph nodes (Gowans, 1957, 1959, Everett et al, 1964, Gowans and Knight, 1964) The route of the migration of the lymphocytes through the postcapillary venules is believed to be through the high endothelial cells (Marchesi and Gowans, 1964) However, lymphocytes also proceed between endothelial cells (Smith et al, 1970), like granulocytes and monocytes Whether this endothelial transit is unique can be questioned since red cells also proceed through the endothelial cell under some circumstances (Johnson et al, 1966) In addition endothelial cells are phagocytic at times and actively engaged in pinocytosis

Much is now known about the migration pathways of the ubiquitous lymphocyte (Fig 4 35) The old concept that there is a major migration stream of small lymphocytes from the blood to the marrow, accounting for the daily replacement factor (DRF), and that these migrants are transformed and serve as stem cells (Yoffey and Courtice 1956) is not now accepted On the contrary, there is no doubt about a substantial proliferation of lymphocytes within the bone marrow and their migration into the blood (Osmond and Everett, 1964 Everett and Caffrey, 1967) The evidence for proliferation of small lymphocytes in the marrow is unequivocal even though the nature of the precursor cell is not clear It is conceivable that the small lymphocyte is in a long G_1 or G_0 phase and undergoes transformation and proliferation The large scale intramedullary production of lymphocytes as well as the minor migration of lymphocytes into the marrow demands either a large scale intramedullary death or else a migration of cells out of the marrow to maintain steady-state conditions Lymphocytes have been seen migrating between the sinusoidal endothelial cells of the marrow (Hudson and Yoffey, 1966) Elegant studies on marrow transplantation using chromosome markers have shown that the bone marrow contains cells capable of repopulating the aplastic thymus, spleen, lymph nodes, and the bone marrow of otherwise fatally irradiated mice (Ford et al, 1956) This depends upon a slow migration of cells that takes several weeks to achieve complete regeneration of hematopoietic tissues The migration rate of marrow lymphocytes under steady-state conditions in the adult has not been established There is also some evidence that bone marrow derived cells are the precursors of antibody-synthesizing cells (Miller, 1967, Mitchell and Miller, 1968, McGregor, 1968)

The evidence for migration of cells out of the thymus during fetal life and in the newborn mouse is likewise unequivocal (Michalke et al, 1969) The lymphocytes leave the thymus both by lymphatics and by blood vessels (Kotani et al, 1966, Iorio et al, 1970) They migrate as shown in Figure 4 36, becoming concentrated first in the spleen at the marginal zone as illustrated in Figure 4 17 of Chapter 3 Apparently the lymphocytes flow at the periphery of the blood in the central arteriole of the white pulp Plasma rich in lymphocytes is skimmed out into the small branches penetrating to the marginal zone (Weiss, 1962), where the labeled

[2] An anatomically characteristic venule with cuboidal endothelium located in paracortex of lymph nodes and seen in tonsils and Peyer's patch Lymphocytes migrate through the wall of this vessel

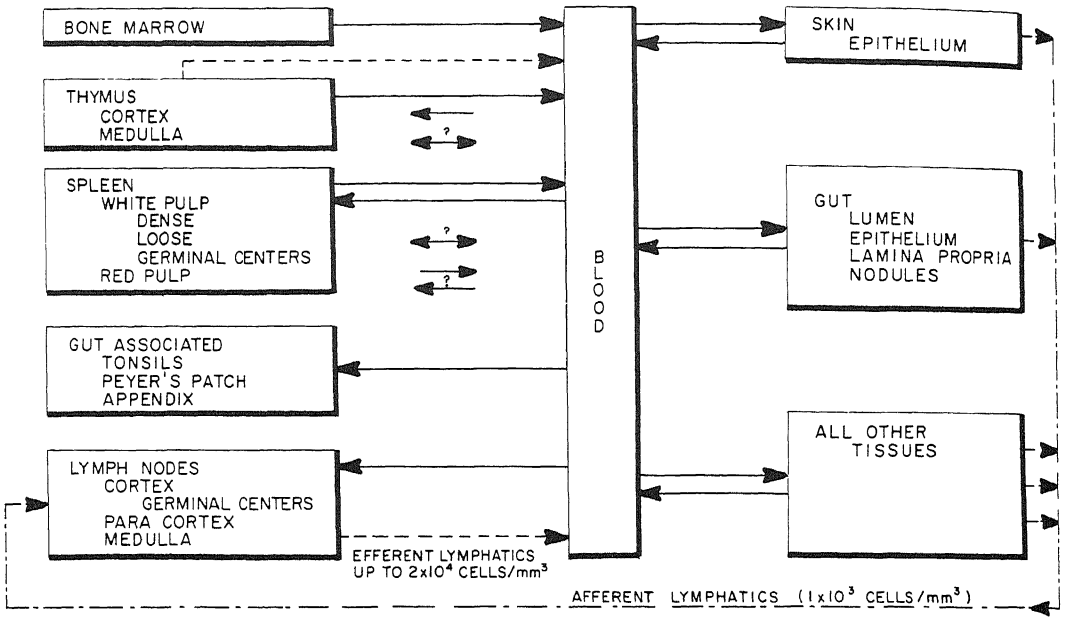

Fig 4 35 The ubiquitous lymphocyte and its exchanges with blood and tissues

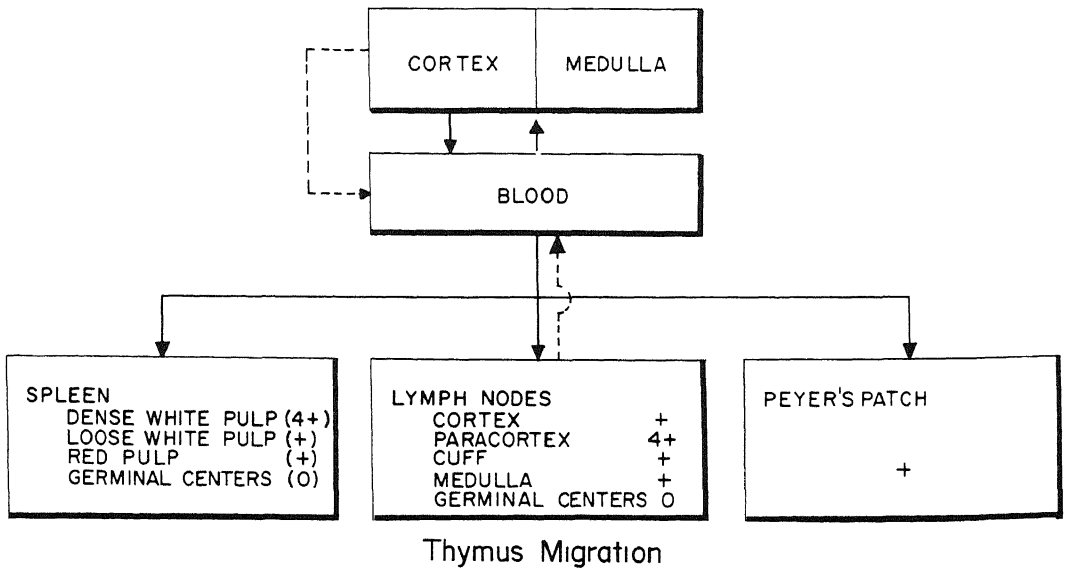

Fig 4 36 Schematic routes of migration of thymic cells showing sites of relative concentrations in the tissues and the return to the corticomedullary junction

lymphocytes are first seen From there they migrate into the periarteriolar lymphoid sheath, then move towards and concentrate around the central arteriole of the white pulp (Goldschneider and McGregor, 1968, Ford, 1969) from which they enter the blood by an undisclosed route The spleen contains no blood vessels similar to the postcapillary venules of lymph nodes

The migration of lymphocytes out of the blood is not exclusively through the endothelium of the postcapillary venules since many cells are also found moving in between the endothelial cells After the cells leave the ven-

ules they pass through gaps in the walls of the lymphatic capillaries and are swept off in the lymph stream The mechanism that directs this large scale, recycling traffic through the endothelium of the postcapillary venules is not understood It has been shown, however that treatment of lymphocytes with trypsin and neuramidase prevents the entry of lymphocytes into the lymph nodes but does not influence their migration into the spleen (Woodruff and Gesner, 1968) These observations suggest that sialic acid plays an essential role in allowing the cells to migrate through the postcapillary endothelium

Although the paracortical areas of the lymph node and the dense white pulp of the spleen have been defined as thymus dependent areas (Parrott et al, 1966), this concept can be questioned Long term studies on the migration of labeled thymic lymphocytes show that these cells "home" not only on the so-called thymic dependent areas but also migrate out into the red pulp, the outer cortex of the lymph nodes and into the medulla An occasional thymic cell migrates back to the thymus in the region of the corticomedullary junction These cells appear to be short lived or else divide rapidly, since none was found in the tissues 96 hr after termination of the study of Iorio et al, (1970)

There is a considerable production of lymphocytes in the spleen Moreover, lymphocytes recycle through the spleen at a rate proportional to their concentration in blood, with a minimum transit time through the spleen of about 2 to 3 hr The route of migration involves the trapping of lymphocytes in the marginal zone from which they enter the white pulp Labeled lymphocytes are first seen in the marginal zone, later in the dense white pulp of the periarteriolar sheath, and then concentrated around the central arteriole and later in the red pulp The lymphocytes that recycle through the spleen can also recycle through the lymph nodes There is also a well-established recycling of lymphocytes through postcapillary venules in the Peyer's patches of the gut A substantial production of lymphocytes occurs in the gut-associated lymphoid tissue with some newly formed cells entering the blood in addition to the recycling There is also a continual migration of lymphocytes into the lumen of the gut (Kotani, et al, 1967) By cannulating afferent lymphatics one can determine that there is a continual flow of lymphocytes from the blood through the interstitial tissue and back into the lymph nodes although the concentration of lymphocytes in normal afferent lymph is very low compared to efferent lymph

If the efferent lymphatic of a single lymph node is cannulated and drained continually the anatomic structure of the lymph node remains the same (Hall and Morris, 1962) These results indicate that the efferent small lymphocytes are recycling through the node from elsewhere in the body and that the large cells produced within the node continue to be produced at the same rate despite their loss from the body

Considerable information has been obtained on the size of lymphocyte pools and the kinetics of their depletion by prolonged drainage of lymph from the body or by extracorporeal irradiation of the blood or lymph In the latter technique either blood or lymph is diverted through a radiation source that delivers a dose sufficiently high to kill the lymphocytes Following their return to the circulatory system they are removed from the circulation and destroyed During depletion studies the thymic cortex is diminished in thickness, and the corticomedullary ratio is decreased Splenic lymph follicles are markedly decreased in size as a result of a loss of small lymphocytes from the cuffs surrounding the germinal centers and there is also a remarkable loss of lymphocytes from the less densely populated areas of white pulp, as well as from the red pulp The germinal centers in the spleen and lymph nodes are intact There is a striking diminution in the population of the paracortical areas of the lymph node and relatively little change in the outer cortex From these studies it has been concluded that lymphocytes in the outer cortex of the lymph node are relatively tightly fixed and mobilized slowly, whereas, the lymphocytes of the paracortical area are mobilized easily (Cottier et al, 1964b, Ruchti et al, 1970) In the rat the mobilizable lymphocyte pool is approximately 7.8×10^9 cells per kilograms of body weight (Caffrey et al, 1962) In the calf the lymphocyte depletion process consists of two exponential components The first component represents a pool of readily accessible lymphocytes that are mobilized with a half time of about 1.2 days The average size of this compartment is about 4.8×10^9 small lympho-

cytes per kilogram (Schnappauf and Schnappauf, 1968, Cronkite et al, 1968) The half time of depletion for the less accessible lymphocyte pool is of the order of 30 days Repletion of the lymphocyte pools follow also a two-component pattern One is relatively rapid and takes place in a few days, whereas, in some animals it has taken over a year for blood lymphocytes fully to attain predepletion levels A schematic presentation of the flow rate of lymphocytes from blood to tissues to lymph nodes based on studies in the calf is shown in Figure 4 37

The injection of complete Freund's adjuvant[3] subcutaneously produces a granuloma having blood vessels resembling postcapillary venules, and sustaining a flow of small lymphocytes in the draining lymphatic about equivalent to that of a lymph node of the same size (Morris, 1968) Regional antigenic stimulation of a lymph node induces transformation and proliferation of lymphocytes that can be seen flowing into the efferent lymph of the stimulated node These cells are secreting antibody and have a well-developed endoplasmic reticulum (Hall et al, 1967) The presumption is that these cells migrate into the tissues and complete differentiation into plasma cells If these lymphocytes are diverted from the body, the immune response is limited to the lymph node But, if they are returned to blood the immune response becomes generalized, thus, proving that the obligatory exit from lymph nodes is through the efferent lymphatics

Even though the cells that emerge from the lymph nodes via the efferent lymphatics after a local antigenic stimulus are antibody synthesizing cells, there remains some controversy as to their origin A concept now in vogue states that they originate in bone marrow, and come to reside in the outer cortex of lymph nodes There is an antigen-reactive cell believed to be thymic in origin (Mitchell and Miller, 1968)

CELLULAR IMMUNITY (DELAYED TYPE HYPERSENSITIVITY, ALLOGRAFT REJECTION AND IMMUNE SURVEILLANCE)

Immune responses can be transferred between genetically identical animals by the transfer of splenic, lymph node, blood, or thoracic duct lymphocytes from the sensitized animal to the nonsensitized animal The pioneering discovery of this phenomenon arose from the classic studies of Landsteiner and Chase's transfer (1942) of delayed cellular hypersensitivity by transfer of cells from the guinea pig This simple observation clearly separated cellular from serum antibody responses and provided an immunological test for analysis of the mechanisms of cellular immunity Living cells were required for the transfer, and the transfer was short lived between unrelated animals because the living cells were rejected In human beings it was possible to transfer delayed cutaneous hypersensitivity by a dialyzable extract of sensitized lymphocytes called the *transfer factor* (Lawrence, 1955) The transfer factor is specific for the antigen that originally sensitized the cells The factor is dialyzable, has a molecular weight of less than 10,000, and is nonantigenic It appears to be a polypeptide-polynucleotide, heat labile at 56° C It converts normal lymphocytes in vitro and in vivo to a specific antigen-responsive state These cells when confronted with antigen transform and proliferate (Lawrence and Valentine, 1970) In addition to delayed cutaneous hypersensitivity transfer factor can transfer allograft sensitivity

When transfer factor is added to lymphocytes in the presence of antigen another material is liberated called *lymphocyte transforming factor* (LTF) that is not dialyzable and distinct from histocompatibility antigens It functions as a "recruiting agent" for nonsensitive lymphocytes Ordinarily, only a very small fraction of lymphocytes become sensitized to a specific antigen When this antigen is reintroduced, there is a transformation and proliferation of the sensitive cells with an increase in the number of cells It is conceivable that the transfer factor and lymphocyte transforming factor are released in vivo and recruit additional nonsensitive cells that can then be engaged by the antigen and so further amplify or escalate the intensity of the immunological response

MIGRATION INHIBITORY FACTOR (MIF)

This factor inhibits the migration of macrophages It was discovered by Bloom and Bennett (1966) and David (1966) The material is released from sensitized lymphocytes by the specific antigen that produced the hypersensi-

[3] Freund's adjuvant is a mixture of mineral oil and an emulsifying agent, it is used as a vehicle for suspension of antigens to be injected subcutaneously

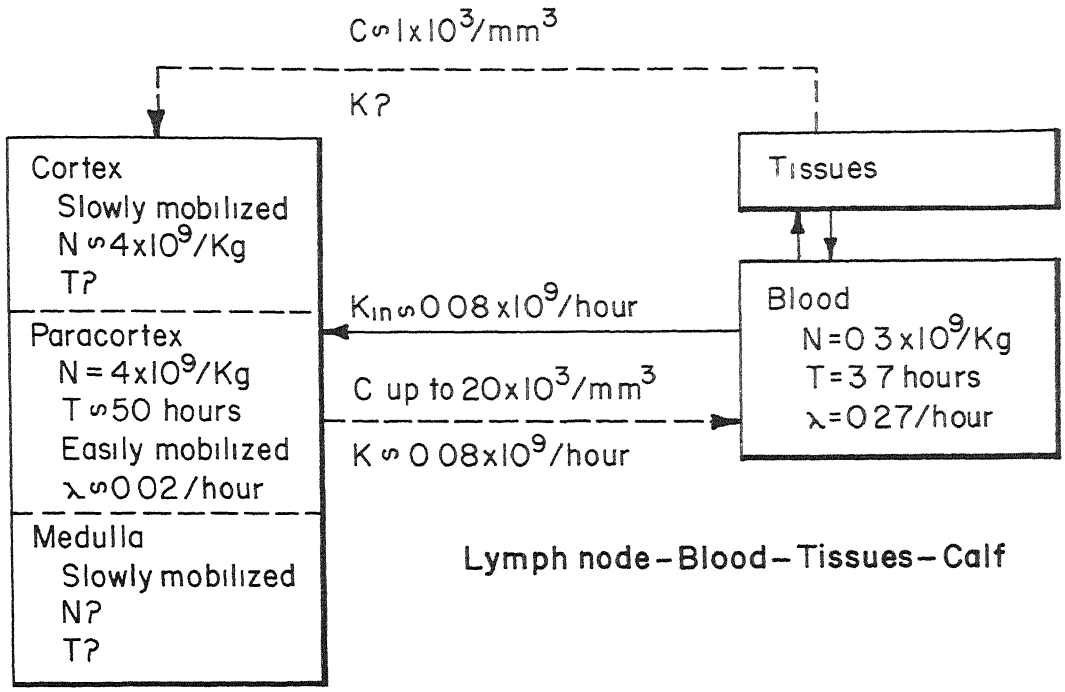

Fig 4 37 Schematic presentation of the flow of lymphocytes from blood to tissues to lymph nodes with estimates of time fluxes and sizes where data are available from experiments on calves N number/kg body T average time in compartment λ fractional turnover/hr K flux (number/hr/kg) C concentration numbers/mm³

tivity reaction Thus, it serves to retain macrophages at area of immunological action where they can attack and destroy the offensive material The detailed properties of MIF are reviewed by Bloom and Jimenez (1970)

LYMPHOTOXIN

This material is released from the lymphocytes following an interaction with the target cell on antigen, or after treatment of lymphocytes with agents inducing transformation such as phytohemaglutinin (PHA) It is difficult to study this reaction in vivo It can be envisioned, however, that whenever a lymphocyte carrying antibody is trapped by the specific antigen this lymphocyte may die and/or release its load of lymphotoxin, and thus, intensify local necrosis This substance may be a major effector in delayed sensitivity and allograft rejection (Granger, 1970)

The Immunological Response, Its Initiation, Perpetuation, and Suppression

The probable sequence of events in immune responses is shown in Figure 4 38 in a diagram that begins at the *allograft* Antigen seems to be transported from the allograft to the regional lymph node either by cells, possibly macrophages, or in solution through the afferent lymphatics Within the lymph node the antigen reactive and antibody synthesizing cells interact in a manner not well understood Cells are triggered into cell cycle from a G_0 stage, undergo hypertrophy as described earlier, and ultimately enter the proliferative cycle and divide In the process of repetitive divisions their protein synthesizing machinery continues to develop and they take on characteristic appearance of intensely basophilic cells with varying degrees of endoplasmic reticulum After 3 to 5 days of proliferation, cells commence to make their exit through the efferent lymphatic and proceed into the blood where they become metastasized through the lymphoreticular tissues, where they set up secondary foci if engaged again by new antigen These cells entering the blood have a large complement of cell bound antibody, and some cytotoxic antibody appears in the serum It can be supposed that as lymphocytes proceed through the allograft that antigen is recognized, and cells are directed out of the blood

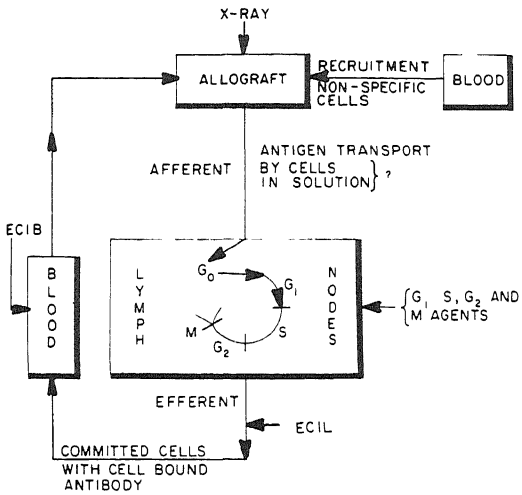

Fig 4 38 Schematic presentation of the role of lymphopoietic proliferation and migration in allograft rejection indicating the sites of attack by radiation and chemical to attain immunosuppression

stream into the allograft Following the entry of even a very few specifically immune lymphocytes, a series of events is initiated First, the cells release transfer factor and lymphocyte transforming factor, which as discussed earlier are believed to be capable of recruiting nonsensitized lymphocytes Upon contact with a specific antigen the cells also release lymphotoxin and migration inhibitory factor The lymphotoxin will set up an inflammatory reaction through death of the cells, which will further attract by chemotactic influences granulocytes and macrophages into the allograft The macophages will be immobilized by the migration inhibitory factor The two phagocytic cell types probably commence cleaning up the necrosis by phagocytosis of debris, and also escalate the inflammatory response by release of their lysosomal enzymes when they in turn are destroyed This outline of what might be happening is different from classical accounts of the reactions, in that here the cell bound antibody is relegated to a position of recognition and not primary destruction A similar sequence of events can be visualized as occurring during cutaneous delayed hypersensitivity if one considers the sensitized cells to be antigenically abnormal, and thus, requiring identification and destruction.

The concept of immunological surveillance of antigenically altered somatic cells has been extended to cancer It is believed, although not conclusively proved, that somatic mutations taking place at random result in an antigenically different cell that can be identified Consequently, the entire sequence of events described above is set into motion to remove this neoplastic cell When the individual either becomes tolerant or when immunological reactivity is suppressed for one reason or another, the tumors grow Whether this hypothesis is valid is not yet known, but it seems plausible and may lead the way to more effective cancer therapy

The notion that nonsensitive lymphocytes are recruited into a specific immunological reaction is enhanced by the studies of Pedersen and Morris (1970) who have shown that the entire immunological sequence of kidney rejection can take place inside of the graft without the help of the regional lymph node They did this by cannulating the lymphatics from a kidney and collecting all of the transformed cells in the lymph

By referring to Figure 4 38, one can also identify the means by which one can launch an attack against the immune response Starting at the lymph node one sees that chemical agents directed at any subdivision of the mitotic cycle may act by destroying cells in that phase For example, as cells emerge from a lymph node via the efferent lymph they can be irradiated to kill the cells, when anatomical relations are such as to make this possible (Chanana et al , 1969) Similarly, the blood can be irradiated to kill that portion of the cells that go through an extracorporeal irradiation shunt One can also irradiate the graft, killing the lymphocytes and other cells that have been recruited into the graft Nevertheless, the relatively poor success of these types of immunosuppression stems from the fact that in suppressing transformation and proliferation of the immunologically committed cells one also produces injury that may be lethal to the bone marrow and epithelial structures

HISTOCOMPATIBILITY ANTIGENS

These antigens (HL-A) are responsible for stimulating an immune response against a transplanted organ or tissue Because the histocompatibility alloantigens reside on cell

membranes they are becoming useful in the study of the surfaces of cells. In the mouse these antigens are glycoproteins. Progress is being made in determination of the amino acid composition, secondary and tertiary structure. Details of structure, experimental approaches and use of histocompatibility antigens has been the subject of a recent symposium (Amos 1970).

CELL MEDIATED IMMUNITY

This is a form of nonhumoral immunity involving *macrophages*. When the macrophage comes into contact with the specific antigen such as tubercle bacillus it becomes activated. The activated macrophage is larger and more complex morphologically and when transferred to glass, it spreads. It also has very active phagocytosis and an increased content of acid hydrolases, and actively proliferates. Its precursor is the blood monocyte. Although this type of cellular immunity persists for the duration of an infection, it is relatively short lived after the infection is over. The immunity is both specific and nonspecific in that when induced by one organism the macrophages throughout the body develop increased activity towards other unrelated organisms. As animals recover from infection their nonspecific resistance does disappear, but they remain resistant to the original infection and express the immunity in part, for example, by the tuberculin skin test, a delayed hypersensitivity. Living lymphocytes from convalescent donors are able to transfer this type of cell mediated immunity. It is exceptionally important in combatting tuberculosis, brucellosis, listeriosis, and other infections. Cell mediated immunity was reviewed by Mackaness (1970).

IMMUNOGLOBULINS

A common characteristic of all types of immunoglobulin is that they may carry antibody activity and that all have the same general 4-peptide chain structure. Two central "heavy" chains are connected by a disulfide bond, and a "light" chain is connected to each of the heavy chains by a disulfide bond. The light and the heavy refer to molecular weights. The immunoglobulins have a bewildering number of synonyms, and are now classified into IgG (*γ globulin*), IgM (*macroglobulin*), and IgA. In human serum the relative amounts are 71%, 7%, and 22%, respectively. Antigenically

[illegible] called. The approximate molecular weights are IgG [illegible], IgM [illegible], and IgA [illegible]. However IgA [illegible] and may have a considerable [illegible] molecular weight [illegible] the [illegible] IgA contain [illegible] IgM [illegible] and IgA [illegible]. The [illegible] and more complex [illegible] rapidly exceed the [illegible] the scope of this discussion.

There are genetically determined variants of particular subclasses of heavy chain or light chain that occur among members of a species. These markers are called allotypes and are useful in genetic studies in man and animals.

IgG is often designated as 7S γ-globulin with reference to the Svedberg sedimentation units, the IgM type as 19S γ-globulin. The light chains from the immunoglobulins of any one individual have the same amino acid composition, molecular weight, electrophoretic mobility, and antigenic specificity. The heavy chains of the three classes are distinct and different in all four of the preceding properties. For details of structure in relation to function see reviews by Deutsch and Fudenberg (1969), Franklin and Frangione (1969), and Cebra (1969).

A newborn infant is relatively speaking immunologically undeveloped, susceptible to bacterial infections that are not pathogenic in older children or adults. Some of the antibodies in the plasma of the newborn infant are acquired by transfer from the maternal circulation. Thus the infant at birth is relatively well endowed with IgG from its mother. Very little IgM or IgA is transferred from the mother. IgA is closely related to defense against intestinal organisms, and the deficiency of this fraction explains in part why the newborn infant is susceptible to Gram negative infections. Infants degrade the maternally transferred IgG relatively rapidly so that practically none exists by 10 weeks of age. In about the 4th to 5th week of age, infants commence synthesizing their own IgG and other immunoglobulins, and by 12 months of age have plasma concentration nearly equal to that of the adult.

Multiple myeloma is an abberation in which there is increased synthesis of abnormal immunoglobulins. Any of the immunoglobulin types may be involved. The Bence Jones protein found in the urine of multiple myeloma

patients has been shown to be the light chain. The bone marrow characteristically shows an infiltration with myeloma cells that resemble plasma cells of varying degrees of immaturity. There is a high concentration of γglobulin in the blood: the disease is fatal.

DISEASES DUE TO IMMUNOLOGICAL DEFICIENCIES

Deficiencies in antibody production are primary or acquired. The *physiological hypogammaglobulinemia* of the infant has already been discussed. Bruton's disease is a sex-linked familial hypogammaglobulinemia in which immunoglobulin levels of 50 mg. or less per 100 ml. of blood are common. The individuals are very susceptible to infection. Secondary hypogammaglobulinemia may develop in the course of chronic lymphocytic leukemia and other diseases. There is a general decrease in plasma cells in the bone marrow, lymph node, and other tissues. Lymph nodes from primary hypogammaglobulinemia show ill-defined germinal centers and a thin cortex; there is slight development of Peyer's patches in the gut; yet, the thymus appears to be relatively normal.

There is a group of diseases in which there is an impaired cellular immunity called *thymic alymphoplasia*. There is little if any immunoglobulin deficiency. There is a lymphopenia. The thymus is very poorly developed, weighing as little as 1 g. Thymus, spleen, lymph nodes, tonsils, and gastrointestinal tract have a markedly reduced content of lymphocytes. There is a marked susceptibility to infections, particularly of mycotic and virus origins.

In another disorder in which there is a combined deficiency of antibody production and cellular immunity, antibodies are practically absent, there is a marked lymphopenia, and the patients are so very susceptible to infection that they die shortly after birth. There are two additional types of thymic alymphoplasia based on inheritance. Both have impaired delayed hypersensitivity reactions, hypogammaglobulinemia, very poor antibody response, few plasma cells, and an atrophic lymphatic tissue.

REGULATION OF THE HYDROGEN ION CONCENTRATION OF BODY FLUIDS

Hydrogen Ion Balance

The normal concentration of H^+ ions in the extracellular body fluids ranging as it does from 44 to 36 nM/liter, and represented by a pH variation from 7 36 to 7 44 (Table 4 16), is the result of a continuously maintained dynamic equilibrium between the intake and production, and the suppression and excretion of hydrogen ions

SOURCES OF HYDROGEN ION

Although a small amount of hydrogen ions may be taken in with the food or as medication, most of them arise from the numerous metabolic activities which are going on unceasingly in the living individual The major sources of new hydrogen ions include

1) Oxidation of Carbon Compounds to Produce Carbon Dioxide. Carbon dioxide is the ultimate end product of the oxidation of carbon compounds In an average adult at rest, about 200 ml (almost 10 mM) of this gas is produced in the tissues, transported by the blood, and eliminated by the lungs per minute, or about 10,000 to 14,000 mM/day The rate of its formation depends upon the rate of metabolism and during severe exercise it may be increased to 10 or more times this amount Carbon dioxide is soluble in water and the actual concentration of CO_2 in the tissue fluids at any one time is determined by the partial pressure of the gas in these fluids This in turn is regulated by the respiratory system, which normally keeps the P_{CO_2} in the pulmonary alveoli and in the arterial blood at about 36 to 44 mm Hg At this partial pressure the concentration of CO_2 in the plasma is 1 1 to 1 3 mM/liter and this is always in equilibrium with a small amount of hydrated carbon dioxide or carbonic acid

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

Any condition which prevents the lungs from excreting carbon dioxide as rapidly as it is formed, or causes them to excrete more than is being produced, will of course result in a change in the CO_2 and carbonic acid concentrations of the body fluids and this, if not counterbalanced, may cause significant changes in blood pH

2) Conversion of Neutral Food Stuffs to Organic Acids A great variety of moderately strong organic acids are produced during the normal intermediary metabolism of neutral carbohydrates, fats and proteins and equivalent amounts of H^+ ions are temporarily released into the body fluids Most of these intermediary acids are oxidized to CO_2 and H_2O or otherwise metabolized and in this way are eliminated almost as rapidly as they are formed As long as this occurs their hydrogen ions disappear again, and no effect is produced on the overall hydrogen ion balance At times, however, because of excessive metabolic activity, or because of the presence of certain diseases or for some other reason, these intermediary organic acids, especially lactic and pyruvic acids may be produced in greater quantities than can be metabolized or excreted When this occurs there will be a greater or less accumulation of H^+ ions and a fall in the pH of the body fluids

3) Oxidation of the Sulfur in Organic Compounds The oxidation of the sulfur containing amino acids methionine and cysteine yields equivalent amounts of hydrogen ion and sulfate ion This can be illustrated by the equation (greatly simplified)

$$2C_5H_{11}N_1O_2S + 15O_2 = 4H^+ + 2SO_4 + (NH_2)_2CO + 7H_2O + 9CO_2$$

methionine — urea

That H^+ are produced in this way is shown by the finding that the administration of a methionine load to an individual is followed by an increase in the renal excretion of H^+, which parallels very closely the excretion of sulfate ions (Relman, 1964)

4) Formation of Inorganic Phosphate. The hydrolysis of phosphoesters and the breakdown of phosphoproteins, nucleoproteins, and phosphatides in foods, result in the formation of inorganic phosphates and the liberation of corresponding amounts of H^+ (Relman, 1964) For the orthomonoester, this can be illustrated by the following equation

$$R{-}O{-}\underset{\displaystyle OH}{\overset{\displaystyle O}{\overset{|}{\underset{|}{P}}}}{-}OH + H_2O = R\,OH + \frac{0\,8HPO_4^=}{0\,2H_2PO_4^-} + 1\,8H^+$$

(Ratio of the phosphates at pH 7 4 is 4 1)

Table 4 16
Range of reaction of some body fluids

Fluid	pH	Hydrogen Ion Conc Nanomols per l
Pure water	7 0	100
Blood		
Normal mean	7 40	40
Normal range	7 36–7 44	44–46
Very severe acidosis	6 8	160
Very severe alkalosis	7 8	16
C S F normal range	7 36–7 44	44–36
Pure gastric juice, normal	1 0	100,000,000
Urine		
Normal average, about	6 0	1000
Maximum acidity	4 5	31600
Maximum alkalinity	8 0	10
Intracellular fluid (muscle) (DMO)[a]	6 8	160

[a] Determined indirectly by the distribution of 5,5-Dimethyl-2,4 oxazolidinedione
Waddell and Butler, 1959

In normal persons, on the usual protein intake, the last three of the above processes produce only about 50 to 90 mM of H^+ per day, but as the acids from which these are derived are nonvolatile or "fixed" they cannot be excreted by the lungs and their elimination must, therefore, be brought about by the action of the kidneys The production of H^+, particularly by the last two mechanisms, will be increased by any acceleration of protein breakdown and especially by the elevated rate of endogenous protein destruction which follows a severe tissue injury or other cause of increased catabolism When these injuries are accompanied by severe renal failure, the increased production of these strong acids, coupled with the impaired renal ability to excrete them may lead rapidly to a serious accumulation of H^+ ions, and to a sharp and dangerous fall in the pH of the body fluids

5) Medication Medication with ammonium salts or with mineral or organic acids, such as mandelic acid, may occasionally add significantly to the load of H^+ ions that must be handled by the body Ingestion of ammonium salts is equivalent, as far as supplying H^+ ion is concerned, to the ingestion of the corresponding amount of the free acid, since each ammonium ion taken in is converted in the liver to urea with the liberation of a proton

$$2NH_4Cl + CO_2 = 2H^+ + 2Cl^- + H_2O + (NH_2)_2CO$$

EXCRETION AND FIXATION OF H^+ IONS

The addition of new H^+ to the body, whether from intake or metabolism, is balanced by the action of chemical or physiological mechanisms which normally remove them as rapidly as they are formed so that the $[H^+]$ of the body fluids remains reasonably constant These mechanisms include

1) Dilution Hydrogen ions formed in excess at any one site—as for example in an exercising muscle—are rapidly distributed by the circulation throughout the whole of the extracellular fluid Although not a regulatory mechanism in the usual sense, the dilution brought about in this way will help to minimize the local increase of H^+ concentration which would otherwise occur

2) Buffer Systems A variety of buffer systems is present in the extracellular and cellular fluids of the blood and tissues These function as the first line of defense in preventing alterations in $[H^+]$ from being produced by the addition of acids or bases, and to help keep the H^+ concentration of these fluids within the normal range (Fig 4 39) These buffer systems are

A) In the Blood Plasma i) The bicarbonate/carbonic acid buffer system Quantitatively the most important buffer in the plasma is the one made up of sodium bicarbonate and carbonic acid The normal ratio of the two components of this buffer system in the plasma is

$$\frac{[HCO_3^-]}{0\ 0301 \times P_{CO_2}\ (43\ mm\ Hg)} =$$

$$\frac{[HCO_3^-]}{[H_2CO_3]} = \frac{26\ mM/liter}{1\ 3\ mM/liter} = \frac{20}{1}$$

As the pK′ of the bicarbonate-carbon dioxide system is 6 1, it can be calculated from the Henderson-Hasselbalch equation that as long as this

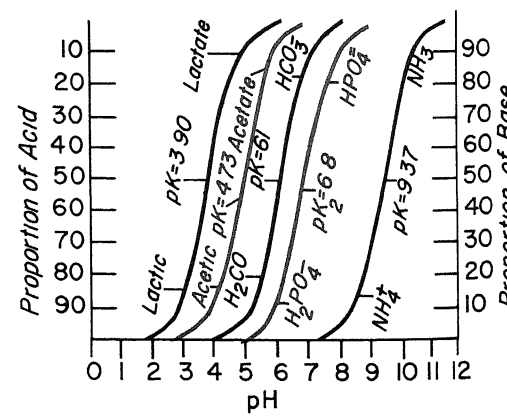

Fig 4 39 Calculated titration curves for several buffer systems showing the relation between [Base]/[Acid] ratios and pH For a discussion of pH titration curves and buffer mechanisms see Clark (1952)

ratio of bicarbonate and carbonic acid is maintained the pH will be 7.4

$$pH = pK' + \log [HCO_3^-]/[CO_2]$$

$$= 6.10 + \log 20/1.0 = 6.10 + 1.30 = 7.40$$

The very great importance of this buffer system in the control of the extracellular pH and its association with the respiratory regulation of carbon dioxide excretion will be discussed below.

ii) The phosphate buffer system. This consists of the mixture of the alkaline and acid phosphates of sodium

$$Na_2HPO_4/NaH_2PO_4$$

In this buffer pair the acid phosphate may be regarded as a weak acid (pK_{A_2}' for phosphoric acid is 6.8) and the alkaline phosphate as the fully ionized salt of the buffer pair. The normal ratio of base to acid in this case at the pH of normal blood is 4/1.

$$pH = pK_{A_2}' + \log ([base]/[acid])$$

$$= 6.8 + \log (4/1) = 6.8 + 0.60 = 7.4$$

iii) Plasma proteins. Plasma proteins act as buffers and, at the pH of the blood, they behave as a mixture of poorly dissociated weak acids and their almost completely ionized sodium salts

$$Na^+ \text{ proteinate}^-/H \text{ proteinate}$$

B) In the Red Blood Cells. Important buffer systems, distinct and separate from those of the plasma, are also present and active within the red blood cells and these are

i) Intracellular organic phosphate complexes such as adenosine diphosphate, creatine phosphate, etc.

ii) $\dfrac{\text{Potassium oxyhemoglobinate}}{\text{H oxyhemoglobin}}$ or $\dfrac{K^+ HbO_2^-}{HHbO_2}$

iii) $\dfrac{\text{Potassium hemoglobinate}}{\text{H hemoglobin}}$ or $\dfrac{K^+ Hb^-}{HHb}$

Within the red blood cells the oxygen-carrying protein, hemoglobin, acts as a buffer to H^+ ions much in the same way as do the plasma proteins, but in this case the buffering is done mainly by the imidazole groups of the histidine in the Hb molecule (Fig. 4.40). There is about four times more red cell hemoglobin than plasma proteins present in a given volume of whole blood (150 g. to 40 g./liter), the protein buffering capacity of whole blood, therefore, is about six times that of a similar volume of plasma. Both the oxygenated and the reduced Hb systems are depicted above, because oxidation of Hb to HbO_2 causes it to become a stronger acid, that is, to donate more H^+ ions, whereas, the deoxygenation of HbO_2 to Hb causes it to become less acid and to become more effective as an acceptor of H^+ ions. The formation of the more acid oxyhemoglobin in the alveoli by the oxidation of reduced hemoglobin will, therefore, compensate in part for the loss of H^+ ions and for the decrease in H^+ concentration at this

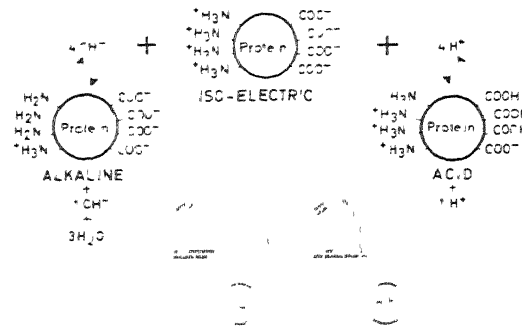

Fig. 4.40 Schematic representation of the buffering of acids and bases by plasma proteins and by the imidazole groups of hemoglobin histidine. (Adapted from Davenport, 1958.)

site resulting from the excretion of CO_2. In the same way the deoxygenation of arterial HbO_2 to Hb in the peripheral circulation where oxygen is given up, enables the hemoglobin molecule to accept and to fix more of the extra hydrogen ions added to the blood by the addition of carbon dioxide from the tissue cells.

C) In the Extracellular Fluids and Tissue Cells. Only a portion of the total buffer capacity of the body resides in the buffers of the blood plasma and red blood cells. The interstitial fluids have a bicarbonate and phosphate buffer concentration similar to that of the circulating plasma, and these play their part in all buffer reactions. In addition to these buffer systems, however, it has been shown by Pitts and his co-workers (1963) and by others, that somewhat more than 50% of the hydrogen ions infused as strong acid intravenously into nephrectomized animals, are transferred into tissue cells in exchange for sodium and potassium ions. These exchange reactions occur across all tissue cell membranes and make available in this way the large quantities of cellular protein and organic phosphate complexes for the buffering of extracellular hydrogen ions. The superficial surfaces of the bones may also play a role in these reactions. Similar ionic exchanges in the reverse direction allow the cellular constituents to take part in the buffering of extracellular base whenever this becomes necessary.

3) The Handling, Transport, and Excretion of Carbon Dioxide. This subject is fully covered in Section 6, Chapter 1 "Uptake and Delivery of Respiratory Gases" so that there is no need here to do more than to review it quickly in relation to H^+ regulation.

The large amounts of potentially acid-producing carbon dioxide, continuously being released from all the body tissues by cellular metabolism, are handled without seriously disturbing the $[H^+]$ of the body fluids in a manner which may be briefly described as follows.

The ultimate regulation of the pH level of the ar-

terial blood is carried out by the respiratory system, which, by controlling the minute volume of respired air, is able to vary the amount of CO_2 excreted to the outside air in such a way that the $[HCO_3^-]/H_2CO_3]$ ratio in the plasma is kept relatively close to the normal value of 10/1 no matter how much or how little carbon dioxide is being produced At this ratio, the pH will be 7 40 If the quantity of CO_2 being removed from the blood by respiration is not sufficient to keep up with that being added by metabolism, the P_{CO_2} and the carbonic acid content of the arterial plasma leaving the lungs and passing through the respiratory center will be slightly higher than normal The $[HCO_3^-]/[CO_2]$ ratio and the pH of this blood will be slightly depressed and the $[H^+]$ will be slightly elevated As a consequence the respiratory center, being very sensitive to changes in the pH and P_{CO_2} of the blood passing through it, will normally be stimulated to increase the degree of pulmonary ventilation More CO_2 will be exhaled and removed from the venous blood and this will continue until the $[HCO_3^-]/[CO_2]$ ratio and the pH of the blood leaving the lungs are restored to normal again On the other hand if too much CO_2 is being lost by respiration this ratio will be increased, and the pH of the arterial blood will be slightly elevated This change in the pH of the blood passing through the respiratory center will cause the pulmonary ventilation to be decreased Less CO_2 will be excreted and more will be retained in the arterial blood until the ratio and pH return once more to the normal values

It is not to be inferred from the above that the plasma bicarbonate buffer system and its regulation by the respiratory apparatus are alone responsible for the buffering of all the changes in $[H^+]$ which may be produced by the addition or loss of acids or bases to the body fluids All the buffer systems of the body are in equilibrium with one another and the effect of the respiratory control on the bicarbonate system is transmitted to all the others

4) Metabolic Events Such as the Oxidation or Utilization of Certain Organic Acids. Most of the organic acids, except uric acid, produced during the breakdown of normal food stuffs, appear only momentarily as intermediary products of metabolism and, as they usually disappear as quickly as they are formed, they normally have little effect on the hydrogen ion regulation Occasionally, however, as for example during severe exercise, lactic acid may be produced in amounts larger than can quickly be metabolized and, in spite of a large increase in respiration and the "blowing off" of large amounts of CO_2, the pH of the blood may be lowered appreciably below the normal range The subsequent disappearance of the lactic acid, resulting from its oxidation or conversion to glycogen, removes the extra protons associated with its accumulation, replenishes the depleted store of HCO_3^- ions and restores the pH back to normal Similarly the low levels of blood pH and of plasma bicarbonate which are present in severe diabetic acidosis are at least partially restored to normal when the excess acetoacetic acid present in the blood is destroyed following adequate treatment with insulin and glucose

5) Renal Mechanisms in the Regulation of Hydrogen Ion Concentration A very important part in the control of the $[H^+]$ of the body fluids and in the regulation of the overall H^+ ion balance is also played by the kidneys This particular activity of the kidneys, along with the many other aspects of renal function, is fully discussed in Section 5, Chapter 1 and little therefore needs to be said about it here In brief the kidneys are able, mainly through the activities of the cells lining the tubular lumina, to excrete widely varying quantities of H^+, both as titratable acid and as ammonium ions (NH_4^+), into the urine or to eliminate excessive quantities of base whenever either of these actions is necessary for the purpose of maintaining a normal level and balance of hydrogen ions The production and excretion of ammonium ions is dependent upon the enzyme, glutaminase I, contained in large amounts in the kidney Terminal renal failure is characterized by an inability of the kidney to continue to excrete excess hydrogen ions as ammonium ions and is typically evidenced by acidosis (An excellent review of the role of ammonium ions in acid-base balance has been published by Pitts, 1971) The tubular cells also help to maintain the concentration of bicarbonate ions in the blood and other extracellular fluids at the normal level of 24 to 28 mM/liter by varying the extent to which bicarbonate ion in the glomerular filtrate is reabsorbed back into the blood again or is passed on to the bladder urine to be excreted to the outside Also, when the normal store of bicarbonate ion in the body is depleted, as it may be by the addition of more nonvolatile acid than can normally be handled, the kidney tubules, in association with their excretion of H^+ ions, form large quantities of new bicarbonate ions, which, when added to the blood, help at least partially to restore the concentration of this ion towards its normal level The decrease in plasma HCO_3^- concentration resulting from diabetic acidosis, for example, would be much more severe and would occur much more rapidly than it does, if it were not for the ability of the renal tubules not only to excrete appreciable quantities of hydrogen ions but also, at the same time, to make new bicarbonate ions to take the place of those which have been used up in the neutralization of the excess acid

Disturbances in the Regulation of H^+ Ion Concentrations in the Blood

ACIDOSIS AND ALKALOSIS DEFINITIONS

In the healthy person the H^+ concentration of the blood and extracellular fluids is main-

tained, and the pH rarely varies more than 0.04 pH units on either side of the average pH 7.40. In a large number of pathological conditions the clinical and metabolic disturbances associated with, or caused by, the illness, subject the mechanisms responsible for the control of the pH of the body fluids to a considerable strain. In all such cases the ability of the body to resist changes in the pH of its fluids may at times be overcome and if this occurs the $[H^+]$ of the body fluids will, depending upon the nature of the underlying primary cause, be either increased or decreased to levels which are more or less beyond the normal range.

1) Acidosis[1] The blood and extracellular fluids may become more acid than normal. Here the pH is depressed to a greater or less degree below pH 7.36 and the hydrogen ion concentration will be correspondingly higher than 44 nM/liter. In the most severe cases the pH may fall as low as pH 6.9 or even pH 6.8.

2) Alkalosis[1] The blood and extracellular fluids may on the other hand become more alkaline (or less acid) than normal. Here the pH is elevated, again to a greater or less degree, above pH 7.44 and the hydrogen ion concentration is less than 36 nM/liter. In the most severe cases the pH of the blood may be as high as pH 7.8.

It is evident that the determining factor for the pH of the blood is the ratio of $[HCO_3^-]$ to $[CO_2]$. When this ratio is decreased the pH of the blood is lowered and a state of acidosis is present, when it is increased the pH is elevated and an alkalosis has developed. The ratio may be decreased or increased by changes either in the concentration of the carbonic acid (the denominator) or of the bicarbonate ion (the numerator) component of this buffer fraction. pH changes in the blood caused primarily by alterations in carbonic acid levels are, as a general rule, brought about by alterations in respiratory function and can, therefore, be referred to as being 'gaseous' or 'respiratory.' On the other hand, pH changes which are primarily due to alterations in the bicarbonate ion concentrations are usually associated with metabolic disturbances and therefore can be called either "metabolic" or 'nonrespiratory.'

With these observations in mind the possible primary abnormalities in hydrogen ion regulation may be listed as in Table 4-17.

Although the various activities briefly described above are reasonably successful in preventing large and dangerous changes in H^+ concentrations the compensation is rarely complete. In most cases of acidosis, other than in those of mild degree, the pH of the blood will be displaced to a greater or less degree below the lower range of normal. Similarly, in most cases of alkalosis the pH will be elevated to levels which are more or less above the upper limit of the normal range (Table 4-18).

TYPICAL ABNORMAL STATES

The four major types of acid-base disturbances may be briefly described as follows.

Respiratory Acidosis *Primary Carbon Dioxide Excess, Carbon Dioxide Retention, Hypercapnia.* In emphysema, pulmonary fibrosis, acute pulmonary edema, pneumothorax and in other pulmonary diseases, in conditions such as abdominal distention, gross obesity, bulbar poliomyelitis, opiate poisoning and in situations in which the air being breathed already has an elevated CO_2 content, the ability of the lungs to excrete even normal amounts of carbon dioxide may be grossly impaired. As a result the P_{CO_2} of the body fluids may become markedly elevated. The $[HCO_3^-]/[CO_2]$ ratio and the pH of these fluids will consequently be depressed below the normal values because of increase in the denominator of the buffer pair and a state of *respiratory acidosis* will be produced. The extent to which these changes do occur will be minimized by the following reactions:

[1] Some will disagree with using the terms "acidosis" and "alkalosis" in the sense in which they are employed in this chapter and would prefer, perhaps, to use the terms "acidemia" and "alkalemia" (or "basosis") in their place. "Acidosis" and "alkalosis" have long been used by clinicians and they are consistent with the initial direction of the change taken by the H^+ concentration in response to the primary clinical disturbance. It does not seem valid to define these terms, as some have done, solely on the basis of the concentration of plasma "bicarbonate," "total CO_2," or "total buffer base," because the determination of any one of these by itself gives no indication at all of the $[HCO_3^-]/[H_2CO_3]$ ratio and it is this *ratio* rather than the absolute amounts of either (or of the sum of both) that determines whether the plasma is more acid or more alkaline than normal. For further discussions of these and other words used in the terminology of acid-base disturbances, see Creese et al. (1962) and also the proceedings of the "Conference on Current Concepts of Acid-Base Measurements," New York Academy of Sciences, November, 1964 (Ann. N. Y. Acad. Sci., 133, 1966).

Table 4 17
Illustrative examples of possible primary abnormalities in hydrogen ion regulation (if uncorrected or uncompensated)

Clinical Condition	Biochemical Abnormality	Plasma $\frac{[HCO_3^-]}{[H_2CO_3]}$ Ratios		
		mM/liter	Numerical	pH
Normal	None	26 mM/1 3 mM	20/1	7 4
Acidosis				
I "Gaseous" or "respiratory" acidosis	Primary CO_2 excess $\frac{[HCO_3^-]}{[CO_2]}$ increased	26 mM/2 6 mM	10/1	7 1
II "Metabolic" or "nonrespiratory" acidosis	Primary bicarbonate deficiency $\frac{[HCO_3^-]}{[CO_2]}$ decreased	13 mM/1 3 mM	10/1	7 1
Alkalosis				
I "Gaseous" or "respiratory" alkalosis	Primary CO_2 deficiency $\frac{[HCO_3^-]}{[CO_2]}$ decreased	26 mM/0 65 mM	40/1	7 7
II "Metabolic" or "nonrespiratory" alkalosis	Primary bicarbonate excess $\frac{[HCO_3^-]}{[CO_2]}$ increased	52 mM/1 3 mM	40/1	7 7

a) Whenever CO_2 tends to accumulate, the respiratory center, if not depressed, will stimulate an increased degree of ventilation if this is possible, and the excess CO_2 will be excreted Often, however, as in conditions such as those mentioned above, the respiratory mechanisms are not able, for one reason or another, to respond to a sufficient degree to the stimulus and the P_{CO_2} remains elevated The respiratory center soon loses its sensitivity to increased CO_2 tensions and a chronic state of carbon dioxide retention is established In severe cases the CO_2 accumulation may continue to elevate the CO_2 concentration in the body fluids and a CO_2 narcosis may eventually develop Mechanical aids to respiration may be necessary to control the accumulation and to prevent the onset of this dangerous complication

b) The buffering actions of the various body buffer systems, including those inside the tissue cells, help to limit the extent of the $[H^+]$ increase associated with the accumulation of the excess carbonic acid and at the same time they cause the HCO_3^- concentration in the plasma and other extracellular fluids to be increased to some degree.

c) The kidneys increase the excretion of hydrogen ions and, by almost completely reabsorbing the bicarbonate ions from the glomerular filtrate and making new bicarbonate ions which are added to the circulation, the renal tubular cells increase the bicarbonate ion content of the body fluids so that the lowered $[HCO_3^-]/[CO_2]$ ratio and the depressed pH are raised towards more normal values

In the acute cases of severe respiratory acidosis there may be insufficient time for the renal mechanisms to compensate for the increased CO_2 retention and the pH may, therefore, be quickly reduced to dangerously low levels In the more chronic cases, the plasma bicarbonate concentration may be elevated to levels high enough to return the pH of the blood close to the normal range Although the pH in the blood of these patients may be almost normal or at most, only slightly depressed, the total plasma CO_2 content and plasma bicarbonate will be much increased Overly enthusiastic ventilation by mechanical means could, by removing some of the excess CO_2, readily convert the disturbance in such a patient into one of respiratory alkalosis

Metabolic Acidosis. *Nonrespiratory aci-*

Table 4 18
Illustrative examples of possible results of complete or partial compensation on $[HCO_3^-]/[CO_2]$ ratios (normal 26 mM/1 3 mM or (20/1)) and pH (normal = 7 40) in the four major types of acid-base disturbances

	Ratios									
	If uncompensated (unlikely)			If fully compensated (unlikely)			If partially compensated (usual)			
	mMolar	Numerical	pH	mMolar	Numerical	pH	mMolar	Numerical	pH

II Metabolic (Numerator ↑)	39 mM/1 3 mM	30/1	7 58	39 mM/1 95 mM	20/1	7 4	39 mM/1 5 mM	26/1	7 52

dosis. Primary bicarbonate deficiency The addition of excess amounts of non-volatile or fixed acids to the body fluids will produce a greater or less degree of metabolic acidosis These acids may have their origin from medication (e g ammonium salts) from overproduction (acetoacetic acid in uncontrolled diabetes mellitus lactic acid in severe hypoxia, formic acid in methanol poisoning) or from inadequate renal excretion of acids produced in normal metabolism as in patients with chronic nephritis or renal tubular acidosis The hydrogen ions of these fixed acids are taken up by bicarbonate ions and other extracellular and intracellular proton acceptors, but by this action the concentration of bicarbonate ion and other available buffer anions may be considerably reduced A similar reduction in the concentration of bicarbonate ion will be produced by the actual loss from the body of this ion by diarrhea or drainage from a biliary, pancreatic or intestinal fistula By any of these means the $[HCO_3^-]/[CO_2]$ ratio is decreased because of a decrease in the numerator of the buffer pair and the pH of the body fluids is correspondingly lowered These changes are compensated in part by an increased pulmonary ventilation, which, by 'blowing off' CO_2, decreases the carbonic acid concentration of the body fluids and thus, by lowering the denominator, helps to elevate the depressed $[HCO_3^-]/[CO_2]$ ratio and the pH of these fluids towards more normal values The kidneys also play their part for not only do the renal tubular cells increase their hydrogen ion excretion in the form of ammonium salts and titratable acid but they also aid in the restoration of the lowered plasma bicarbonate ion by almost completely reabsorbing this ion from the glomerular filtrate, and by forming new bicarbonate ion which is added to the circulating blood

Respiratory Alkalosis. *Primary CO_2 deficiency* Excessive hyperventilation, due, not to an elevated P_{CO_2} or increased hydrogen ion concentration, but to voluntary effort, hysteria, anoxic anoxemia, central nervous system disease, or to toxic stimulation of the respiratory center (as in salicylate poisoning), will cause an excessive excretion of carbon dioxide from the body, a decrease in the CO_2 tension and carbonic acid content of the body fluids and, because of the decrease in the denominator, an elevation of the $[HCO_3^-]/[CO_2]$ ratio to levels

higher than the normal 20 to 1 The pH of the body fluids will be elevated and a respiratory alkalosis established In compensation, the decrease in $[H^+]$ of the body fluids will be partly buffered by protons derived from the buffer systems of the extracellular and cellular compartments The renal tubules conserve H^+ by ceasing to excrete ammonium ions and titratable acid Reabsorption of bicarbonate ion from the glomerular filtrate is sharply diminished and considerable amounts of bicarbonate ion are excreted in the urine The plasma $[HCO_3^-]/[CO_2]$ ratio and pH are thus lowered towards normal by decreasing the numerator and at the expense of some of the extracellular bicarbonate In respiratory alkalosis the plasma bicarbonate concentration may be decreased to below the normal range

Metabolic Alkalosis. *Primary bicarbonate excess, Nonrespiratory alkalosis* This type of alkalosis can result from the ingestion of excessive amounts of sodium bicarbonate (or of salts such as sodium citrate or sodium lactate which are transformed by metabolic oxidation into sodium bicarbonate) for therapeutic reasons, or it may be caused by the loss of H^+ ion from the body by the vomiting of hydrochloric acid containing gastric juice In each of these cases the plasma bicarbonate concentration, the $[HCO_3^-]/[CO_2]$ ratio, and the plasma pH all become elevated and a metabolic alkalosis results The increased amount of cation is buffered by protons from extracellular and intracellular buffers The elevated pH depresses the respiratory center and a compensating retention of CO_2 by the lungs may occur to some degree But the simultaneous decrease in oxygen intake, caused by the decreased ventilation, prevents this type of compensation from being very effective Hydrogen ions are conserved by the kidney and some of the elevated plasma bicarbonate is excreted into the urine In the presence of the depressed H^+ concentration in the tubular fluid a reabsorption of sodium by the distal renal tubules is accomplished by exchange for secreted K^+ instead of H^+, and this may lead to an increased K loss in the urine and to a depletion of body potassium If not replaced from exogenous sources, the loss of potassium from the extracellular fluids is partly replaced by potassium liberated from tissue cells in exchange for extracellular H^+ and Na^+ This transfer of H^+ from the extracellular fluid to the cells accentuates the extracellular alkalosis and tends at the same time to cause an intracellular acidosis Similarly, in other cases of potassium depletion, no matter how produced, the loss of H^+ from the extracellular fluid to the cells in exchange for a part of the cellular K decreases the $[H^+]$ of the extracellular fluids and causes the development of an extracellular alkalosis Also, in the potassium depleted individual, the low potassium content of the distal renal tubular cells causes the Na^+ reabsorption occurring at this site to take place mainly in exchange for secreted H^+ instead of K^+ In such cases the urine may be acid (paradoxical aciduria) in spite of the extracellular alkalosis, and the loss of H^+ produced in this way may tend to aggravate the alkalotic state In these cases too, it may be possible to relieve the alkalosis only by supplying the missing potassium

"Mixed" Acid-Base Disturbances Although the four different major types of acid base disturbances described above have been dealt with as distinct and separate entities, it must be remembered that "mixed" types are not uncommon and that a primary abnormality of one kind may readily be superimposed upon one of a different variety A patient with respiratory acidosis from pulmonary emphysema may, for example, develop a metabolic acidosis from uncontrolled diabetes, or a potassium depletion metabolic alkalosis from large doses of steroids used in the treatment of an attack of status asthmaticus, or a patient with a metabolic disturbance may develop an acid-base upsetting abnormality of respiration

Table 4 19
Biochemical abnormalities of the blood plasma in the four principal types of H^+ disturbances

	pH	P_{CO_2}[a]	HCO_3^-	$\frac{[HCO_3^-]}{[CO_2]}$
		mm Hg	*mM/liter*	*Numerical ratio*
Normal	7 4	43	26	*20/1*
Respiratory acidosis	↓	↑	↑	↓
Respiratory alkalosis	↑	↓	↓	↑
Metabolic acidosis	↓	↓	↓	↓
Metabolic alkalosis	↑	↑	↑	↑

[a] mM/liter $[CO_2] = 0\ 0301 \times P_{CO_2}$ at 38° C

The likelihood that such a 'mixed' picture is present will frequently be obvious or be suggested by the history and physical examination The biochemical upset however may be quite complicated, since depending upon the nature of the disturbances, some of the effects of one may either be partially cancelled out or greatly augmented by those of the other In these "mixed" conditions, it is particularly necessary to know not only the 'total CO_2 content" but also the pH and P_{CO_2} of the blood as well In addition, the concentrations of sodium, potassium, and other constituents of the blood should also be determined if a full and correct assessment of the actual acid-base status of the individual is to be made

Investigation and Assessment of Disturbance in H^+ Regulation

The direction of the deviations from normal shown by the more important biochemical characteristics of the blood in each of the four major types of acid-base disturbance are set forth in Table 4 19 As the data in this table show, a depressed pH would be found in both the respiratory and metabolic type of acidosis a lowered P_{CO_2} could indicate the presence of either a respiratory alkalosis or a metabolic acidosis, and an elevated plasma bicarbonate concentration could be a characteristic of either a respiratory acidosis or a metabolic alkalosis Although, in most cases, the nature of the responsible clinical disturbance would suggest the type of acid-base abnormality present,

AC D-BASE EVALUATION   MAY 15, 1969    5:51 PM

SERUM ELECTROLYTES (MEQ/L):

   NA      =
   CO2     =  24
BLOOD PH   =
BLOOD PCO2 =

 IN THE ABSENCE OF A MEASURE OF BLOOD PH OR PCO2 WE CANNOT DETERMINE
WHETHER THE ELEVATED PLASMA BICARBONATE CONCENTRATION IS DUE TO
COMPENSATORY ACIDOSIS, METABOLIC ALKALOSIS, OR TO A MIXED ACID-BASE
DISORDER
DO YOU WISH TO
   1) ASSUME THAT THE DISORDER IS ENTIRELY RESPIRATORY
   2) ASSUME THAT THE DISORDER IS ENTIRELY METABOLIC
   3) SUPPLY THE COMPUTER WITH BLOOD PH OR BLOOD PCO2
PLEASE ENTER A NUMBER> 2

PATIENT'S WEIGHT (IN POUNDS)     = 148

DO YOU HAVE A COMPLETE SET OF SERUM ELECTROLYTES>          NO

IT WOULD PROBABLY BE USEFUL TO OBTAIN THEM

     IF WE ASSUME THAT THE ACID-BASE DISTURBANCE IS ENTIRELY METABOLIC
THE COEFFICIENT OF 36 MEQ/L IMPLIES THAT A PH MUST BE 7 AS UNITS AND
PCO2 46 MM HG RESPECTIVELY THESE ARE THE VALUES THAT WOULD BE COMPATIBLE WITH UNCOMPLICATED METABOLIC ALKALOSIS

     WHILE AWAITING A COMPLETE SET OF ELECTROLYTES IT SHOULD BE
RECALLED THAT METABOLIC ALKALOSIS IS MOST COMMONLY CAUSED BY:
   1) VOMITING OR GASTRIC ASPIRATION
   2) DIURETIC THERAPY (THIAZIDES, MERCURIALS, ETHACRYNIC ACID OR
      FUROSEMIDE)
   3) HYPERADRENALISM (CUSHING'S SYNDROME, PRIMARY OR SECONDARY
      ALDOSTERONISM, ADRENAL STEROID THERAPY)
   4) EXCESSIVE ALKALI INTAKE (ALKALOSIS USUALLY TRANSIENT)
   5) POST HYPERCAPNIA (PARTICULARLY IF CHLORIDE INTAKE IS SMALL)
   6) HYPERCALCEMIA (POSSIBLE - DATA NOT CLEAR)
   7) BARTTER SYNDROME (HYPOKALEMIA, HYPOCHLOREMIA AND METABOLIC
      ALKALOSIS WITH, IN SOME INSTANCES, HYPONATREMIA, SHORT STATURE
      AND MENTAL RETARDATION)

     IF HYPERADRENALISM AND HYPERCALCEMIA ARE ABSENT THEN IT SHOULD
BE POSSIBLE TO CORRECT THE METABOLIC ALKALOSIS BY ADMINISTERING
SUFFICIENT CHLORIDE TO REPLACE PREVIOUS LOSSES AND TO ALLOW A
URINARY CHLORIDE EXCRETION OF AT LEAST 10 TO 20 MEQ PER DAY

THE TOTAL CALCULATED CHLORIDE DEFICIT IS APPROXIMATELY 130 MEQ
IT IS SUGGESTED, HOWEVER, THAT IN ADDITION TO REPLACING KNOWN CHLORIDE
LOSSES, 100 MEQ OF SODIUM, POTASSIUM, OR ARGININE CHLORIDE BE
GIVEN INTRAVENOUSLY DURING THE NEXT 24 HOURS, AND THAT SERUM ELECTROLYTES AND BLOOD PH BE MEASURED AT LEAST DAILY UNTIL SIGNIFICANT
IMPROVEMENT IN THE ACID-BASE ABNORMALITY OCCURS

     THANK YOU FOR REFERRING THIS INTERESTING PATIENT TO US.

Fig 4 42 Entry of patient's data and computer-generated evaluation Underlined information was typed by the physician everything else by the computer Note that the initial potassium entry was rejected as being unreasonable and that the computer supplied the P_{CO_2} when the physician pressed only the enter button The bicarbonate deficit is calculated on the basis of two-thirds of total body water but the suggested dose (usually less than the deficit) is rounded off to the nearest ampoule when the patient's weight exceeds 50 kg Reproduced from Bleich (1969)

it is obvious that it is not possible to be certain of the exact diagnosis on the basis of the determination of any single biochemical characteristic of the blood plasma, such as the pH or the bicarbonate ion concentration, by itself alone A complete interpretation of the situation in any given patient will require accurate information about each of the three responsible variables: the pH, the P_{CO_2} (H_2CO_3 = 0 0301 × P_{CO_2}), and the bicarbonate ion concentration

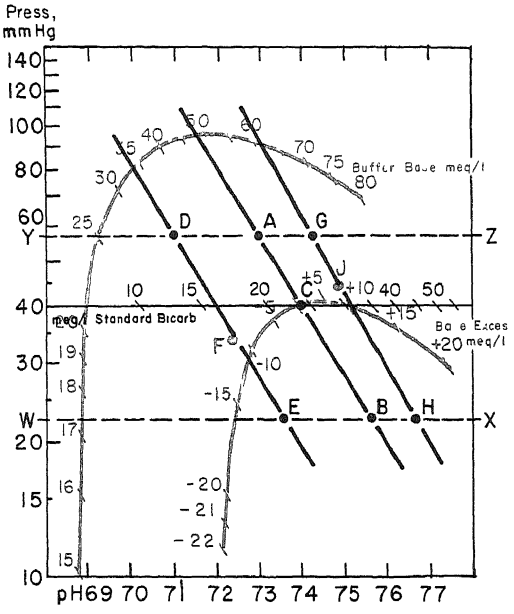

Fig 4 43 The Siggaard-Andersen Nomogram The abscissa is pH and the ordinate is a logarithmic scale of P_{CO_2} Included also are buffer base base excess and standard bicarbonate scales from which these blood values may be determined Buffer lines for three blood samples are shown representing normal acid-base balance (*ACB*) mild metabolic acidosis (*DFE*) and mild metabolic alkalosis (*GJH*) To illustrate the interpolation method of P_{CO_2} determination consider the normal subject (buffer line (*ACB*) The actual pH of the subject's blood is first measured and found to be 7 40 Then small samples of blood are equilibrated with two tensions of carbon dioxide in this example 22 5 and 57 mm Hg corresponding to horizontal broken lines *WX* and *YZ* The pH s of these equilibrated blood samples are measured and found to be 7 566 (for P_{CO_2} 22 5) and 7 302 (for P_{CO_2} 57) these values are plotted on the nomogram (points *A* and *B*) and connected by a straight line which is the buffer line for this blood sample The actual pH (7 40) is then located on this buffer line (point *C*) and the corresponding actual P_{CO_2} value (40) read from the ordinate scale On the acidosis and alkalosis buffer lines shown points *D E G*, and *H* represent equilibrated values and points *F* and *J* represent the actual pH-P_{CO_2} points This illustration is reproduced with the permission of the Radiometer Corporation and Dr O Siggaard-Anderson Copenhagen Figure and legend reproduced from Sharp (1969)

of the arterial plasma Only when the values of all three are known will it be possible to understand accurately the true nature of the disturbance

An inspection of the Henderson-Hasselbalch equation

$$pH = pK' + \log([HCO_3^-]/[CO_2])$$

indicates that if the pK′ of the system is known and if any two of the other three unknowns (pH, concentration of base, concentration of CO_2) can be measured, the third unknown can then be calculated (Fig 4 41) With the development of modern measuring devices it is now possible to measure all three with great accuracy provided the necessary care is taken to collect the blood in such a way that its contents are not disturbed, and to carry out the measurements under the exact conditions of temperature, and O_2 and CO_2 tension which actually exist in the blood

In recent years, the medical use of computers has been increasing An excellent example is the application to the assessment, diagnosis, and treatment of acid-base disturbances This is illustrated in a sample output (Fig 4 42) of a program developed by Bleich (1969) Laboratory results and other data are simply typed, as asked for by the program, on a typewriter console An off-shoot of computer use has been the development of "self-instruction programs" on various subjects in book form The reader is referred to a very fine publication on acid-base physiology by Winters, Engel, and Dell (1967)

Of more widespread use, however, is the excellent Siggaard-Andersen nomogram (Fig 4 43) The nomogram is used with pH measurements of the blood in the Astrup method of determination of P_{CO_2} Whole blood measurements enable graphic estimation of P_{CO_2}, standard bicarbonate and total buffer base (BB) of the blood (Singer and Hastings, 1948), the last being essentially equal to the sum of bicarbonate and proteinate It also enables quick determination of the base excess (BE) of the blood which is the buffer base (BB) found minus the normal buffer base of the blood in mEq /liter Negative values of BE indicate a situation in which a deficit of buffer base exists.

Although the computer is most helpful and nomograms simplify manual calculations, it must be emphasized that a thorough understanding of the interplay of acids and bases in the body's control of hydrogen ion concentration is essential and without substitute

22 FLUID DISTRIBUTION AND EXCHANGE

Measurement of Fluid Volumes

The total volume of water in the body varies among species, in man it has a mean value of approximately 65% of the body weight, or roughly one-third (It is about 65% also in the dog, and about 73% for guinea pigs and rabbits) It is difficult to establish proper mean values for body water, because its total volume is related to the mass of the lean tissues of the body rather than to the body weight In an obese person it is a much lower percentage of the body weight than in one who is lean The values, therefore, vary widely both between persons and different species of animal in accordance with their fatness or leanness

The total volume of the body water can be determined by injecting into the blood stream a known amount of water containing deuterium or tritium, or antipyrine which becomes uniformly distributed throughout the body fluids (intracellular and extracellular), and then determining its concentration in a sample of serum Tritium-labeled water may be more conveniently measured than deuterium-labeled water because of the radioactivity of tritium A further method using *N*-acetyl-4-aminoantipyrene has also been described

The *extracellular fluid*, which comprises the blood plasma, the tissue or interstitial fluid, lymph and the fluid in the serous cavities, amounts to about 24% of the body weight, the plasma water constitutes only about 4% of the body weight in man The fluid within the cells, the *intracellular fluid* amounts to 41% of the weight of the body, or about two times the extracellular fluid The skeletal muscles contain about half, the skin about one-fifth and whole blood only about one-tenth of the total body water (Table 4 20)

Substances, such as sucrose, mannitol, inulin, thiocyanate, and to a large extent chloride, when introduced into the body, become uniformly distributed throughout the extracellular fluids but do not enter the cells in important amounts and, since they are not metabolized and are not excreted too rapidly, can be employed to estimate the volume of the extracellular fluid in the living animal When, for example, a known amount of thiocyanate is injected into the blood stream and sufficient time allowed for equal distribution to occur, the volume of the extracellular water can be calculated from the concentration of the solute in a sample of serum Radioactive sodium or chloride may also be employed for such determinations, but since these solutes are not excluded from all types of cells they are not as dependable as thiocyanate or sucrose, especially if absolute values are sought The extracellular fluid is visualized as occupying a space of the determined volume, and according to the solute used in the estimation, it is customary to speak of the *thiocyanate space*, *sucrose space*, etc It is well to appreciate that some of the methods for determining extracellular fluid volume, because they measure only the volume of fluid into which the test substances can freely diffuse, exclude a certain amount of the fluid that is outside cells, such as eye humors, cerebrospinal fluid, and secretions of glands, whereas these fluids are usually included in the estimation of total body water

The values for the *total body water* and for the *extracellular water* having been determined by the methods just outlined, the *intracellular water* volume can be found by subtraction (see Table 4 21 for percentages) Intracellular water under ordinary conditions is a rather fixed quantity, a loss of one-fourth of the body water is usually fatal

Under physiological conditions the interstitial fluids show the greatest changes In dehydration the proportion of the total water lost from extracellular and intracellular compartments varies with the manner in which the negative water balance is produced When, for

B Intracellular	41

example, the dehydration is caused by sucrose diuresis, about 85% of the excreted water is derived from extracellular and 15% from intracellular sources Whereas, in dehydration resulting from water deprivation, the water loss is from 57 to 67% intracellular

Water Balance

In health, except when new tissue is being formed, the body's intake of water obviously must balance the output When the output exceeds the intake, the body's water content is reduced and the body is then said to be in negative water balance, dehydration results When, as during growth, convalescence from an acute illness or in pregnancy, new tissue is being formed, or for a time after a subject has been placed upon a reducing diet, the water balance is positive, the intake exceeding the output, i e , water is retained

The antidiuretic principle of the hypophysis constitutes part of the mechanism regulating the volume of body water In dehydrated states, increased amounts of the pituitary hormone are excreted in the urine (sect 5)

WATER INTAKE

Body water is replenished in two main ways, *a*) by the ingestion of liquids, semisolid, and "solid" food (cooked lean meat, for example, is from 65 to 70% water), and *b*) by the water formed in metabolism through the oxidation of the hydrogen of the food, or of the body tissues themselves Table 4 22 gives the quantities of water produced by the metabolism, respectively, of the three main food stuffs and of alcohol Water is also formed in the tissues through the polymerization or synthesis of various compounds, i e , through a metabolic process the reverse of hydrolysis An ordinary mixed diet yields as a result of oxidative processes from 300 to 350 gm of water daily, or about 14 gm /100 kcal When no food or drink is taken, the body materials themselves are utilized for this purpose, the glycogen, protein, and fat supplying important quantities of water The camel's hump, for instance, which is largely composed of fat, is a reservoir for large amounts of water, and the clothes moth kept in a desiccator and fed upon perfectly dry food lays eggs which are 80% water

For the adult, the amount of water from all sources and under ordinary circumstances which must be ingested daily is around 2500 ml or about 1 ml /kcal of food intake This usually means that about 1000 ml of water as such or in beverages must be drunk in order to maintain the water balance

The water intake under conditions of average temperature, humidity, and diet is summarized in the following Table 4 23 The volume of body water is held constant through a nicely balanced adjustment between intake and output The intake is regulated mainly by the sensation of thirst (sect 9, chap 7)

WATER OUTPUT

Water is lost from the body in the feces, urine and saliva, and by the evaporation of water from the skin and lungs The daily loss through these several channels is given in the following Table 4 24 for a man of average size at light occupation in a temperate climate Under usual conditions of air temperature (23 to 25° C), humidity, and diet, the heat lost from the lungs and the surface of the body by the evaporation of water amounts to about 24% of the total heat production The measurement of this *insensible water loss* under standard conditions may therefore be employed as a

basis for the determination of the basal metabolic rate

The water lost through the skin and lungs varies greatly with the temperature and relative humidity of the atmosphere and with the extent of the muscular exercise indulged in At ordinary temperatures slight secretion by the sweat glands is not perceived since the sweat evaporates as quickly as it is formed This *insensible perspiration*, as it is called, includes the loss of a greater amount of water by evaporation from the moist tissues beneath the skin, this loss is quite apart from the actual secretion of visible sweat The diffusion of water through the skin and evaporation from the surface under ordinary comfortable conditions of room temperature and humidity is around 1 mg/cm ^{2} of skin surface in a period of 10 min The rate of diffusion is little different for living or dead skin and whether sweat glands are present or absent When the air is hot or the body temperature raised, the rate of evaporation of water from the skin is much more rapid In hot climates the daily secretion may amount to 3000 ml daily, and in very torrid atmospheres it may be as much as 10 liters When heavy work is done in a hot environment, sweat may be secreted at the rate of 2 liters/hr This necessitates the drinking of an equal quantity of fluid in order to maintain the normal water content of the body since the intake must equal the output

At ordinary temperatures the inspired air contains negligible quantities of water whereas the expired air is almost saturated with moisture Any condition which increases the pulmonary ventilation therefore increases the water lost by this route

REGULATION OF VOLUMES AND OSMOLARITY

The isotonicity of the body fluid which depends mainly upon its concentration in sodium and chloride is maintained constant by the retention or elimination of both water and electrolytes the kidneys playing the primary role in this regulation Just how this regulation is achieved is not clearly understood The hypothalamus is important in controlling both the liberation of antidiuretic hormone by the posterior pituitary gland, and water intake (sect 9, chap 7) There must be, however, some means of regulating the absolute amount of body water The basic factor in this control may be the regulation of sodium excretion by the kidney (sect 5, chapt 1) Circulatory changes are also important Factors leading to a reduction in circulating blood volume, venous return, or cardiac output appear to reduce the excretion of salt and water and increase the water intake, whereas factors increasing blood volume or the venous return and cardiac output increase the excretion of salt and water and inhibit thirst

Changes in the diet can bring about changes in the total body water Protein is laid down in the body with water (about 3 gm of water per gram of solid) During growth or convalescence from wasting diseases, retention of water therefore occurs, i e , the intake of water, including that derived from solid food, exceeds the output Fat is laid down with a minimal amount of water (only that in the protein of the connective tissue framework), the deposition of glycogen is accompanied by a small storage of water Water retention therefore follows a sudden change from a high fat to a high protein diet, and to a lesser degree from a fat diet to one high in carbohydrate A change

from a diet high in carbohydrate or protein to one high in fat is followed by the loss of water

Reduction of the caloric value of the diet below the energy requirement is accompanied for a time by the retention of water During the 1st week or so on a reducing diet the subject's weight may for this reason show little or no change, the fat catabolized being replaced by water In a prolonged fast after the fat stores have been depleted, protein is also partly replaced by water, the muscles of animals dying of starvation showing a marked reduction in the proportion of protein

DEHYDRATION

Major Causes of Dehydration *1) Water Depletion or Primary Dehydration a) Simple deprivation of water* from whatever cause shipwreck, desert travel, dysphagia, extreme weakness, mental patients refusing to drink, etc Under such circumstances, though there is an effort to conserve the stores of body water, through a reduction in the amount excreted by the kidney, in the sweat and by other routes, some water is always lost though none be drunk Dehydration occurs more quickly in fever or if the environmental temperature is high

b) Excessive water loss may result from persistent vomiting (e g , pyloric or intestinal obstruction), prolonged diarrhea, or the excretion of large quantities of urine or sweat, especially when accompanied by a restricted water and salt intake In the acute diarrheas of infants, dehydration and loss of weight may occur very rapidly Such water loss is accompanied by serious depletion of electrolytes

In water depletion the osmotic concentration of the extracellular fluid rises, water is drawn from the cells, and both extracellular and intracellular compartments shrink Extreme thirst is experienced

2) Reduction in the Total Quantity of Electrolytes, Salt Depletion, or Secondary Dehydration The electrolytic concentration of the body fluids, both extracellular and intracellular, is maintained constant through the elimination or retention of water. That is, a reduction or increase in the total electrolytes, which comprise chiefly the cations Na^+ (extracellular) and K^+ (intracellular) and the anions, HCO_3^- and Cl^-, is accompanied by a corresponding decrease or increase in the volume of body water. The sum of the cations and anions of course must balance Loss of Cl^- can be made good by the retention of CO_2 and a rise in plasma bicarbonate Excreted cation, however, can be replaced only by basic substances supplied in the food The total concentration of electrolytes in the body fluids is therefore dependent upon the stores of total cation For example, in pyloric or high intestinal obstruction, fluid is secreted in large quantities into the gastrointestinal tract The fluid may be vomited or may collect and remain in the dilated part of the canal above the obstruction In either case the secretion of large quantities of gastric juice entails a loss of blood chloride, and an appreciable quantity of K^+ The chloride depletion causes at first no ill effects, the normal concentrations in electrolytes of the blood and tissue fluids being maintained for a time by the retention of CO_2, and, as a consequence of this, an increase in bicarbonate The compensation for the Cl^- loss may lead, however, to alkalosis which is then countered by an increased excretion of Na^+ in the urine This of course is accompanied by diuresis, marked dehydration results

On the other hand, the continued loss of pancreatic juice to the exterior causes an immediate depletion of cation, plasma bicarbonate is reduced In the adjustment of the acid-base balance the excess of anions is excreted in the urine, this again entails a loss of water Similarly, the ingestion of acid-producing salts causes a depletion of cations, which are used for the neutralization and excretion of the acid radicles Such salts therefore act as diuretics and dehydrating agents

In salt depletion the extracellular fluid is hypotonic, water enters the cells, so that the volume of intracellular fluid is maintained or even increased, whereas the extracellular fluid (especially the interstitial) is reduced

Clinically, the leaching of salt from the body of a seriously ill patient by glucose infusions used to be a not uncommon cause of salt depletion

3) The Injection of Hypertonic Solutions into the Blood Stream When a strong sugar or salt solution is injected, the temporary rise in the osmotic pressure of the blood causes a flow of fluid from the tissues into the vascular system until equilibrium is re-established The blood volume is increased, but is soon returned to normal by the loss of the excess material

into the tissues and its eventual excretion via the kidney and bowels A net loss of body water results

Effects of Dehydration *a) Loss of weight* due to the reduction in tissue water as well as to the actual breakdown of body substance which occurs in the effort to furnish water for the maintenance of physiological processes Fat and carbohydrate stores are first drawn upon for this purpose and later, protein *b) Disturbances in acid-base balance* usually toward the acid side The diminished quantity of circulating fluid (loss of plasma water, anhydremia) and the consequent depression of oxidative processes in the tissues are held responsible for the excessive production of acid metabolites, e g , lactic acid The slowing of the renal circulation also leads to a reduced excretion of urine and the retention of anions, e g , phosphate and sulfate, which under normal circumstances are eliminated *c) Rise in the nonprotein nitrogen of the blood d) Rise in plasma protein concentration* and of chloride though there is no absolute increase There is an absolute increase in blood sugar, especially when the stage of exhaustion approaches *e) Rise in body temperature* as a result of the reduction in circulating fluid (sect 9, chap 7) *f) Increased pulse rate and reduced cardiac output g) Thirst* This occurs in water depletion but not in salt depletion Any fall in the water content of the tissues is reflected in the glandular activities especially of the salivary glands Secretion is suppressed, the mouth and throat become dry In dehydration thirst is extreme and the mouth parched *h) Dryness, wrinkling, and looseness of skin* and a pinched expression to the features result from the loss of subcutaneous fat and of water from the deeper layers of the skin Other manifestations are, reduced intraocular tension and recession of the eyeball and, in infants, depression of the fontanelle *i) Exhaustion and collapse*

WATER INTOXICATION

When an animal is given large quantities of water by stomach tube, especially if urinary secretion is reduced by the administration of pitressin, the tissues become "water-logged," serious symptoms ensue, e g , depression of temperature, vomiting, convulsions, and coma, which shortly end in death Similar effects also follow in man if large quantities of water are given to a patient with nephritic edema or, if in a subject of diabetes insipidus, pituitrin be administered while the water intake is maintained at the usual level The manifestations of water intoxication are believed to be due to the dilution of electrolytes in the body fluids, and the damage caused thereby to the tissue cells

Adrenalectomy reduces the renal response to water drinking, and thus increases the susceptibility to water intoxication This susceptibility is reduced by the administration of desoxycorticosterone or of 17-hydroxy-11-dehydrocorticosterone or of thyroid hormone A similar protective action is exerted by these principles upon normal animals

In water intoxication the protein and chloride of the plasma are diminished, although much of the water retained in the body enters the cells of blood and tissues which become swollen The artificial administration of inordinate amounts of water in the form of glucose solution, especially after surgical operations when there is some tendency toward antidiuresis, may cause serious disturbances in water metabolism The effects of an excess of body water induced in this way can be corrected readily by the administration of hypertonic saline

Blood Volume

Blood volume regulation is largely a question of balance between the fluid within the vessels and in the tissues When conditions arise which tend to lower or raise the volume of blood, counter forces come into play which restore the normal level When circulating fluid is lost, the vessels replenish themselves from the extravascular spaces On the other hand, any tendency for the blood volume to rise is met by a discharge of the excess fluid into the tissues and later from the body in the urine So, a balance is struck, and in health the blood volume is maintained remarkably constant For example, after the intravenous injection of a large quantity of saline, the volume of circulating fluid (although raised temporarily) is brought back toward normal within 30 min or less On the other hand, the loss of whole blood, as by hemorrhage, immediately calls into action processes which tend to replenish the blood volume When an animal is bled to death, at a not too rapid rate, the blood which is withdrawn is found after a few minutes of bleeding to have become diluted—clearly demonstrating the promptness

with which fluid (water and salts) has been absorbed into the vessels

Blood volume estimations are of value in many clinical conditions associated with a loss or gain of fluid by the body, or for the purpose of checking the results of corpuscular and hemoglobin estimations It is also sometimes of interest to know, in experimental investigations and in metabolic studies in man, the *total* amounts of certain blood constituents, e g , protein, calcium, sodium, etc , as well as their concentrations

DIRECT METHOD FOR THE ESTIMATION OF BLOOD VOLUME

The first attempts to measure the total quantity of blood in the body were made upon animals by Welcker (1854) His method consisted in taking a small measured quantity of the animal's blood and diluting it to 1 in 100 with normal saline The animal was then bled, and after the blood had ceased to flow, its vessels were washed out and the muscles minced and extracted with water Water was then added to the collected fluid—blood and washings—until its color matched precisely the tint of the original diluted blood specimen The total collected fluid divided by 100 gave the blood volume

This method was also employed upon decapitated criminals (Bischoff, 1857) in order to obtain a value for the blood volume of man, but since its applicability was obviously very limited, indirect methods were later devised

INDIRECT METHODS FOR ESTIMATION OF PLASMA VOLUME

Several methods are available for the determination of the blood volume during life

Method Using T-1824. The dye method was originally devised by Keith, Rowntree, and Geraghty (1915) The degree of dilution in the plasma of a known amount of dye injected into the circulation is employed as the basis of calculation The color of the stained plasma is compared in a colorimeter with that of a standard dye solution of known concentration There are several qualifications required of a dye before it can be considered suitable for blood volume measurements In the first place, of course, it must be innocuous It must not diffuse too rapidly from the blood stream, it must color only the plasma, and not be adsorbed by the cells of the blood nor by the walls of the blood vessels It must not change color itself after entering the blood, nor cause the liberation of pigment from the red cells (hemolysis), and it must be capable of mixing evenly and thoroughly with the plasma If it lacked these qualifications, the colorimetric readings obviously would be undependable

The dye most commonly employed is a blue dye, T-1824 (Evans blue) Evans blue has the advantage that the error due to any discoloration of the plasma by hemoglobin (hemolysis) is minimized This dye is also eliminated very slowly (4 8 %/hr) from the circulation It remains in the circulation because it combines with protein, although this combination apparently is not strong, for the two can be separated by paper electrophoresis

In making an estimate of blood volume a sample of plasma is obtained before the dye is injected Then a known amount of the dye is injected intravenously and blood samples are obtained at 10-, or 20-, 30-, 40-, and 50-min intervals after the injection The concentration of dye in the plasma is measured Because the dye leaves the circulation to some extent, it is necessary to determine the fall in concentration of the dye with time By extrapolating back to zero time from the curve of concentrations, the concentration of the dye at zero time can be computed and this is used to calculate the blood volume Because T-1824 leaves the circulation slowly, in normal persons it is usually possible to obtain a reasonable estimate of the blood volume from a sample taken 10 min after the dye has been injected, but under conditions when mixing is slow, the extrapolated values are preferable From the concentration of dye in the sample and the amount of dye injected, the dye dilution, and hence the plasma volume can be computed

Method Using ^{131}I. Plasma volume may also be estimated by the injection of albumin "tagged" with ^{131}I This is not affected by hemolysis or lipemia, nor does it stain the tissues, but it also has the disadvantage of requiring information concerning its disappearance rate Because only minute amounts of radioactivity are used in each test, repeat determinations can be made accurately and in rapid succession This technique has been adapted for use at the bedside with the advent of improved equipment, and has largely supplanted the use of Evans blue Measurements of plasma volumes by the use of T-1824 and by means of ^{131}I albumin give similar results

Dextran Method. Another procedure has been developed using a dextran fraction which leaves the circulation very slowly. This method has the advantage of requiring only two blood samples, one of which is a control. It is unaffected by lipemia or hemolysis, employs a colorless material and requires no highly specialized equipment for its estimation.

CALCULATION OF BLOOD VOLUME

These various procedures give an estimate only of the *plasma* volume. In order to obtain the value for the total blood volume, the proportion of cells to plasma must be determined by means of the hematocrit. If the *packed cell volume* thus obtained is, for example, 45%, the plasma volume is therefore 55%. Thus, the total blood volume can be calculated from the plasma volume and the hematocrit reading.

In calculating the blood volume from the plasma volume and the hematocrit reading it is necessarily assumed that the proportion of red cells to plasma is the same throughout all parts of the vascular system, but experimental evidence is strongly against such an assumption. In capillaries the proportion of red cells to plasma may be considerably less or more than in the larger vessels. To eliminate the error of unequal distribution of red cells throughout the circulation, methods have been devised for the estimation of the total circulating red cell volume. These use the dilution of injected red blood cells which have been "tagged" with radioactive iron (^{59}Fe), radioactive chromium (^{51}Cr) or radioactive phosphorus (^{32}P). This method is based on two assumptions—*i*) that none of the radioactive atoms escape again after being taken up by the erythrocytes, and *ii*) that all the labeled cells become mixed with the recipient's cells equally throughout the circulation. Only the principle of the method can be given here, for details the reader is referred to the original papers (Hahn et al., 1942, Gibson et al., 1946). Radioactive chromium is the isotope used most frequently for this purpose.

In order to determine the total blood volume, the plasma volume is measured, for example, by the ^{131}I method, and that result is added to the value obtained for the circulating red cell volume.

NORMAL VALUES FOR PLASMA AND WHOLE BLOOD VOLUMES

In normal subjects, blood makes up roughly 7% of the body weight, with plasma volume a little over 4% and red cell volume about 3%. The plasma volume of adult males is about 40 ml., the red cell volume about 29 ml., and the whole blood volume in the neighborhood of 70 ml./kg. of body weight. The blood volume of a man of average weight (70 kg.) is therefore around 5 liters. The blood volume in terms of body weight shows considerable variation from person to person. Changes in body density alter this relationship of blood volume to body weight. The relationship between blood volume and body height shows a similar variability. The most constant relationship is found between a combination of body weight and the cube of body height.

ALTERATIONS IN BLOOD VOLUME

Major Causes of Reduction of the Blood Volume. *1*) A loss of *whole blood* as in hemorrhage. *2*) *Reduction in the total number of red cells* as a result of increased destruction or diminished production (see anemia, chap. 3). *3*) Loss of *plasma* alone from the vessels as in burns or shock from other causes. *4*) *Loss of blood water*. This is called *anhydremia* and is simply a part of a general dehydration and so results from the same causes as the latter. *Acute exposure to cold* causes a moderate loss of water from the blood to the tissues (chiefly skin, muscle and probably liver), the total water content of the body remaining unaltered. It is not altogether clear by what means this movement of water is brought about. The blood volume of the human subject after 30 min. or so in the *erect posture* is some 15% less than that in recumbency. A fluid of low protein concentration leaks from the vessels of the lower limbs into the extracapillary tissues as a result apparently of the increased hydrostatic pressure in the capillaries of these parts. For this reason, a subject must be in the recumbent position in order to obtain an accurate measurement of blood volume.

Increase in Blood Volume. *1*) *High Temperatures*. In hydrated subjects, exposure to a high temperature leads to an increase in blood volume. This increase reaches a maximum in about 7 days after which it may return toward normal. The extracellular fluid volume increases also, although initially the greater part of this increase is reflected in the elevated plasma volume. In the first few hours after exposure to heat the changes are slight and inconsistent.

2) *Muscular Exercise*. The effect of a bout of

vigorous exercise in man is to decrease the plasma volume The magnitude of this decrease may be exaggerated when measurements are made by the dye method because of a change in the optical properties of the plasma However, the protein concentration of the plasma, and the red cell count increase The increase does not seem to be progressive Some elevation in blood volume may occur with muscular training This can be demonstrated in dogs, but in men accustomed to hard physical work, the red cell volume in relation to height and weight is only slightly increased over that of sedentary individuals

3) *Emotional Excitement* in animals and in man causes an increase in blood volume

4) *Pregnancy* In pregnant women, the blood volume though somewhat variable increases on the average by 20 to 30%, though in the last few weeks of pregnancy tends to fall again There is an increase in plasma volume and in interstitial fluid Associated with this is a retention of sodium Restriction or the administration of salt reduces or increases, respectively, the volume of extracellular fluid The increase in plasma volume in pregnancy, combined with a lower protein concentration of the plasma is responsible, in part at least, for the edema of the lower limbs which commonly occurs in the pregnant state Hemoglobin determinations in the last trimester of pregnancy give a falsely low indication of total red cell mass

5) *Congestive Heart Failure* As a result of the retention of sodium, the extracellular fluid undergoes a pronounced increase

6) *The Administration of Desoxycorticosterone* causes a retention of salt and, as a consequence, a rise in the volume of plasma and interstitial fluid This depends on the salt load Aldosterone is much more active than desoxycorticosterone in its effect on sodium retention It helps to keep in equilibrium the fluid volume and sodium retained, fluid retention varying directly with that of sodium

PATHOLOGICAL STATES ASSOCIATED WITH ALTERATIONS IN BLOOD VOLUME

Reduction. *a) Hemorrhage* (loss of whole blood), *b) Burns* (loss of plasma), *c) Dehydration* (loss of water), *d) Pernicious Anemia* (reduction in red cells, with a moderate increase in plasma), *e) Certain Chronic Anemias Other Than Those of the Pernicious Type* In these the total blood volume, as a rule, is not greatly below normal as calculated upon the basis of weight or of surface area *f) Obesity* The blood volume per kilogram of body weight is much reduced but is normal when considered in relation to the body surface *g) Myxedema* (reduction of both red cells and plasma but mainly of the former)

Increase. *a) Polycythemia Vera* (increase mainly of red cells but also of plasma), *b) Cirrhosis* of the liver (increase of plasma), *c) Leukemia* (increase in white cells and plasma), *d) Splenomegaly* with anemia—Banti's disease (increase in plasma), *e) Hyperthyroidism* (equal increases both in red cells and plasma), *f)* congestive heart failure (increase in plasma)

It should be pointed out that the proportions of red cells and plasma may vary from the normal though the total blood volume remains unaltered With regard to the blood volume and the proportion of cells to plasma there are therefore nine possible blood states

THE EFFECTS OF HEMORRHAGE

When more than 30% of the blood volume is lost rapidly, the body is usually unable to repair the loss unaided and, unless transfusion is resorted to, death results In a healthy man the loss of 30% or less of his blood calls readjusting mechanisms into play which may bring the blood volume back to the normal level within a remarkably short time, 500 ml or so of blood drawn for transfusion purposes are said to be replaced within an hour or so The restoration of the blood to its previous concentration in erythrocytes, however, takes about 7 weeks on the average This time may be shortened considerably by the administration of iron and a diet containing a liberal quantity of high quality protein Fowler and Barer found in a study of 200 blood donors that, after the removal of 550 ml of blood, the average fall in hemoglobin was 2 3 gm /100 ml Regeneration of hemoglobin occurred at the rate of 0 049 gm /100 ml for men and 0 040 gm /100 ml for women per day

The protective mechanisms which automatically come into action after hemorrhage are several and may be divided into two groups—*immediate* or *early* and *delayed*

Immediate or Early Effects. If the loss of blood is large, especially if it is of sudden occurrence and from an artery, there is a prompt fall in blood pressure as a result simply of the

reduction in circulating fluid If not too great the fall in pressure is salutary since it helps to prevent further bleeding A moderate loss of blood, 10% of the total amount, produces little or no drop in pressure This is especially true if the blood is lost gradually and if it comes from a vein i e beyond the peripheral resistance Under these circumstances compensatory mechanisms easily maintain the pressure of blood at its normal height Three main compensations relating to the vascular system occur *a)* reduction in the capacity of the vascular bed, *b)* increased peripheral resistance, and c) fluid entry from the tissues

Reduction in Capacity of the Vascular Bed and Redistribution of the Blood When the flow of blood has been stopped or considerably lessened by a complete or partial closure of the wound in the vessel, the blood pressure, if this had fallen, rises again This is the result mainly of a readjustment of the capacity of the vascular system, whereby it is made to conform more nearly to the lessened volume of blood It is this reduction in the vascular capacity which prevents the initial fall in pressure when the loss of blood is gradual It is effected by the reflex narrowing of innumerable small vessels (vasoconstriction) in regions such as the skin, mucous membranes, intestine, and other parts not immediately essential to life If the hemorrhage has not been too severe the reduction in the capacity of the vascular bed may result in maintenance of an adequate venous return and consequent maintenance of cardiac output and of arterial blood pressure If the hemorrhage is somewhat greater, then the venous return and cardiac output may fall, but the blood pressure may be maintained by an increase in peripheral resistance along with a reduction in the capacity of the arterial vessels If the hemorrhage is still greater, then the arterial blood pressure will fall and may be restored by restoration of blood volume through the entrance of fluid into the blood vessels from the tissues The vascular response is called into play by the underfilled state of the arteries and large veins feeding the heart (see vascular reflexes, sect. 3, chap 8)

These measures, whereby the blood remaining in the vascular system is confined to a smaller space are of the utmost importance, they enable the essential centers in the medulla to be supplied with blood under adequate pressure to sustain their vitality Also a greater quantity of blood than would otherwise be possible is brought to the heart to supply its muscle, fill its cavities and maintain the circulation The withdrawal of blood from the less important parts of the body is responsible, however for some of the characteristic manifestations of hemorrhage notably the pallor of the skin and mucous membranes and the coldness of the body surface The cerebral anemia causes sensations of giddiness or faintness, flashes of light or ringing in the ears (tinnitus)

Delayed Effects *Replacement of the Lost Fluid* This, it has already been mentioned, commences almost upon the instant that the blood is lost, but takes a variable length of time, depending upon the extent of the blood loss to become complete It occurs as a result of the low hydrostatic pressure within the capillaries Fluid from the tissues moves into the vessels and dilutes the blood The corpuscular concentration is therefore reduced and since fluid is entering the capillaries directly from the tissues and not by way of lymphatics, less protein is returned with the fluid from the tissues, and for a short time after hemorrhage the protein content of the plasma is markedly depressed Very soon, however, the concentration of protein in the plasma shows a rise again as a result of the mobilization of protein stores probably from the tissue stores The extreme thirst (sect 9, chap 7) which the subject of acute hemorrhage suffers is the call of the tissues for fluid and indicates that their own fluid stores are being drawn into the underfilled vessels The administration of water will therefore aid the body in recovering its water balance and replenishing the blood volume

Replacement of the Blood Cells finally occurs through the increased activity of the blood-forming organs This takes several days or weeks, the rapidity of the process depending to a large extent upon the nutrition and recuperative power of the individual and upon the diet as well as the amount of blood lost While the repair process is in progress reticulocytes are found in increased numbers in the blood

Interchange of Fluid Between the Tissues and Capillaries

The physical factors which determine the flow of fluid from the tissues into the blood stream as well as in the reverse direction—from the vessels to tissue spaces—are the *os-*

motic and *hydrostatic pressures* of the fluids in the two situations *Osmosis* is diffusion through a membrane separating water—or an aqueous solution—to which the membrane is permeable, from another aqueous solution to whose dissolved materials the membrane is impermeable Such a membrane that permits the passage of water or of some substances in solution, but acts as a barrier to the molecules of certain other substances, is called *semipermeable* Osmosis is explained in section 1, chapter 2

Isotonic, *hypertonic*, and *hypotonic* are terms employed to denote the osmotic activity of a solution as compared to that of some other solution If, for example, two salt solutions of equal strength are separated by a semipermeable membrane neither will develop an osmotic pressure, they are said to be *isotonic* If the solution on one side of the membrane is stronger, the net amount of water passing to this side will therefore be greater and the solution here is said to be *hypertonic* The weaker solution from which there is a net transference of water is termed *hypotonic*

In physiology these terms are used most commonly to indicate the osmotic activity of a solution as compared with that of the body fluids For example, excised organs or sections of tissue upon which experiments are to be performed are kept moist and viable by a saline solution isotonic with the tissue fluid Shrinkage of the cells through the loss of water (as would result from the use of a hypertonic solution) or swelling by endosmosis (as would occur if the solution were hypotonic) is thus avoided Similarly, in order to prevent either shrinkage or swelling of the red blood cells, they must be suspended in a solution, such as plasma, that is isotonic with the fluid in their interiors This subject is reviewed in chapter 6 of this section

The other important factor in the interchange of fluid between the blood and the interstitial (and hence, the intracellular) fluid is the *hydrostatic pressure* within the capillaries, i e , the intracapillary blood pressure and its relation to the pressure in the tissue around these small vessels The concept that fluid exchange across capillary membranes is governed by the net difference between the osmotic and the hydrostatic pressures is known as the Starling (1896) hypothesis or principle.

THE RELATION OF OSMOTIC TO HYDROSTATIC PRESSURE ACROSS THE CAPILLARY MEMBRANE

The walls of the capillaries (generally throughout the body, as already mentioned) permit the free passage of water and substances of small molecular size dissolved in the plasma, e g , glucose, inorganic salts, urea, etc But, the capillary wall is relatively impermeable to the larger molecules such as the plasma proteins, the presence of which is responsible for the difference in osmotic pressure on the two sides of the capillary membrane It is important to recognize that some protein molecules do penetrate capillary membranes Since the albumin has the smallest molecule of the three plasma proteins, it escapes through the vessel in relatively greater amounts than do the globulin and fibrinogen fractions By the use of ^{131}I labeled albumin, it has been found that the amount of plasma protein passing through the capillary wall into the interstitial fluid is considerable, amounting to more than the total protein of plasma each day The rate of return of protein from interstitial fluid is very important in the maintenance of plasma protein levels The lymphatic system plays a major role in this return (chap 9)

The manner in which osmotic and hydrostatic pressures act in regulating the interchange of fluids between the tissues and the muscles may now be seen The blood at the arterial end of a capillary has a pressure, let us say, of 30 mm Hg (this is an arbitrary figure and will vary according to the activity of the part) This is a force driving the water and the dissolved crystalloids through the capillary membrane But the hydrostatic pressure of the tissue fluid on the outer side of the membrane offsets, in part, that within The pressure of fluid in the tissue spaces is difficult to determine but it is considerably less than that in the capillaries It probably varies considerably in different regions, being low in those containing much loose areolar tissue But for illustration let it be assumed to be 10 mm Hg The hydrostatic pressure, therefore, which is effective in forcing fluid out of the vessel (filtration pressure) is only the difference between the pressure within and that on the outside of the vessel, namely, 20 mm Hg But the osmotic pressures of the plasma and tissue fluids

must be taken into account In the plasma it amounts to about 25 mm Hg The tissue fluids have a lower protein content and consequently a lower osmotic pressure The latter amounts to about 15 mm Hg Owing to this disparity of 10 mm Hg between the osmotic pressures of plasma and tissue fluid, there would be a net tranference of water and diffusible substances inwards across the capillary membrane if such transference were unopposed by any other force But a net hydrostatic pressure of 20 mm Hg is set against it at the arterial end of the capillary leaving a balance amounting to 10 mm Hg which serves to filter water, salts, etc, and a little protein out of the plasma Now as the blood flows rather slowly through the capillary and loses water in this way by filtration, the protein concentration and consequently its osmotic activity, rises Coincidently with the progressive rise in osmotic activity the hydrostatic pressure declines, until at the venous end of the capillary there may be a balance of net osmotic pressure over net hydrostatic pressure Water accompanied by freely diffusible materials is therefore absorbed into the circulation This picture of filtration at the arterial end of the capillary and absorption at the venous end is going on continually at the periphery of the vascular bed But it is subject to considerable variation, not only in the same capillary from time to time but in different parts of the peripheral circulation at any moment As explained in chapter 9, when a tissue is active most of the water that escapes from capillaries is returned to the circulation via the lymphatics

Table 4 25
Pressures that move fluid

Blood		Tissue Fluid
Hydrostatic pressure 30 mm Hg		*Hydrostatic pressure* 10 mm Hg
Effective hydrostatic pressure 20 mm Hg	Capillary wall	
Osmotic pressure 25 mm Hg		*Osmotic pressure* 15 mm Hg
Effective osmotic pressure 10 mm Hg		

[a] Driving force → 10 mm Hg (20 – 10)

As the blood flows through the capillary as a result of the passage of water outwards there is a consequent rise in the concentration of protein Moreover the metabolic processes in the tissues bring about changes, whereby larger molecules are being broken down into smaller ones other molecules are removed or built up into larger ones In this way alterations in molecular concentrations and in the diffusibility of the constituents of the tissue fluids with consequent variations in osmotic relationships are occurring ceaselessly The actual exchange of water across the capillary wall is rapid Studies with deuterium and tritium-labeled water indicate that in 1 min an amount equal to the total plasma water is exchanged

Under any circumstance in which the blood volume is increased or diminished, either the hydrostatic pressure or the osmotic pressure or both are altered, and it is through such changes that the blood fluid tends to be restored automatically to its previous level After hemorrhage, for example, the hydrostatic pressure is lowered in the capillary area but the osmotic pressure is unchanged Fluid will therefore be absorbed from the tissue spaces Moreover constriction of the capillaries tends to reduce, dilation to increase the capillary pressure Therefore, the capillary constriction which follows a severe hemorrhage will slow the filtration rate at the arterial end of the capillary and increase absorption of interstitial fluid at the venous end Again, when water is drawn from the blood, in consequence of excessive loss of fluid by the kidney, sweat glands, or bowels, concentration of the plasma proteins will result The increased osmotic pressure of the plasma will then hasten the rate of absorption from the tissues The intravenous injection of large quantities of isotonic saline, on the other hand, will have the twofold effect of diluting the colloids and temporarily increasing the hydrostatic pressure The excess fluid in consequence is rapidly eliminated from the blood stream into the tissues and later through the kidney and bowels

The Excretion of Urine

5 URINE FORMATION

Introduction

STRUCTURE OF THE HUMAN KIDNEY

The functional unit of the kidney is the *nephron* (Fig 5 1), each kidney being composed of approximately one million such units The nephron begins at a blind end enclosing a leash of capillaries In this structure, known as the *glomerulus* (*renal corpuscle, Malpighian corpuscle*), urine formation begins by the separation, from the blood perfusing the glomerular capillaries, of an essentially protein-free filtrate of plasma The glomerular space or *Bowman's capsule* is continuous with the lumen of the *renal tubule*, a long coiled structure structurally and functionally divisible into three segments proximal convoluted tubule loop of Henle, and distal convoluted tubule The nephron as an individual unit ends with the distal convoluted tubule, but groups of distal convoluted tubules empty into a series of *collecting tubules*, which in turn coalesce to form *collecting ducts* The collecting ducts in turn empty into the short *papillary ducts of Bellini* which open into the renal calyces at the tips of the papillae

The glomerulus consists of a leash of capillaries interconnected by short anastamotic channels These capillaries are invaginated into and covered on their outer surfaces by the visceral layer of the epithelium of Bowman's capsule This layer of flattened cells is continuous with the parietal layer of epithelium and with the lining cells of the renal tubules Blood enters the glomerulus from the short afferent arteriole, and the coalescence of the glomerular capillaries forms the efferent arteriole, the glomerular capillaries are thus unique in being interposed between two arterioles. The glomerulus averages about 200 μm in diameter and the total surface of glomerular capillaries in the two human kidneys is estimated to be about 1.5 m.^{2}. The glomeruli are found only in the cortex.

The proximal convoluted tubule is a tortuous structure averaging about 55 μ in diameter and 14 mm in length It lies in the renal cortex usually in close proximity to the glomerulus to which it is conjoined It is lined with a single layer of cuboidal cells, each interdigitated with the adjoining cells in a highly complex manner The border facing the tubule lumen is characterized and distinguished from that of other segments by delicate villiform projections which constitute what is known as the brush border The terminal portion of the proximal tubule becomes straight and dips toward the medulla to become the loop of Henle

The loop of Henle commences with a descending limb which dips down into the medulla As it does so, the cuboidal cells are suddenly replaced by the flattened cells of the *thin segment* The loop penetrates into the medulla for a varying distance, the depth depending upon the location of the glomerulus from which the tubule is derived Those loops derived from tubules with glomeruli situated near the surface of the kidney penetrate only a short distance into the medulla before turning back toward the cortex, those arising from tubules with glomeruli close to the corticomedullary junction (*juxtamedullary glomeruli*) penetrate deeply to near the tip of the papilla before turning back The first part of the ascending limb does not differ in general appearance from the thin portion of the descending limb, but as the ascending limb reaches the outer medullary zone it widens and becomes lined with a cuboidal epithelium which continues into the distal tubule The tubule continues into the cortex and comes into contact with the glomerulus from which it arose, this contact being marked by a region of closely packed nuclei designated as the *macula densa*

The distal convoluted tubule may be defined as beginning at the macula densa Like the proximal tubule with which its loops are generally entwined, the distal convoluted tubule lies in the cortex It is distinguished by

tain substances from the peritubular blood and deposits them in the fluid within the lumen Thus, three individual processes, glomerular filtration, tubular reabsorption (from lumen to blood), and tubular secretion (from blood to lumen) are involved in the process of urine formation These three processes will be considered in detail in subsequent sections

Glomerular Filtration

The idea that the glomerulus is a device for filtering fluid from the blood perfusing the glomerular capillaries goes back to Bowman who in 1842 first described the relationship of the glomerular capsule to the renal tubules Bowman believed that only the water of the urine was contributed by this filtration process, the solutes being added by secretion in the tubule Shortly thereafter Ludwig (1844) offered the view, which has since been amply confirmed, that the glomerulus acts as an ultrafilter, separating from the plasma a solution which contains all of the solutes of plasma except the proteins and each at a concentration identical to that in the plasma water except as modified by the absence of protein The cornerstones of the evidence indicating that the glomerulus is indeed an ultrafilter were supplied by A N Richards and his associates who showed that the composition of fluid collected from glomeruli in amphibians was, with respect to an extensive list of constituents, that required of a plasma ultrafiltrate The studies were later extended, with respect to a limited number of substances, to fluid collected directly from mammalian glomeruli by Walker and co-workers (1941) In addition it was shown that the hydrostatic pressure in the glomerular capillaries is sufficient to supply the driving force for the filtration process

VARIABLES THAT AFFECT FILTRATION

As in the case of other capillary beds, and in accord with the Starling hypothesis, the rate of filtration through the walls of the glomerular capillaries is determined by a balance of forces favoring and opposing filtration The main driving force is the hydrostatic pressure—the intracapillary blood pressure (P_b) Opposing filtration is the osmotic pressure exerted by the plasma proteins (π_b) and the hydrostatic pressure of the fluid in Bowman's capsule (P_c) The rate of glomerular filtration (GFR) may thus be expressed as

$$GFR = K_p([P_b - P_c] - \pi_b) \quad (1)$$

where K_p is a constant relating net filtration pressure to filtration rate and thus related to the area and the permeability of the glomerular capillary walls

The glomerular capillaries differ from those of other capillary beds in being interposed between two arterioles, in maintaining a higher hydrostatic pressure, and in having a higher permeability Pappenheimer and his associates (1951) have estimated that the permeability of glomerular capillaries is approximately one hundred times that of the capillaries in the limbs (muscles), the difference is presumably largely in the fraction of the total capillary surface occupied by the pores through which filtration actually occurs The membrane which constitutes the significant filtration resistance and which is penetrated by the pores of critical size is probably the capillary basement membrane

Some idea of the size of the pores can be obtained from the characteristics of those solutes that are filtered through the glomerular capillary membrane as compared with those that are not The normal glomerular membrane is virtually completely impermeable to the proteins of plasma The smallest of these, albumin, has a molecular weight of about 70,000 and appears in the glomerular filtrate either not at all or at a very low concentration (less than 0 2 to 0 3% of its concentration in plasma) Recent measurements in samples from the early part of the dog proximal tubule indicate that the concentration is usually less than 5 mg/100 ml Hemoglobin (molecular weight 68,000), on the other hand, is excreted at a rate which would indicate that it appears in glomerular filtrate at a concentration equal to about 5% of its concentration in the plasma. (The concentration referred to is that not combined, in the plasma, with larger protein molecules.) The hemoglobin molecule is somewhat less elongated than the albumin molecule, but the difference is relatively small In any case, it is clear that the pores in the glomerular membranes cannot be far removed in size from the dimensions of these molecules

Also pertinent is the passage through the

glomerular membrane of certain polysaccharides. Most important among these is inulin, a polymer of fructose which has found a central role in the study of renal function. Its molecular weight is usually estimated to be 5200, but different inulin molecules probably differ in size, some being smaller, others larger. In addition the molecule is greatly elongated, a characteristic which reduces its diffusibility and filtrability compared to a compact molecule of the same molecular weight. Nevertheless, the glomerular membrane appears to offer no hindrance to the passage of inulin, and its concentration in glomerular filtrate is the same as in the plasma from which the filtrate is derived. Dextrans (polysaccharides composed of glucose) of a molecular weight approximately equal to that of inulin have been found to pass the glomerular membrane freely, but their passage is progressively restricted as their molecular weight increases and those with molecular weights above 55,000 do not appear in the urine from normal kidneys (i.e., kidneys producing protein-free urine) (Wallenius, 1954).

Although different theoretical treatments will yield different dimensions for the size of the pores in the glomerular membrane, the permeability can be interpreted as attributable to pores approximately 100 Å in diameter.

Equation (1) indicates that glomerular filtration is a function of three variables as well as the area and permeability of the glomerular membrane. It is important to consider the possible contribution of changes in each of these to the physiological regulation of glomerular filtration.

The Glomerular Membrane *1) Permeability.* The permeability of the glomerular membrane per unit of functioning surface is presumably fixed by its anatomical nature and not subject to physiological variation. Although changes do occur with disease, the effect of change in permeability as opposed to change in effective filtering area is difficult to evaluate. The diseased membrane may permit the passage of molecules larger than those which normally penetrate, but the predominant effect appears to be a decreased permeability.

2) *Area.* The effective area available for filtration depends upon the number of glomeruli active at any time and the number of functioning capillaries in the glomeruli. The [illegible] in the number of functioning glomeruli [illegible] are [illegible]. In the interpretation [illegible] and there are those who believe that variation in the number of glomeruli contributing to the formation of urine is a major factor in determining the rate of glomerular filtration. Subsequent treatment of the subject in this section will be based on the assumption that all the glomeruli are continuously involved in the formation of glomerular filtrate.

Capillary Blood Pressure (P_c). The major variable in the regulation of the rate of glomerular filtration is the pressure within the glomerular capillaries. The pressure at which blood enters the afferent arterioles is not much lower than that in the aorta, the decrease in pressure between aorta and glomerular capillaries is largely determined by the resistance of the afferent arterioles. Thus other factors remaining equal, constriction of the afferent arterioles will decrease and dilatation will increase glomerular filtration. The effect of changes in the caliber of the efferent vessels is in general the converse of parallel changes in the afferent vessels.

It is to be noted that it is the *pressure not the blood or plasma flow*, in the glomerular capillaries which determines glomerular filtration rate. Thus the rate of glomerular filtration need not bear any particular relationship to the cardiac output. A low level of cardiac output is, at least in theory, quite compatible with a normal rate of filtration provided this output is sufficient to maintain a normal blood pressure and provided that renal vasoconstriction is not a part of the general vasoconstriction necessary to maintain the normal arterial pressure.

Although the renal nerves play a role in the regulation of the renal arteriolar resistances and thus in the maintenance of a stable rate of glomerular filtration (and, particularly in man, this function is maintained at a remarkable constant level under normal conditions), the nerves are not essential to this stability. The kidney even when totally isolated, shows only slight changes in glomerular filtration rate (and blood flow) as perfusion pressure is varied over a wide range. This process, frequently designated by the term autoregulation, has at-

tracted considerable interest among physiologists It is probably attributable to spontaneous adjustments of the arteriolar resistances

Intracapsular Hydrostatic Pressure (P_c) Under ordinary conditions variations in the pressure within Bowman's capsule probably contribute little to changing glomerular filtration rate With ureteral obstruction this pressure may rise until the rate of filtration is reduced to negligible levels, but such obstruction does not, of course, occur under normal circumstances It is also likely that in the extremes of solute diuresis produced experimentally, the pressure required to drive the greatly increased flow of urine against the resistance offered by the tubules may be sufficient to reduce filtration

Colloid Osmotic Pressure of the Plasma Proteins (π_c) The osmotic effect of the plasma proteins is the equivalent of a hydrostatic pressure of some 25 to 30 mm Hg opposed to glomerular filtration Glomerular filtration must, therefore, cease when the net hydrostatic pressure across the capillary membrane falls to this level Although this osmotic effect is large enough for changes to exert appreciable effects on net filtration pressure, it is doubtful whether such changes contribute significantly to the physiological regulation of glomerular filtration Experimentally, it can be shown that sudden dilution of the plasma proteins by the administration of isotonic sodium chloride solution produces an increase in glomerular filtration and urine flow (dilution diuresis) but the changes are small compared to those which can be produced experimentally in other ways

MEASUREMENT OF GLOMERULAR FILTRATION RATE

The difference between the rate at which a substance is filtered at the glomeruli and the rate at which it is excreted in the urine represents the rate at which the substance is removed from or added to the urine as the latter traverses the renal tubules The rate at which a substance is filtered is given by the product of its concentration in the plasma (or more accurately, the concentration of unbound substance in the plasma water) and the rate of formation of glomerular filtrate The rate of excretion is easily determined as the product of urine flow and the concentration in the urine of the substance in question Thus the measurement of glomerular filtration rate plays a central role not only in the evaluation of glomerular filtration itself, but in the assessment of the processes of reabsorption and secretion as well

The rate of glomerular filtration can be determined if there is some substance which is neither reabsorbed nor secreted by the tubules and if the concentration of this substance in the glomerular filtrate can be deduced from its concentration in the plasma If a substance is neither reabsorbed nor secreted as the urine flows through the tubules, then, in the steady state, the rate of excretion of the substance must be the same as the rate at which it is filtered Given the rate at which the substance is filtered and its concentration in the filtrate the volume of the filtrate can be calculated

For example, consider some substance X which we will assume has the requisite characteristics of 1) being freely filterable at the glomeruli, 2) being neither reabsorbed from nor excreted into the tubule lumen Suppose we measure the flow of urine over a 10-min period during which 20 ml of urine are collected to yield a flow (V) of 2 ml /min

The concentration (U_x) of substance X in the urine is determined and found to be 120 mg /ml

The rate of excretion, then, is given by the product of flow and concentration

$$U_xV = 120 \text{ mg /ml} \times 2 \text{ ml /min} = 240 \text{ mg /min}$$

Since for substances which are neither reabsorbed nor secreted the rate of excretion is equal to the rate of filtration, the rate of filtration of substance X is also 240 mg /min But the rate of filtration of a substance is equal to the product of the rate of formation of filtrate (GFR) times the concentration of the substance in the filtrate which, in this case, is defined above as being the same as the concentration in the plasma (P_x) Assume the concentration in the plasma in this case is determined and found to be 2 mg /ml

Thus, the rate of filtration of X is the product GFR $P_x = U_xV$ and

$$\text{GFR} = \frac{U_xV}{P_x} = \frac{240 \text{ mg /min}}{2 \text{ mg /ml}} = 120 \text{ ml /min}$$

The desirability, for the evaluation of renal function, of a substance which fulfills the criteria for measuring glomerular filtration is apparent It is generally accepted that *inulin*, a starchlike polymer of fructose obtained from

dahlia tubers, has the requisite characteristics and can be used for the measurement of glomerular filtration in all vertebrates including man (Shannon, 1935, Shannon and Smith, 1935, Richards, et al , 1938)

Use of the Term Clearance The expression U_xV/P_x denotes a quantity which is generally referred to as the *clearance* of substance X and abbreviated C_x As can be seen, it is the volume of plasma needed each minute to supply the substance in question at the rate at which it is excreted in the urine It is thus a measure of the efficiency of the kidney in the excretion of a particular substance, the larger the value of its clearance, the more effectively it is excreted The term is derived from the fact that one may consider the clearance to be that volume of plasma which completely yields its content for excretion and is thus cleared of the particular substance each minute Some confusion arises when the latter concept of clearance is used since the volume cleared of a particular substance is usually virtual rather than real The same clearance is obtained if 50 ml of plasma yield all of their content, if 100 ml lose half or 200 ml yield one-fourth

The clearance of a substance such as inulin is the volume flow of glomerular filtrate By comparison of the clearance of any other substance with that of inulin we may infer the nature of the processes involved in its excretion If it is filtered but neither reabsorbed nor excreted by the tubules, its clearance must be identical with that of inulin If its clearance is lower, it must be reabsorbed from the tubules, if higher, it must be secreted by them

Thus, if P_x is the concentration of X filterable in the plasma, T_x the amount of X which is secreted into or reabsorbed from the tubule each minute and C_{In} the inulin clearance taken as equal to the rate of formation of glomerular filtrate, then,

$$C_{In}P_x = \text{filtered X}$$

$$C_{In}P_x + T_x = \text{excreted X} = U_xV$$

(where T_x will have a negative value if X is reabsorbed from the tubules)

Then

$$C_{In} + (T_x/P_x) = U_xV/P_x = C_x \qquad (2)$$

It can be seen from equation (2) that if for any reason the capacity of the tubule (T_x) to reabsorb or secrete a particular substance is limited, the clearance of that substance will approach the rate of glomerular filtration as the plasma concentration is progressively increased, since as P_x approaches infinity, the term T_x/P_x approaches zero It will be shown that this is the case with most substances transported by the renal tubules

Rate of Glomerular Filtration in Man. The clearance of inulin in a man of average size under normal basal conditions (except for the water usually administered during the determination of such clearances) averages slightly in excess of 125 ml /minute It is customary, in order to compare individuals of varying size, to normalize the clearance values by "correcting" them to what is generally considered an average normal value of body surface area, 1 73 m^2 Women have glomerular filtration rates some 10% lower than those found in men even after "correction" to the same value of surface area

The large value for the rate of formation of glomerular filtrate emphasizes the similarly great magnitude of many of the processes of reabsorption carried on by the renal tubules Thus, if we assume that the rate of 125 ml /min is maintained throughout the day we may calculate that some 7 5 liters are filtered each hour or 180 liters/day in an individual of normal size Since ordinarily such an individual will excrete only a liter or two of urine in a day, it is clear that an amount approaching 180 liters is also reabsorbed The total body water of a 70 kg man is of the order of 45 liters, so that on the average all of the body water is filtered into the renal tubules and reabsorbed four times each day On the same basis we may calculate that the extracellular fluid (approximately 12 liters) is filtered and reabsorbed some 15 times/day, the plasma volume (roughly 3 liters) some 60 times

We may further multiply this volume by its content of the various filtrable solutes of plasma to estimate the amounts of these filtered and by comparison with the amounts excreted in the urine, calculate the amounts of each reabsorbed Illustrative data are indicated in Table 5 1. It is apparent from this table that very large quantities are turned over by the kidney each day and that only a small percentage departure from normal in the process of reabsorption could result in very large changes in excretion.

Other Measures of Glomerular Filtration. In man, except for inulin, no substance has

Table 5 1

Uric acid	8 5	50	0 8	5	7 7	45

[a] These are typical normal values Wide variation is found depending on diet

been found which can be considered to give an accurate and reliable value for the rate of glomerular filtration Approximations can be made using one of several substances, and such approximations are useful for comparative purposes but not for the evaluation of tubular reabsorptive and secretory processes Most commonly the creatinine clearance is used and gives a value, under most conditions, not too different from the clearance of inulin

This is probably the result of compensating errors, since creatinine is excreted into the lumen by the tubules of the human kidney It is possible that it is also reabsorbed and in addition the methods usually used for determining the concentration of creatinine in plasma are not specific and include small amounts of other substances which apparently are reabsorbed Under some conditions, particularly in the presence of renal disease, the departure of the creatinine clearance from the rate of glomerular filtration may be considerable

Other substances which have been used to approximate the rate of glomerular filtration in man are certain hexitols (mannitol, sorbitol, dulcitol), particularly mannitol (Smith et al, 1940) and allantoin The mannitol clearance is about 10% lower than the clearance of inulin, indicating that about 10% of the filtered mannitol is, on the average, reabsorbed (Berger et al, 1947)

A fairly close approximation to the rate of glomerular filtration can be obtained through the use of vitamin B_{12} labeled with radioactive cobalt Although vitamin B_{12} is bound to plasma proteins, the binding capacity is relatively small and can be saturated by the administration of a moderately large dose of non-radioactive B_{12} Consequently the bound becomes a negligible fraction of the total plasma B_{12} and, since there is no measurable reabsorption or secretion of B_{12}, the clearance is close to the filtration rate (Nelp et al, 1964)

In many lower mammals, as well as in amphibians, the creatinine clearance does not have the limitations which reduce its usefulness in man The clearance of creatinine is, for practical purposes, identical with that of inulin in the dog, cat, and rabbit

Tubular Reabsorption

The quantitative importance of the process of reabsorption in the renal tubules has been indicated above by the magnitude of the amounts of material involved An understanding of the nature of the mechanisms by which this reabsorption is effected is essential to a grasp of the function of the kidney

MECHANISMS OF REABSORPTION

The processes involved in tubular reabsorption are divided into two categories, passive and active (Ussing, 1949)

Passive Reabsorption. It is clear that the volume of the urine is greatly reduced as it flows through the tubules If, in the course of this reduction in volume, some solute is retained in the lumen to a greater extent than water, its concentration will rise above that in the glomerular filtrate and above the concentration in the plasma and interstitial fluid which surround the tubules A concentration gradient for the substance is thus created between the lumen and the environment of the tubule and, provided the tubule is permeable to some extent to the substance in question, it

will diffuse from the lumen of the tubule to interstitial fluid and blood This type of process is designated by the term *passive reabsorption* and is typified by the reabsorption of urea, the excretion of which will be considered in more detail later

More generally, the movement of any substance across a biological membrane (in this case the complex membrane is the renal tubule epithelium) is considered *passive* when it can be explained entirely by gradients of concentration and/or (in the case of charged particles) gradients of electrical potential In such a context, the movement of urea is a passive process requiring no mechanism in the tubule cells specific for urea and no expenditure of energy by the tubule cells for the movement of urea itself However, it should be noted that work must be done to raise the urea concentration so that it may diffuse out passively It will be shown that in this instance the primary active process is the removal of salt from the lumen by the activity of the tubule cells, the movement of water is the passive consequence of the transport of salt and the movement of urea is in turn secondary to the movement of water

Active Reabsorption The reabsorption of many substances from the renal tubules cannot be explained by gradients of concentration or electrical potential The process involved in the movement of these solutes is designated as *active reabsorption* The best known and possibly simplest example of an active reabsorptive process is probably that for glucose A consideration of glucose reabsorption will illustrate the characteristics of these mechanisms

ACTIVE REABSORPTION THE REABSORPTION OF GLUCOSE

Under normal conditions approximately 100 mg of glucose are filtered at the glomerulus each minute Of this, none but the merest trace is excreted in the urine Clearly, the transport of glucose is effected against a *concentration gradient* and, since glucose carries no electrical charge, its transport is, by definition, *active*

If the concentration of glucose in the plasma is progressively increased, it is found that, for a time, the urine remains free of glucose However, when a sufficiently high plasma glucose concentration is reached, glucose appears in the urine in appreciable quantities Further increments in plasma glucose concentration are then accompanied by proportional increments of glucose excretion The basis for the relationship of plasma glucose concentration and glucose excretion becomes clear when the glomerular and tubular events are analyzed by the simultaneous determination of glomerular filtration rate (inulin clearance) From the product of inulin clearance and plasma glucose concentration,[1] the filtered glucose is calculated, the difference between filtered and excreted glucose is the amount reabsorbed It is then found that as the plasma glucose concentration increases (the filtered glucose of course, increasing proportionately) the reabsorbed glucose increases remaining equal to the filtered, until a limiting value of glucose reabsorption is reached As the filtered glucose increases beyond this level there is no further increase in glucose reabsorption and the excess glucose is excreted in the urine (Shannon & Fisher 1938) These relationships are illustrated in Figure 5 3 The relationship among the various quantities is expressed by the equation

$$U_G V = C_{In} P_G - T_G$$

where T represents the amount reabsorbed per minute from the tubule and the subscripts G and In refer to glucose and inulin respectively

T_G is seen to increase, remaining equal to the filtered glucose (frequently referred to as the *load* or *filtered load*), until T_G reaches a maximum This maximum, which represents the capacity of the tubules to transport glucose, is conventionally designated as the glucose T_m or T_{mG} The existence of such a limited capacity subject to saturation is a characteristic feature of active transport processes and is one of the criteria by which they may be identified

The limitation which characterizes the transport mechanism involved in glucose reabsorption and other similar mechanisms is believed to derive from the involvement of a "carrier" in the process In this view, the tubule cell membrane is virtually impermeable to glucose in the free state However, the

[1] In determining the amount filtered in the case of substances, such as glucose, which are rapidly metabolized by the tissues, it is important to measure the arterial plasma concentration, since the venous concentration may be appreciably lower and since it is arterial plasma from which glomerular filtrate is derived

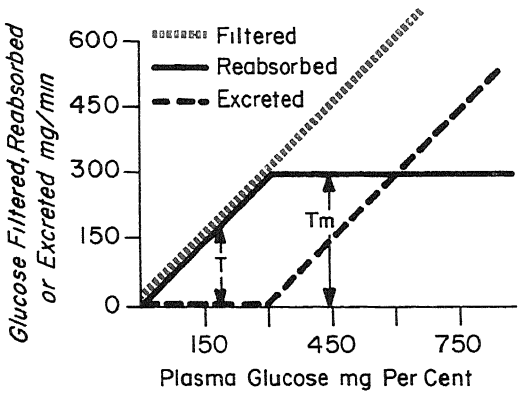

Fig 5 3 Diagramatic and idealized representation of the relationship among filtration reabsorption and excretion of glucose The figures are calculated on the assumption that glomerular filtration rate was 100 ml per minute

membrane contains certain molecules which can combine reversibly with glucose, and in this state the glucose, now in combination with its carrier, is able to penetrate the membrane Having reached the inside of the tubule cell, the carrier-glucose complex dissociates releasing free glucose which, we may assume, is free to diffuse out of the cell into the peritubular fluid and blood The carrier is then available to repeat the process

The reactions involved may be represented

$$A + B \overset{(1)}{\rightleftharpoons} AB \overset{(2)}{\rightarrow} T + B$$

where A is glucose in the tubule lumen, B the carrier, AB the glucose-carrier complex and T the glucose which has been transported (e g , into the tubule cell) Some step in the process requires an input of energy since the expenditure of energy is necessary to drive the reaction "uphill" from the low concentration in the lumen to the higher one in the cell This energy might be involved in driving reaction (2) or possibly the carrier might be modified in the transport process and require activation before it can again combine with glucose in the lumen. When the mechanism is saturated, all the carrier is interpreted as in the combined state AB and the maximum rate of transport (T_m) reflects the total amount of carrier in the tubule cells and the rate constant for the dissociation of AB to yield B and T Although, theoretically, the rate of such transport processes could be limited by the amount of energy available to drive them, there is no evidence that this actually occurs, and the same tubule cells are able simultaneously to carry out the transport of a number of solutes among which there is no mutual interference

Although the existence of carriers with the properties described is fairly generally accepted, it should be noted that none has ever been isolated or identified chemically The interaction between carrier and transported substance may be considered analogous to that between an enzyme and its substrate, in fact the reactions suggested above correspond to those to which the kinetic behavior of enzymatic reactions is attributed Transport reactions also show certain other characteristics of enzymatic reactions, particularly in being subject to inhibition, both competitive and noncompetitive

The glucose transport mechanism is fairly specifically inhibited by the glycoside, *phlorizin.* The administration of this inhibitor in adequate dosage completely abolishes glucose transport so that the clearance of glucose becomes equal to the glomerular filtration rate This property is also shared by the glycoside of the adrenocortical steroid, desoxycorticosterone Several monosaccharides (e g , xylose, fructose, and galactose) are reabsorbed to some extent apparently by the same transport mechanism responsible for the reabsorption of glucose, and their reabsorption is also inhibited by phlorizin

Micropuncture studies have clearly shown that the reabsorption of glucose occurs high in the proximal convoluted tubule and that when the plasma glucose concentration is normal the glucose has largely been removed before the urine reaches the middle of the proximal tubule (Fig 5 4)

In human beings, the normal capacity to reabsorb glucose (glucose T_m) averages approximately 375 and 300 mg /min /1 73 m ^{2} of body surface area in men and women, respectively If we compare the capacity to reabsorb glucose with the rate of glomerular filtration we may deduce what concentration of glucose in the plasma would be required to yield enough filtered glucose to saturate the glucose T_m Since the average normal rate of glomerular filtration is 125 ml /min it is apparent that a plasma glucose concentration of 3 mg /ml or 300 mg /100 ml is required to yield a filtered load equal to reabsorptive capacity of 375 mg./min. From the idealized and oversimplified diagram of excretion and reabsorption versus load plotted in Figure 5.3 it would be predicted that *no* glucose should appear in the

urine until the plasma glucose is 300 mg /100 ml , at that point, filtered load should be exactly equal to reabsorptive capacity and reabsorptive capacity should be fully saturated Further increases in plasma glucose should give no increase in glucose reabsorption In actual practice this is not the case In Figure 5 5 is reproduced the observed relationship between plasma glucose (filtered glucose) and excretion and reabsorption in normal man It is seen that glucose begins to appear in the urine when the filtered glucose is only about three-fourths of the capacity of the tubules to reabsorb and that the reabsorption does not reach its maximum rate until the amount filtered is some 50% greater than this maximum

The departure from the idealized relationship is due to two factors Two assumptions are implicit in the construction of the idealized relationship, and neither is completely valid *1*) each tubule reabsorbs all the glucose presented to it until its capacity is fully saturated, and *none* of the filtered glucose escapes reabsorption until saturation is achieved, and *2*) all of the tubules are functionally identical so that the kidney may be looked upon as a single nephron We may now consider why these assumptions are valid only as first approximations

The hypothetical basis of transport in terms of the formation of a substrate-carrier complex was presented above The initial reaction is visualized as the reversible formation of the complex

$$A + B \rightleftharpoons AB$$

If we write the mass action expression for this reaction, we obtain

$$K = [A][B]/[AB]$$

where the brackets signify concentration and K is the dissociation constant for the substrate-carrier complex The smaller the value of K, the greater the affinity of the carrier for the transported substance

It is apparent from this that the residual (unreabsorbed) substrate will be very small only *1*) if the value of K is very small or *2*) when there remains an appreciable concentration of unsaturated carrier (B) Conversely (once the total A available is equal to the total transport capacity) there will be negligible unutilized transport capacity only *1*) when K is very small or *2*) when there remains a considerable amount of unreabsorbed substrate.

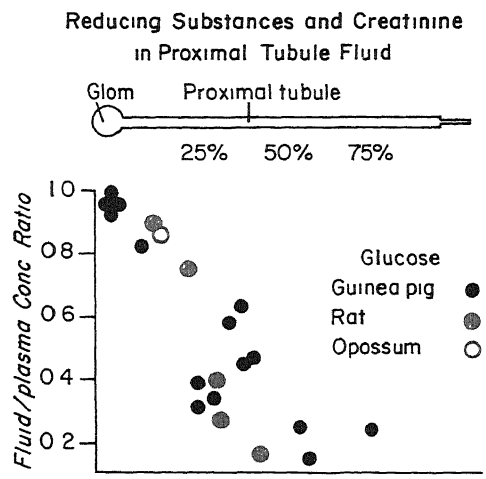

Fig 5 4 Chart showing concentration ratios of glucose between blood plasma and fluid collected from glomeruli and proximal tubules Sites of fluid collection can be identified by reference to the diagrammatic tubule (*top*) From Walker et al 1941

Thus, the relationship will approach the ideal as the value of K becomes infinitely small and for any finite value of K there will be some departure from the ideal (Fig 5 3) Actually among the various substances actively reabsorbed by the renal tubules there are varying degrees of departure from ideality presumably reflecting differences in the value of K The departure from ideality in the case of glucose is small compared to that for many other substances, suggesting a low value for the dissociation of the glucose-carrier complex

The type of relationship plotted in Figure 5 5 is commonly referred to as a *titration curve*, and the departure from the sharp break of the ideal relationship is called the *splay* of the titration curve

The nephrons are clearly not all identical nor is its reasonable to expect them to be so The heterogeneity of the nephron population which is pertinent to the shape of reabsorptive titration curves is heterogeneity of what is called *glomerulotubular* balance, that is, the relationship between the filtering capacity of the glomerulus and the reabsorptive capacity of the tubule attached to that particular glomerulus Thus if we deal with a tubule with an average capacity to reabsorb glucose but a filtration rate of twice the average, it will become saturated with glucose when the plasma glucose concentration is only half that required to saturate the average nephron Conversely nephrons with small glomerular filtering ca-

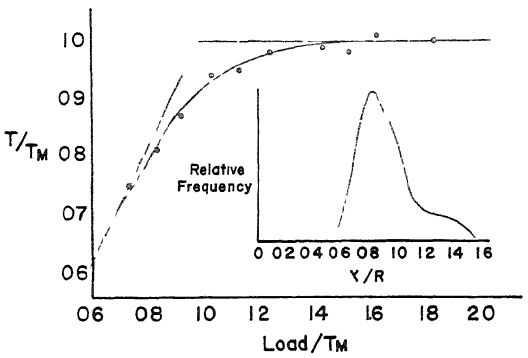

Fig 5 5 Titration of the capacity to reabsorb glucose Based on average data from 10 normal individuals The ordinate (T/T_m) is the ratio of glucose reabsorbed at a particular value of filtered glucose to the maximum capacity to reabsorb glucose in the same individual It is thus the fractional saturation of glucose reabsorptive capacity The abscissa ($load/T_m$) is the amount of glucose available for reabsorption again related to the capacity of the individual to reabsorb glucose

The frequency distribution curve shows the proportion of nephrons having various ratios (r) of filtration rate to reabsorptive capacity as related to the average of this ratio (R) for the two kidneys as a unit

The data are those of Smith Goldring Chasis Ranges and Bradley 1943

pacity and large reabsorptive capacity will become saturated only when the plasma glucose is much higher than that which would saturate the average nephron

The titration curve in Figure 5 5 can be analyzed to yield the distribution of glomerular activity in relation to glucose reabsorptive capacity if it is assumed that the titration curve in each individual nephron is ideal (that is, if the kinetic contribution to splay is disregarded). What is obtained is a distribution of the ratios of filtration to reabsorption for the nephron population as these ratios relate to the average ratio for the kidneys taken as a unit This distribution curve, included in Figure 5 5 indicates that in the normal human kidney no appreciable number of nephrons has a ratio of filtration to reabsorption of glucose departing more than 50% from the average

The earlier literature on the physiology of the kidney divides substances which may appear in the urine into *threshold* and *no-threshold substances*. A threshold substance was one which did not appear in the urine until its concentration in the blood exceeded some value, this value being designated as the renal threshold No-threshold substances were those which appeared in the urine at all concentrations in the plasma Clearly glucose (and most other substances actively reabsorbed by the tubules) would fall in the category of "threshold" substances However, with improvements in the methods of study of renal function, this terminology has in large measure lost its usefulness, and it is greatly preferable to consider the specific mechanisms involved in the excretion of a particular substance and the quantitative aspects, formerly subsumed in the "threshold," in terms of the rates of filtration, reabsorption and secretion

OTHER SUBSTANCES ACTIVELY REABSORBED BY THE TUBULES

The reabsorption of glucose is the prototype of a number of reabsorptive processes which are qualitatively similar In several instances the site of reabsorption has been identified, and in each case the proximal tubule is the segment concerned It is probable that, except for those mechanisms involved in the movements of the more important monovalent electrolytes and water (these will be considered separately later), the active reabsorptive (and secretory) processes are confined to the proximal convoluted tubules

The normal urine contains only traces of *amino acids* although, of course, a number of amino acids are present in plasma Several separate transport mechanisms are involved in their reabsorption (Pitts, 1944) The basic amino acids arginine, lysine and histidine appear to share the same mechanism since elevation of the plasma concentration of any one depresses the reabsorption of the others (Beyer et al, 1947) Reabsorptive T_m's have been demonstrated for lysine and arginine but not for histidine, the reabsorption of which is still increasing at the highest levels produced experimentally A second transport mechanism is responsible for the reabsorption of leucine and isoleucine which compete, but the capacity for reabsorption is so high that no T_m has been demonstrated Glycine appears to be reabsorbed by a separate mechanism which also is involved in the transport of proline and hydroxyproline In those instances in which T_m's have been demonstrated, there is considerable excretion of the amino acid when the reabsorptive capacity is far from saturated. Presumably this represents a relatively high degree of dissociation of the carrier-substrate

complex *Creatine* is reabsorbed by a mechanism closely related to, if not identical with, that involved in glycine reabsorption

Phosphate is reabsorbed by an active process which can be saturated on elevation of the plasma concentration The transport mechanism seems to be modified by a number of factors (Pitts and Alexander, 1944) It is probable, that parathyroid hormone depresses the phosphate transport system Acidosis increases phosphate excretion in part by what appears to be an increase in the splay of the titration curve

Sulfate reabsorption is effected by a mechanism which becomes saturated with only a slight increase in the plasma concentration above the normal level (Lotspeich, 1947) The reabsorption of sulfate can be depressed by the administration of thiosulfate which competes for reabsorption by the same mechanism

The study of *uric acid* reabsorption is complicated by the fact that uric acid is probably also secreted by the tubules (Gutman, et al, 1959) The reabsorptive capacity for urate is far greater than the amount normally contained in the glomerular filtrate and it is therefore almost certain that this capacity is never saturated in the normal individual The source of the urate normally excreted in the urine is therefore somewhat uncertain, although it might be urate which escapes reabsorption by virtue of the great splay in the reabsorptive titration curve, it is generally believed that it represents urate secreted into the tubules by a secretory process of low capacity Whatever its role may be in regulating excretion under normal conditions, urate reabsorption is remarkable for the number of substances known to inhibit it and thereby to yield marked increases in urate excretion These inhibitors include other reabsorbed compounds, such as glycine, as well as a number of drugs which are best known for their ability to inhibit the secretion of organic anions by the tubules (e.g , carinamide, probenecid, phenylbutazone)

Among other substances actively reabsorbed by the tubules are *ascorbic acid* and *betahydroxybutyric* and *acetoacetic acids*

Tubular Secretion

The processes by which materials are removed from the peritubular fluid and transferred to the tubule lumen are designated by the term *tubular secretion* The term *tubular excretion* is often used synonymously In the present section the secretion of the monovalent ions potassium, hydrogen and ammonium will be omitted, and the discussion will be concerned with the somewhat simpler transport processes involved in the secretion of certain organic electrolytes

The first substance for which tubular secretion was demonstrated was phenol red (phenolsulfonphthalein, PSP) The critical experiment was that of Marshall and Vickers (1923), who showed that as much as 75% of the phenol red contained in the arterial blood could be removed as the blood traversed the kidney, whereas, because of a high degree of binding of phenol red to plasma proteins, only 20 to 25% of the phenol red in the arterial plasma is free and filterable Clearly, no matter what fraction of the plasma was converted to glomerular filtrate, filtration alone could not account for the excretion of phenol red These experiments put an end to a prolonged controversy over the existence of tubular secretory processes

A large number of substances are now recognized to be transported into the tubules by the same mechanism responsible for the secretion of phenol red Among these are *hippuric acid* and a variety of its iodo-, hydroxy-, and amino derivatives (Smith et al, 1945), *penicillin*, 5-hydroxyindoleacetic acid (a metabolite of serotonin), a number of *sulfonphthaleins* in addition to phenol red, several of the iodinated compounds that have been used for x-ray contrast study (intravenous pyelography) of the urinary tract (Diodrast, Iopax, Neoiopax, Skiodan) [2] Also, although their tubular secretion in man has not been identified, it has been shown that glucuronides and ethereal sulfates are so transported in other animals, and the same is probably true in man It is notable that the list contains no normal constituents of the body, but under normal conditions it seems likely that the mechanism serves for the rapid excretion of the conjugates of ingested foreign substances, these conjugates being in

[2] While the iodine is important for X-ray density, it is not related to the susceptibility to transport which undoubtedly derives from the organic structures to which the iodine is attached The first three of those mentioned are derivatives of pyridine-N-acetic acid, the last is an organic sulfate

the form of hippurates, glucuronides and sulfates

The tubular secretory process, which is also located in the proximal tubule, resembles those involved in reabsorption in many respects, except for the reversal of direction

At low concentrations of the transported substance the mechanism is able to transport all of the material presented to it The most commonly studied substance, *p*-aminohippuric acid (PAH) may be used, as an example If PAH is administered intravenously in small amounts, so as to maintain a low concentration in the arterial plasma, it is found that the blood leaving the kidney in the renal vein may be almost free of PAH An average of some 90% of the PAH reaching the kidney in the plasma is removed Since some of the blood reaching the renal vein has probably perfused tissue which does not transport PAH, it is apparent that very little can be left over from that plasma which passes through the active areas This extremely effective *extraction* of PAH is the basis of the use of this substance for the estimation of renal plasma flow which is considered below

As the plasma concentration of the transported substance is increased, the rate of tubular excretion increases until a maximum is reached and no further augmentation of secretion occurs The relationship between plasma PAH concentration and PAH excretion in the urine is illustrated in Figure 5 6 The dotted line passing through the intercept is the amount of PAH filtered at the glomeruli calculated from the product of inulin clearance and the plasma concentration of free PAH (Since PAH is, to a small extent, bound to plasma albumin the total concentration must be corrected for this binding to obtain the filtered amount) At every level of plasma PAH the rate of excretion exceeds the rate of filtration

$$U_{PAH}V = C_{In}P_{PAH}f + T_{PAH}$$

where f is the fraction of the plasma PAH which is filterable. As the plasma PAH is increased, the rate of excretion at first increases sharply, the slope of the line relating excretion to plasma concentration being equal to the renal plasma flow. When the plasma concentration is further increased, the rate of excretion increases less rapidly, and it is found that the excess of excreted over filtered has become constant This excess represents the maximum

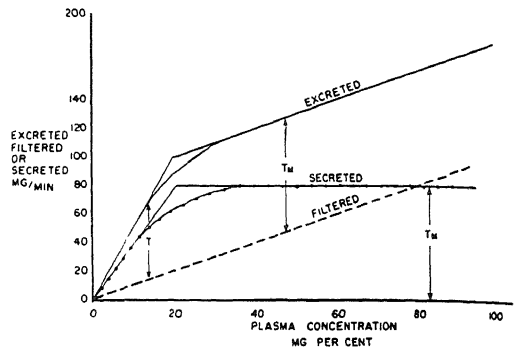

Fig 5 6 Relationship between plasma concentration and filtered secreted and excreted amounts of a substance excreted by tubule secretion See text for details

rate of tubular secretion and is designated as T_{mPAH}

If the rate of tubular secretion is determined by subtracting the filtered from the total excretion the relationship shown in Figure 5 6 is obtained Again, the actually observed titration curve differs from the idealized intersection of two straight lines and for reasons analogous to those involved in tubular reabsorption *1*) the dissociation of substrate-carrier complex and *2*) heterogeneity of nephron function The pertinent heterogeneity in this case, however, is in the ratio of perfusion to transport capacity since it is blood supply, rather than glomerular filtration, which, along with plasma concentrations, will determine the amount available for secretion by the tubules

Any of the various substances listed above as being secreted by this particular transport mechanism can be shown to compete with the others Thus a high concentration of one will reduce the secretion of another and vice versa Presumably they share a common carrier, and when some of the carrier sites are occupied by one, it has less capacity for the transport of another

Several substances that are effective inhibitors of this mechanism have been discovered (carinamide, probenecid, phenylbutazone) These compounds are competitive inhibitors but are themselves only slowly excreted because subsequent to their secretion into the tubule they are reabsorbed by the process known as *non-ionic diffusion* (see p 5–37) (It is interesting to note that these inhibitors have found their major practical application as inhibitors of the *reabsorption* of urate in the treatment of gout)

The mechanism is also inhibited by dinitrophenol and by mercurial diuretics The effect of dinitrophenol has been attributed to the property of this substance of uncoupling phosphorylation from oxidation and has been interpreted as indicating that phosphate bond energy is important in the transport process However, the finding that the dinitrophenol inhibition appears to be competitive casts doubt on this interpretation The effect of mercurial diuretics is noncompetitive and, for unknown reasons, is striking in man but entirely absent in the dog

The transport of PAH is enhanced by acetate and lactate and inhibited by a number of the dicarboxylic acid intermediates of the Krebs cycle

All of the substrates of the secretory process responsible for the tubular excretion of PAH are weak organic anions A separate and distinct mechanism is capable of transporting a variety of organic bases including N-methylnicotinamide, tetraethylammonium ion and tolazoline These compete with each other but show no interaction with the organic anions The normal substrate for this mechanism has not been recognized (Weiner and Mudge, 1964)

UTILIZATION OF TUBULAR SECRETION FOR THE MEASUREMENT OF RENAL BLOOD FLOW

As was noted above, several substances that undergo tubular excretion are very nearly completely removed from the blood that perfuses the kidney This has made them singularly useful for the estimation of renal blood flow Diodrast and *p*-aminohippurate (PAH), because they are well adapted to chemical analysis, have particularly been used for this purpose, and we will consider the use of PAH as an example

In accordance with the Fick principle, if the rate of removal of a substance from the blood as it flows through an organ is known, and if the concentration in the blood entering and leaving the organ can be determined, the blood flow can be calculated:

$$F = R/(A - V)$$

where F is the flow, R the rate of removal, and A and V the concentration in arterial and venous blood, respectively.

In applying this to the measurement of renal blood flow using PAH, the following experimental facts are important *1)* there is no metabolism, production nor storage of PAH in the kidney, all of the PAH removed from the blood is excreted in the urine, *2)* all of the PAH removed from the blood is removed from the plasma, the concentration in the red blood cells does not change significantly as blood passes through the kidney Then the above equation can be modified to yield

$$RPF = U_{PAH}V/(P^{A}_{PAH} - P^{RV}_{PAH})$$

where RPF represents renal plasma flow and P^{A}_{PAH} and P^{RV}_{PAH} represent concentrations of PAH in arterial and renal venous plasma, respectively

Now, as it stands in this form the determination of renal plasma flow would require measurement of the rate of excretion of PAH and the concentrations in arterial and renal venous blood plasma All of these are feasible in man, but the collection of renal venous blood is considerably more difficult than the remainder of the procedures However, since we know that at low concentrations of PAH in the arterial plasma the removal of PAH as blood passes through the kidney is very nearly complete, we may as a first approximation consider the concentration in renal venous plasma to be zero and write

$$ERPF = U_{PAH}V/P^{A}_{PAH} = C_{PAH}$$

or that the *effective renal plasma flow* is equal to the PAH clearance In practice it is not necessary to measure arterial plasma PAH since, when arterial concentration is constant, there is no measurable removal of PAH by peripheral tissues, and the PAH in peripheral venous plasma is the same as that in arterial plasma Therefore, the effective renal plasma flow can be simply estimated by measurement of the plasma PAH clearance when the plasma PAH is maintained at a low level (As plasma PAH is increased, the extraction becomes less complete and the clearance falls further below the true plasma flow) From the effective renal plasma flow the corresponding renal blood flow can be calculated if the hematocrit is known

$$ERBF = ERPF/(1 - Hct)$$

It is interesting to note that Homer Smith and his associates (1938) deduced that the

clearance of diodrast could be used to measure renal plasma flow in man before the technique for obtaining renal venous blood by venous catheterization had been devised and the virtually total extraction of Diodrast confirmed [3] This was based on the very high value (approximately 650 ml /min) of the Diodrast clearance, thus, plasma flow of at least 650 ml /min was required to supply the Diodrast at the rate it was excreted It was reasoned that this was already such a large volume flow that the true plasma flow could not be much higher

RENAL BLOOD FLOW AND FILTRATION FRACTION IN MAN

The remarkably high value of the renal plasma flow has been mentioned above A plasma flow of 650 ml /min corresponds to a blood flow of about 1200 ml /min , an amount approximately equal to one-fourth of the cardiac output under basal conditions The ratio of the renal blood flow to cardiac output is frequently referred to as the *renal fraction* of the cardiac output

The demonstrated equivalence of PAH clearance and (effective) renal plasma flow has made it possible to measure the renal blood flow in man with a minimum of manipulation and disturbance Thus, it has been possible to measure changes in blood flow with disease as well as to determine the effects of various changes in physiological state and the effects of drugs, etc (Chasis et al , 1938)

In considering changes in the renal plasma and blood flows, it is pertinent to take account of the fraction of the plasma lost as glomerular filtrate as the plasma flows through the glomerular capillaries Since all of the renal blood flow under normal conditions passes through the glomeruli, the volume given up as glomerular filtrate is derived from the total plasma flow and the ratio of filtration rate to plasma flow (inulin clearance to PAH clearance) is a measure of the extent to which, in the average glomerulus, the plasma volume is reduced and the plasma protein concentration increased by the process of glomerular filtration The ratio of filtration rate to plasma flow is known as the *filtration fraction*

While, as was noted in an earlier section, the rate of glomerular filtration is a remarkably stable function, the renal blood flow manifests a fairly marked degree of lability, and may be modified by any of a number of stimuli Most of the changes are mediated via the sympathetic nerve supply and are in the direction of decreases In fact, although the subject has long been debated and no consensus has been achieved, the only physiological effects clearly shown to be mediated by the nerve supply to the kidneys are vasomotor, and the renal nerves have not been shown to play a significant role in the regulation of transport processes in the renal tubules

The renal blood flow is diminished by fright, pain, exercise, epinephrine, norepinephrine and stimulation of several areas of the central nervous system, and by a number of other stimuli In general, anything that lowers blood pressure will reduce renal blood flow, not so much because of the reduction in perfusion pressure, but because the kidney takes part in the general vasoconstriction which is the homeostatic response to a lowering of blood pressure Thus there may be a marked decrease in renal blood flow with only a trivial reduction in aortic blood pressure Drugs that reduce blood pressure also reduce the renal blood flow However, in general, the reduction in flow is less than with equivalent reductions in blood pressure due to, for instance, hemorrhage or orthostasis, since the blood pressure reducing drugs usually inhibit renal as well as peripheral vasoconstriction A special case appears to be hydrazinophthalazine which may increase renal blood flow while reducing systemic blood pressure, probably through a specific renal vasodilator action

A more or less unique phenomenon is the marked renal vasodilation and hyperemia produced by the pyrogenic reaction The latter phenomenon, the most striking clinical feature of which is chills and fever, is most often a response to bacterial products (certain bacterial polysaccharides, typhoid vaccine) It is accompanied by intense hyperemia of the kidney, and the renal blood flow may reach twice its normally very high value Interestingly, the

[3] It should also be noted that if, for some reason, renal venous blood is collected so that true plasma and blood flow can be determined, PAH and similar substances lose their unique value Then any substance that is removed by, but not produced, metabolized, or stored in the kidney can be used for the measurement, since the Fick principle can be applied directly. A high degree of extraction, under these conditions, has only the virtue of minimizing experimental error.

renal response to pyrogenic materials is not abolished by the administration of antipyretic drugs although the latter may completely suppress the chills and fever

With all of the above changes in renal blood flow there are frequently only slight changes in glomerular filtration rate and such changes are frequently entirely absent Thus the changes in filtration fraction are the inverse of the changes in blood flow

What Happens to Typical Constituents

REABSORPTION AND EXCRETION OF WATER

One of the most striking features of the function of the mammalian kidney is the capacity to excrete urine differing in osmotic pressure from the blood from which it is derived It is through this capacity to excrete concentrated or dilute urine that the solute concentration (osmotic pressure) of the body fluids is maintained within remarkably narrow limits despite wide variation in the intake of solute and water When, because of water loss or solute gain, the solute concentration of body fluids rises, the urine becomes concentrated, solute is excreted with less than the equivalent amount of water, and the solute concentration of the body fluids is restored to normal Conversely, when the body fluids become diluted by water intake or solute loss, a dilute urine containing an excess of water is excreted, and the osmotic pressure of body fluids is returned to normal Before considering the mechanisms by which the renal tubules effect these changes, it may be helpful to digress briefly to review the concept of osmotic pressure and its measurement

If two solutions containing different concentrations of solute are separated by a membrane permeable to the solvent (water in all cases with which we are concerned) but not the solute, there will be a movement of water from the more dilute to the more concentrated of the solutions The movement of water is due to the fact that the presence of solute reduces the chemical activity of water, and water will move from the solution in which its activity (analogous to concentration) is high to one where it is lower Water will move from dilute to concentrated solution until both have the same solute concentration or, if the movement of water is opposed by the application of a hydrostatic pressure, until the hydrostatic pressure balances the concentration difference The hydrostatic pressure which would be required to maintain a solution at constant volume when it is separated by an ideal semipermeable membrane[4] from pure water is the osmotic pressure of that solution The term osmotic pressure is applied although the osmotic pressure is never actually determined Instead, some other property of the solution dependent upon total solute concentration is measured most commonly the freezing point, occasionally the vapor pressure

The *colligative properties* (osmotic pressure, freezing point depression, vapor pressure depression) depend on the ratio of the total number of solute particles to the number of moles of solvent The nature of the solute is, to a large extent, indifferent, ideally, a protein molecule of molecular weight 100,000 has an effect equal to that of a sodium ion of weight 23, and a mole of sodium chloride, since it dissociates to yield two particles, has twice the effect of a mole of urea or glucose One mole of ideal solute dissolved in a kilogram of water depresses the freezing point of the solution by 1 86 C Such a solution is defined as an *osmolal* solution and is said to contain one osmol/kg of water Since most biological fluids are considerably more dilute, it is convenient, in order to avoid decimals, to deal with *milliosmols* or *micro-osmols*, one milliosmol being one one-thousandth of an osmol, one micro-osmol one-thousandth of a milliosmol The milliosmolality of a solution is defined as its freezing point depression in degrees Centigrade divided by 0 00186 Thus normal plasma is about 285 milliosmolal (abbreviated 285 mOs) and has a freezing point of about −0 53°C [5]

It will facilitate consideration of the processes that take place between the filtration of

---

[4] An ideal semipermeable membrane is one permeable to solvent but impermeable to all solute

[5] Note that osmotic pressure depends on the number of solute particles per unit of solvent The amount of water in a given *volume of solution* will vary with concentration as well as with the nature of the solute There is, therefore, no simple way to convert from osmolality to a number of solute particles per unit volume of solution It is, however, the practice to disregard the inaccuracy involved and multiply volume by osmolality to obtain the approximate amount of solute in a given volume.

an isotonic fluid (one which has the same osmotic pressure as blood plasma) and the excretion of dilute and concentrated urine, if we first consider the gross behavior of water excretion and its extrarenal control (Findley and White, 1937) Under basal conditions the urine is usually moderately concentrated and the urine flow is small If under such conditions an individual ingests a moderately large volume of water, e g , one liter, it is found that after an interval of some 15 to 20 min the urine flow begins to rise The flow increases rapidly to reach a peak of some 12 to 15 ml /min at 40 min to 1 hr , and, when an amount approximately equal to that ingested has been excreted, returns to the same low level as obtained before the water ingestion (Of course, if the water ingestion is continued so that a positive balance is maintained, the high rate of flow may continue for prolonged periods) If these events are analyzed more carefully, it is found *1*) that the osmotic pressure of the blood shows a distinct drop (though only a few percent) well before the onset of the increase in urine flow (*diuresis*), *2*) that the change in urine flow is almost entirely due to a change in the amount of water excreted, manifested by a shift in urine osmolality from hypertonic to markedly hypotonic to plasma, solute excretion shows little or no change, *3*) if glomerular filtration has been measured it is found that the increase in urine flow occurs without or with only trivial changes in the rate of formation of glomerular filtrate, the change in water excretion is due to a change in the absorption of water in the renal tubules, *4*) if at the peak of the urine flow, additional water is ingested, the urine flow does not increase further but remains at a value of some 12 to 15% of the volume of the glomerular filtrate, *5*) if, at any point in the course of the diuresis, vasopressin, the antidiuretic hormone of the posterior pituitary, is administered, the diuresis is immediately interrupted, and the urine again becomes more concentrated than the blood

The concentration of the urine is normally continuously regulated by the secretion of antidiuretic hormone (ADH) by the posterior lobe of the pituitary gland This hormone is believed to be produced in the supraoptic nuclei of the hypothalamus and to migrate via the supraopticohypophyseal tracts to the posterior lobe of the pituitary where it is stored and released into the blood in response to stimuli mediated from the hypothalamus via the same tract system Within the supraoptic nuclei certain cells (*osmoreceptors*) are believed to behave as tiny osmometers, taking up water and swelling when the osmotic pressure of the surrounding body fluids is reduced and giving up water as the osmotic pressure of the bathing fluid rises The swelling and shrinking of these cells is believed to lead to the transmission of nervous impulses which modulate the release of antidiuretic hormone from the posterior pituitary Thus a reduction of the osmotic pressure of the blood leads to inhibition of ADH release,[6] an increase of osmotic pressure stimulates ADH secretion In turn, the ADH is carried by the blood to the kidney, and in the kidney ADH regulates the reabsorption and excretion of water

The work of Verney (1947), to whom we owe much of our understanding of the pituitary control of water excretion, showed that injection into the internal carotid artery of the dog of enough sodium chloride to raise the osmotic pressure of the blood by about 2% resulted in immediate inhibition of water excretion Injection of the same amount into a peripheral vessel had no such effect since it was then diluted with a large volume of blood before being delivered to the sensitive area in the brain Injection of the osmotically equivalent amount of urea into the internal carotid was also virtually without effect In this case the ineffectiveness is presumably due to the fact that urea readily penetrates cells When the urea concentration of their environment is raised, the osmoreceptor cells take up urea rather than lose water Since the receptors do not shrink, there is no induction of ADH secretion Thus, *only those solutes to which cells are relatively impermeable make up the effective osmotic pressure in response to which ADH secretion is regulated* [7]

Our knowledge of the location in the renal tubule and the nature of the processes by which water excretion is regulated is due

[6] The latent period from water ingestion to onset of diuresis is attributable *1*) to the time required for water absorption to produce sufficient dilution of the body fluids and thus inhibit ADH secretion, *2*) for the circulating ADH to disappear

[7] The above describes the normal control of ADH secretion A number of other stimuli such as fear, trauma, nausea, certain drugs, and many others may produce secretion of ADH under conditions unrelated to the osmotic pressure of the body fluids

largely to the application of the micropuncture technique—in amphibians by Richards and his associates (1936, 1938), and in mammals by Walker et al (1941), and more recently and extensively by Wirz (1956) Gottschalk (1959, 1964) and others

The glomerular filtrate has the same osmotic pressure as the plasma except for the absence of the plasma proteins [8] As the fluid flows through the proximal tubule, its volume is reduced to a fraction of that which enters the glomerular space Although, because of inaccessibility from the kidney surface no samples have been collected from the last 40% of the proximal tubule, it is generally estimated that approximately one-third of the filtered volume reaches the end of the proximal tubule and enters the loop of Henle This reduction of volume occurs *without change in osmotic pressure* whether the urine being produced is dilute or concentrated Thus the large fraction of fluid reabsorbed in the proximal tubule does not take part in the concentration and dilution processes, and, in fact, is lost to the process of osmoregulation The water thus reabsorbed in the proximal segment has been termed by Smith (1952) *obligatory water reabsorption* to distinguish it from the *facultative water reabsorption* in the more distal portions of the nephron where water reabsorption is subject to regulation in accordance with the excess or deficit of water in the body fluids

A considerable body of evidence indicates that the water reabsorption in the proximal tubule is entirely a passive process and that the active process which underlies it is the transport of salt (predominantly sodium salts) out of the tubule lumen (Windhager et al, 1959) As sodium salts are transferred from lumen to peritubular fluid, there is a tendency to produce dilution of the tubule contents and hypertonicity of the surroundings The proximal tubule is highly permeable to water and, in response to the osmotic gradient, water follows the salt out of the tubule Within the limits of the determinations the proximal tubule contents are always isotonic with the blood

Although the loop of Henle is far less accessible to puncture in situ than the convoluted tubules, it has been possible through puncture of limited segments in vivo and by perfusion in vitro to define the characteristics of the loop The descending limb has a high permeability to water so that the fluid in the descending limb retains the same osmotic pressure as the surrounding interstitial fluid Near the bend of the loop there is an abrupt decrease in the permeability to water so that the continued removal of salt leaves the fluid in the lumen dilute (Morgan and Berliner, 1968) The urine emerges into the distal convoluted tubule with its osmotic pressure reduced to about half that of plasma whether the final urine is to be dilute or hypertonic

The changes that take place in the distal tubule depend upon whether a dilute or concentrated urine is to be produced In the *formation of dilute urine*, the dilute fluid that enters the distal tubule is further diluted by the continued removal of salt, and the salt removal probably continues through the collecting system The urine is thus rendered hypotonic by the active reabsorption of salt in a region which clearly has a low permeability to water (Otherwise the osmotic gradient would be dissipated, as it is in the proximal tubule, by the escape of water to the more concentrated surroundings) The low permeability to water which characterizes the distal convoluted tubule and collecting system during the formation of dilute urine is dependent upon the absence of ADH

In the *formation of concentrated urine*, the events are similar up to the point at which the fluid enters the distal convoluted tubule In the presence of antidiuretic hormone, however, the collecting tubules and collecting ducts and possibly the distal convoluted tubules become permeable to water [9] Consequently, as the

[8] It is important to make a clear distinction between the total osmotic pressure, with which we are concerned in the process of urine dilution and concentration, and the colloid osmotic pressure or oncotic pressure due to the plasma proteins which play such an important role in the distribution of fluid across capillary membranes (because the latter are so highly permeable to all the other solutes) The colloid osmotic pressure of plasma is equivalent to about 25 mm Hg (1 to 2 mOs) while the total osmotic pressure is of the order of 6 atm (285 mOs)

[9] Antidiuretic hormone has been shown to have the property of increasing water permeability in isolated membranes (frog skin, toad skin, toad bladder) by causing the dilation of water-filled pores (Andersen and Ussing, 1957, Sawyer, 1957) It has also been shown directly, in vitro, to increase the permeability to water of rabbit cortical collecting tubules and rat medullary collecting ducts (Grantham and Burg, 1966, Morgan and Berliner, 1968) In the rat,

fluid flows through the distal nephron the osmotic gradient established by the reabsorption of sodium and chloride, is dissipated, and, despite additional salt removal in the distal nephron, the dilute character of the urine is lost so that it regains isotonicity before it enters the medullary portion of the collecting system It is important to emphasize that it enters the medulla isotonic, never hypertonic The additional water loss which renders the urine more concentrated than blood occurs in the medullary segments of the collecting system

The nature of the mechanism by which urine is rendered hypertonic to the body fluids was long one of the more intriguing problems of renal physiology, and its apparent elucidation, largely through the efforts of Wirz and his associates (1951) is one of the more important and interesting achievements Although some of the details of the mechanism are relatively complex, the essentials are quite simple and directly related to the anatomical organization of the kidney The convoluted tubules are cortical structures, the loops of Henle and the collecting ducts lie in the medulla The latter structures are thus relatively isolated from the cortical structures in which most of the transport activity of the kidney takes place In addition, the blood supply of medulla and papilla forms a looplike system derived from the efferent vessels of the juxtamedullary glomeruli, running down into the medulla, and looping back to the cortex Thus, both loop of Henle and the blood supply of the medullary region form *countercurrent* systems in which the outflowing fluid flows counter to and in proximity to inflowing fluid We will for the moment defer consideration of the importance of this particular arrangement

As was noted above, as fluid flows through the ascending limb of the loop, sodium and chloride are removed while the water remains behind in the tubule lumen and the urine becomes diluted The sodium and chloride removed are transferred to the interstitial fluid of the medulla, increasing the osmotic pressure of this fluid The diluted urine emerges into the cortex where, in the presence of ADH, it loses its excess of water and is further reduced in volume as solute is removed in the distal tubule This water loss occurs in the cortex, spatially separated from the salt left behind in the medulla, and in an area where, because of the very large flow of blood, the excess water produces only a minimal change in osmotic pressure Now the remaining urine, greatly reduced in volume and isotonic with the blood, enters the collecting system and flows through the medulla The interstitial fluid of the medulla, however, has a high osmotic pressure because of salt transported by the loop and, the collecting duct being permeable to water in the presence of ADH, the urine loses water to attain the same osmotic pressure as the interstitial fluid Thus the hypertonicity of the urine is produced These events are illustrated diagramatically in Figure 5 7 Because the volume flow through the loop is several times larger than that in the collecting ducts, a relatively small change in concentration in the loop is sufficient to yield enough solute to raise the concentration of the urine in the collecting ducts severalfold

If the sodium salts transported into the medullary interstitial fluid are to raise the osmotic pressure of the latter, they must not be immediately carried away by the blood flowing through the area The retention of excess solute in the medullary interstitial fluid is made possible by the arrangement of the blood flow which constitutes a countercurrent exchanger The principle of the countercurrent exchanger is illustrated in Figure 5 8 Outflowing blood tends to lose its solute to the inflowing blood As a result, solute is recirculated in the medulla This characteristic makes it possible not only to retain sodium salts but to trap urea as well, the special role of urea in the concentration process is considered with the excretion of urea

The loop arrangement has an additional physiological advantage As the fluid flows down the descending limb of the loop of Henle into an environment made hypertonic by the activity of the ascending limb, it loses water so as to retain the same osmotic pressure as the environment The loss of water raises the concentration of sodium salts in the loop contents so that the transport of sodium salts out of the ascending limb is against only a small gradient

---

the permeability of the distal convoluted tubule to water is regulated by antidiuretic hormone (Wirz, 1956) In the dog and in the monkey the distal tubule is unaffected by antidiuretic hormone and the permeability change is presumably first manifested in the cortical collecting tubules (Clapp and Robinson, 1966; Bennett et al , 1968)

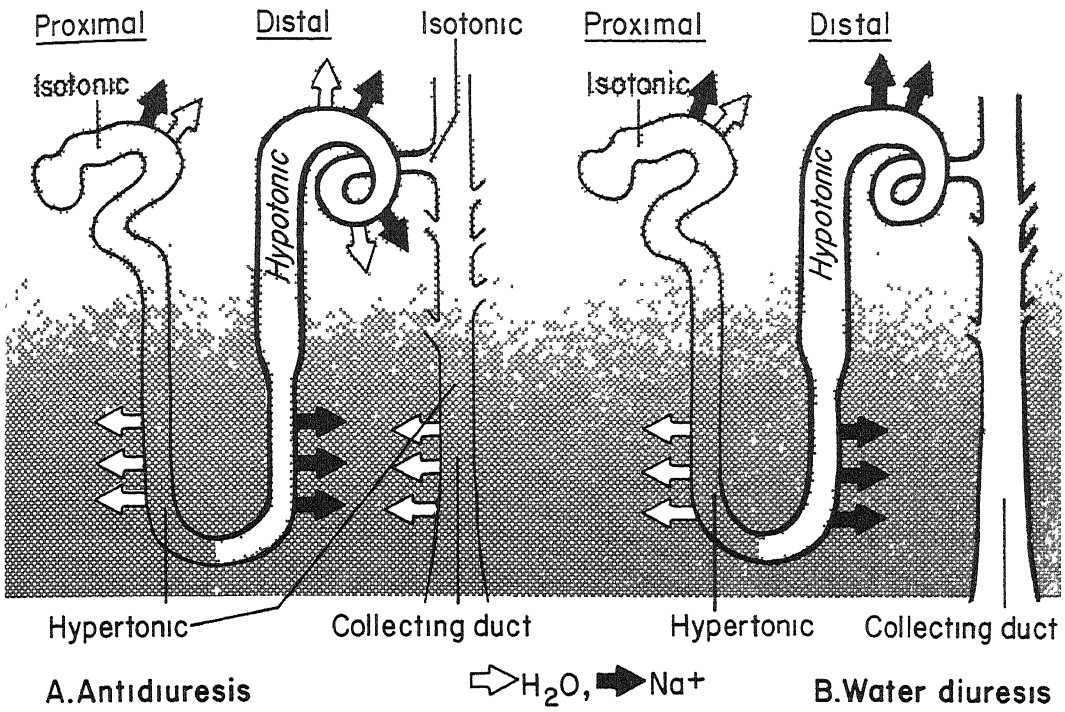

Fig 5 7 Diagramatic representation of changes in the tonicity of fluid in the tubules during the formation of concentrated and dilute urine Dark and light *arrows* indicate movements of sodium chloride and water respectively and the relative permeability of the tubule wall to water is indicated by its thickness

of concentration despite the very high concentration of sodium salts in the interstitial fluid surrounding the loop This arrangement is that of a *countercurrent multiplier*, so called because the small concentration gradient from the loop contents to environment is multiplied in the longitudinal direction from cortex to tip of papilla

The highest concentration achieved by the human kidney is generally about 1200 to 1400 mOs (a relatively modest maximum compared with some other mammals, e g , dog 2300 to 2500 mOs , rat 3000 to 3200 mOs , kangaroo rat over 5000 mOs), the lowest concentrations observed are of the order of 30 to 40 mOs Thus, the kidney is able to produce urine four to five times more concentrated than or one-seventh to one-tenth as concentrated as the blood (roughly 300 mOs)

In clinical practice, the specific gravity, rather than the osmolality, is generally used as an index of concentration and dilution Urine of specific gravity 1 008 to 1 010 is approximately isotonic with plasma, but the two scales are not directly interchangeable since the specific gravity depends not only on the concentration of solute but also on the latter's nature The chief value of the specific gravity lies in the simplicity of its determination

The highest and lowest concentrations are produced only when solute excretion is at a relatively low level, as solute excretion increases dilute urines become less dilute and concentrated urines less concentrated The basis for this change can be deduced from the mechanisms for dilution and concentration described above and is more easily understood if the urine flow is considered to be divided into two parts as suggested by Smith One fraction is considered to contain all of the solute excreted at the same concentration as plasma, the other fraction is the amount of water contained in excess of this isotonic fraction The isotonic fraction is calculated by dividing total solute excretion by the osmolality of plasma Solute excretion is given by the product of urine flow and urine osmolality $U_{os}V$ and when this is divided by the plasma

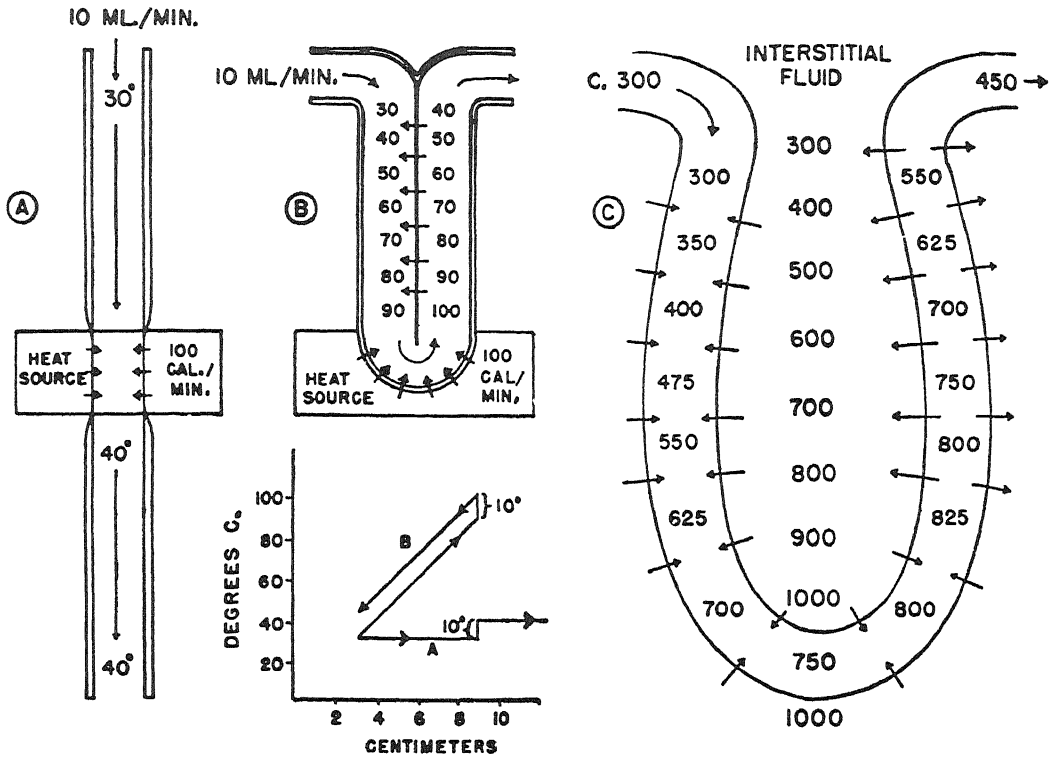

Fig 5 8 Principle of the countercurrent exchanger A and B 100 calories/min raise the temperature of 10 ml/min of water 10° in both A (straight flow) and B (countercurrent flow) However since the incoming water is heated by the outgoing water in B the *maximum temperature* attained in the countercurrent system is considerably higher than with straight flow The graph compares the temperature along the flow tubes in each system C countercurrent flow as applied to the capillary loop showing that it is not necessary for the limbs of the loop to be in direct contact In the *hypothetical* illustration given both limbs are in contact with the same interstitial fluid of progressively increasing concentration Sodium salts (*arrows*) at first enter the capillary blood later partly return to the interstitial fluid Note the analogy between B in which heat is recirculated and C in which sodium salts are similarly retained in an area

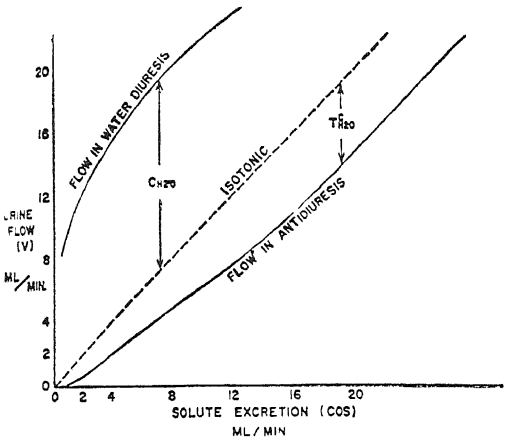
osmolality, the resulting value has the dimensions of a clearance and is generally called the osmolal clearance (C_{os})



$$C_{os} = U_{os}V/P_{os}$$

When the urine is dilute the flow exceeds the osmolal clearance by an amount which Smith has designated the *free water clearance* (C_{H_2O}) This is the volume of water which must be removed from one minute's flow of urine to return the urine to isotonicity Thus

$$V - (U_{os}V/P_{os}) = C_{H_2O}, \qquad C_{H_2O} = V - C_{os}$$

From the mechanism described above it may be seen that, provided no water has escaped from distal tubule or collecting duct, C_{H_2O} is the volume of water which originally contained the salt reabsorbed in ascending limb, distal tubule and collecting duct The capacity of these segments to reabsorb sodium salts, therefore, sets the limit on the amount of water which can be excreted above that containing the urinary solutes in isotonic solution It is this limited capacity to excrete water freed of solute which accounts for the increasing concentration of dilute urine as solute excretion increases, the isotonic portion of the urine flow (C_{os}) constituting an ever larger fraction of the total flow (V) Actually C_{H_2O} may be less than maximal *1)* because insufficient sodium salts are delivered to the distal portions of the tubule to saturate the reabsorptive capacity or *2)* because some of the water "freed" by salt removal diffuses out of the distal tubule Even in the total absence of ADH some permeability to water persists, and this permeability may be increased by amounts of ADH that are too small to yield a maximal effect and thus a concentrated urine

When the urine is concentrated the flow is

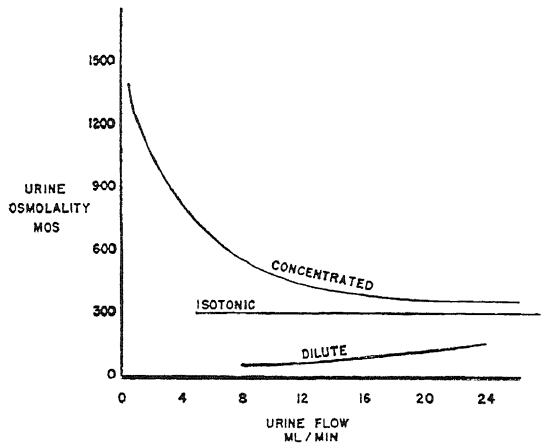


Fig 5 9*a* (*left*) Relationship between urine flow and solute excretion in water diuresis and during the formation of concentrated urine

Fig 5 9*b* (*right*) Relationship between urine flow and urine osmolality when urine flow is modified by changing solute excretion See text for explanation

smaller than the osmolal clearance, that is, water must be *added* to the urine to render it isotonic Thus C_{H_2O} assumes a negative value, this has been designated as $T^c_{H_2O}$ by Smith (1952) The driving force for the removal of water from urine flowing through the collecting ducts is provided by the salt transported out of the ascending limb of the loop of Henle Therefore the amount of water thus removed ($T^c_{H_2O}$) can not be greater than the osmotic equivalent of the salt deposited in the medulla by the loop [10] Since the value of $T^c_{H_2O}$ is limited, as solute excretion increases the urine concentration falls, again because the isotonic portion of the urine (C_{os}) constitutes an ever greater fraction of the total (V) ($V = C_{os} - T^c_{H_2O}$) The flows and concentrations of dilute and concentrated urines as solute excretion is varied are illustrated in Figures 5 9A and 5 9B

In considering the effects of antidiuretic hormone and the change from dilute to concentrated urine, it is important to emphasize that by far the most important effect is that in the cortical segments of the nephron system which involves the change from dilute to isotonic urine The relative quantitative importance of the dilution and concentration processes can be illustrated in a person excreting enough solute to require the excretion of 2 liters of isotonic urine in 24 hr If he were to produce maximally dilute urine for this period, he would excrete approximately 20 liters of urine Therefore, if ADH were to effect a rise in urine concentration only to isotonicity with plasma, some 18 liters of water would be conserved If, on the other hand, the same solute were to be excreted in a maximally concentrated urine, the volume would be reduced to about 500 ml, a further saving of about 1 5 liters Clearly, the water saved in not putting out a dilute urine is quantitatively much more important than that conserved in forming a concentrated urine

[10] This is equivalent to saying that the production of a concentrated fluid (urine) in the medulla must be balanced by the production of a dilute one (the fluid emerging from the ascending limb of the loop)

REABSORPTION AND EXCRETION OF SODIUM AND CHLORIDE

The regulation of the osmotic pressure of body fluids tends to adjust the amount of water in the body to the amount of solute in the body fluids Thus, so long as osmotic pressure regulation remains normal, the volume of the body fluids will depend on the amount of solute in the body Since sodium salts constitute some 90% or more of the solute of extracellular fluid, the volume of the extracellular fluid is largely dependent on the regulation of renal sodium excretion

We have already considered, in relation to the regulation of water excretion, how sodium reabsorption is distributed in the renal tubule It has been pointed out that a major fraction of the filtered solute and water are reabsorbed in the proximal tubule Since most of this solute

is composed of sodium salts and since the fluid remains isotonic in the process of this reabsorption, there is ordinarily little reduction of sodium concentration in the proximal tubule However, the reabsorption involves active sodium transport since *1*) the reabsorption occurs despite a small difference of electrical potential (3 to 4 mv , lumen negative to interstitial fluid) opposing the movement of sodium, and *2*) if some nonreabsorbable solute (e g , mannitol) is present, the sodium concentration does fall well below that of the peritubular fluid as sodium is reabsorbed (However, because of a relatively high permeability the gradient of sodium concentration that can be established is limited because of diffusion from peritubular fluid) Since chloride reabsorption is favored by the small electrical potential, and usually by a higher concentration of chloride in the lumen than in the interstitial fluid, there is no reason to believe any specific transport mechanism for chloride reabsorption is present

The reabsorption of sodium in the more distal segments of the nephron does result in the establishment of gradients of sodium concentration which may, indeed, be very steep since sodium may be virtually absent from the urine The difference between proximal and distal tubules probably resides not so much in the character of the transport mechanism, as in the passive permeability of the tubule epithelium, there is less tendency, in the distal area, for the sodium to diffuse back into the lumen and dissipate the gradient However, in the distal convoluted tubule the removal of chloride may be the consequence of an active transport process since at least one study has been reported as showing that the concentration may fall to levels too low to be accounted for by the electrical force provided by the sodium transport

In addition, in the distal tubule, not all of the reabsorption of sodium is accompanied by reabsorption of anion Some of the sodium reabsorbed in the distal segment is replaced by potassium, and some is replaced by hydrogen and ammonium ions These aspects of the sodium reabsorptive mechanism will be considered in relation to potassium excretion and the renal regulation of acid-base balance in later sections of this chapter.

The mechanism by which sodium is transferred from lumen to peritubular fluid is poorly understood It is probably very closely related to that mechanism (also poorly understood) common to virtually every cell of the body, by which sodium is extruded from and potassium maintained at a high concentration in the intracellular fluid No entirely satisfactory and generally applicable model is available, but it is believed that an ATPase requiring both NA and K for its activation may play an important role

REGULATION OF SODIUM EXCRETION

A number of circumstances are known to influence the rate of sodium excretion The way in which these factors are integrated to determine and regulate the rate of sodium excretion is not so well known To say that the rate of sodium excretion is determined by the balance between filtration of sodium at the glomeruli and reabsorption of sodium by the renal tubules is merely to state the obvious What is required is a knowledge of how these two processes are interrelated and modified to maintain a normal body sodium content Although we can indicate qualitatively some of the determinants of sodium excretion, they can not be put together as, for instance, in the case of glucose, to predict the rate of salt excretion

Glomerular Filtration. Under average normal conditions only a very small fraction of the sodium contained in the glomerular filtrate is excreted in the urine—a person on an average salt intake puts out only about one-half of one percent of the amount filtered. It is clear, therefore, that an increase of only 1% in the rate of glomerular filtration[11] supplies enough additional sodium in the filtrate to double or triple the sodium excretion were none of the extra sodium reabsorbed by the tubules It is also clear, however, that when the glomerular filtration rate increases, the increment of filtered sodium is never quantitatively excreted In fact, unlike the situation with respect to the reabsorption of such substances as glucose and phosphate, changes in the rate of glomerular filtration are attended by parallel changes in the rate of sodium reabsorption

[11] Changes in the amount of sodium filtered are generally due largely to changes in the rate of glomerular filtration since the plasma sodium concentration is normally maintained within a very narrow range, reflecting the constancy of osmotic pressure to which sodium salts contribute such a major share

When glomerular filtration increases, sodium reabsorption increases, when filtration decreases, reabsorption likewise decreases When changes in glomerular filtration occur the reabsorption of salt in the proximal convoluted tubule changes very nearly in exact proportion However, because similar changes do not take place in reabsorption in the remainder of the nephron, changes in the filtration of sodium are not accompanied by proportional changes in excretion As a matter of fact, acute changes in the filtration of sodium produce relatively very large changes in sodium excretion However, if the filtration rate changes are maintained for a protracted period compensatory changes in reabsorption occur so as to restore sodium balance

These circumstances are very clearly demonstrated by the experiments of Mueller and his associates (1951) In dogs operated upon to make it possible to collect the urine from each kidney separately, these investigators placed constricting clamps on one renal artery It was found that if the artery was constricted so as to produce a barely detectable decrease in glomerular filtration rate, there was a marked drop in the amount of sodium excreted by the affected kidney Such a kidney might excrete only 10 to 20% of the daily sodium intake, the remainder being excreted by the normal control kidney so as to maintain sodium balance This situation might persist indefinitely If, however, the normal kidney was then removed there was a prompt increase in the salt excreted by the kidney with the constricted artery When the full load of maintaining sodium balance was placed on the experimental kidney, compensatory adjustments of reabsorption overcame the effects of reduced glomerular filtration

Adrenocortical Steroids. The best known of the influences that modify reabsorption of sodium by the tubules is that exerted by the steroid hormones of the adrenal cortex The natural hormone with the greatest effect on sodium reabsorption is aldosterone, but similar effects are produced by desoxycorticosterone, cortisol, and others, as well as a number of synthetic steroids All of the active steroids exert qualitatively identical effects on sodium transport by the renal tubules, increasing reabsorption in all its forms—that is, sodium reabsorption accompanied by chloride reabsorption as well as sodium exchange for potassium and hydrogen ions However, the various steroids may produce differing effects on sodium *excretion* not only because they differ in potency with respect to their capacity to modify sodium transport, but probably in part because glucocorticoid activity is associated with the specific property of increasing the rate of glomerular filtration

The control of salt excretion by the adrenal cortex is mediated largely by the secretion of aldosterone The secretion of aldosterone is stimulated by angiotensin, a small peptide hormone formed in the blood from a circulating precursor globulin by the action of the enzyme renin Renin is secreted by the juxtaglomerular apparatus of the kidney in response to a stimulus which has not been clearly established, but which appears to be related in some way to the effective circulating blood volume Contraction of blood volume leads to increased secretion of renin which in turn yields increased formation of angiotensin and, in turn, increased secretion of aldosterone, increased reabsorption of sodium (and chloride) and secondarily, by an increase in the retention of water, to expansion of volume

The action of aldosterone is to increase the formation of a protein which plays some as yet unidentified role in the sodium transport process

It should be clearly understood that the transport process proceeds very well in the absence of the corticosteroids, the effect of the hormones is, in a sense, the fine adjustment of a process which is largely autonomous

When adrenal salt-retention hormones are administered to normal individuals there is a brief period of salt retention but the decreased salt excretion is relatively short-lived After retaining a modest amount of salt, the individual comes back into balance This does not indicate the development of resistance to the effect of steroid on sodium transport but compensation for this effect by other factors

Other Controls. In recent years it has become apparent that factors other than glomerular filtration rate and adrenocortical steroids play a dominant role in the regulation of sodium excretion Although these factors are still poorly understood a considerable amount of experimental data that relate to their operation has been amassed If an animal is given massive doses of aldosterone or other salt retention hormones and then infused with iso-

tonic Ringer's solution, a sharp increase in sodium excretion occurs even if the rate of glomerular filtration is markedly reduced by clamping the renal artery or the aorta, the increased salt excretion occurs in denervated kidneys and when the plasma oncotic pressure is maintained by inclusion of albumin in the infused solution (De Wardener et al , 1961) A part of the effect has been shown to be a marked reduction of reabsorption in the proximal convoluted tubule, but additional effects on reabsorption in more distal segments are required for the full expression of the increased sodium excretion

Numerous attempts have been made to identify, in the blood of saline infused animals, humoral depressors of sodium transport by the tubules No conclusive evidence for the existence of such humoral agents has yet been adduced although factors that modify transport in several assay systems have been reported to occur in the plasma of saline infused animals and to be absent in that of hydropenic animals While a regulatory role for some of these agents is a possibility, much work remains to be done before this can be considered established

At the same time it has been shown that the rate of reabsorption by the tubules can be modified by changes in the oncotic and hydrostatic pressures in the peritubular capillaries, presumably through some poorly understood effect of these factors on the rate of transport by the tubules (Martino and Earley, 1967) The regulatory role of such factors also remains to be clarified

Osmotic Diuresis. The excretion of sodium is increased by any circumstance which leads to an increase in the excretion of solute (Wesson and Anslow, 1948) Perhaps the most common such event is elevation of the blood glucose to levels at which the reabsorptive capacity of the tubules is saturated and glucose is excreted in the urine The same effect may be produced by the administration of poorly reabsorbed substances such as urea or mannitol This phenomenon is known as *osmotic diuresis* Sodium excretion is increased because the presence of the other solute depresses sodium reabsorption in the proximal tubule As sodium is reabsorbed, the other solute, which remains behind in the tubule, forms a larger and larger fraction of the total solute Since the fluid retains the same total solute concentration as the blood, the sodium concentration must fall, the decrease in concentration impairs reabsorption

Excretion of Poorly Reabsorbed Anions or Anions Subject to Tubular Excretion When large amounts of some anion are excreted in the urine, there must be an equivalent amount of cation excreted To some extent sodium may be substituted for by potassium, ammonium, or hydrogen ions, but the capacity to do this is limited Thus, under conditions where large amounts of sulfate, phosphate, *p*-amino hippurate (PAH), etc , are excreted, sodium excretion is increased

Specific Inhibition of Sodium Transport. The commonly used diuretics,—organic mercurials, thiazide diuretics, furosemide, ethacrynic acid, carbonic anhydrase inhibitors, etc , all owe their efficacy to the capacity to depress sodium transport by the renal tubules

EXCRETION OF POTASSIUM

Potassium holds a unique place among the normal constituents of the blood and urine in being subject to both reabsorption and secretion by the tubules The average rate at which potassium is excreted in the urine is only about 15% of the rate at which it is filtered at the glomeruli, on the other hand, if large amounts of potassium salts are administered, or if the secretion of hydrogen ion is inhibited, the rate of excretion of potassium may rise to levels equivalent to twice the rate at which it is filtered There is considerable evidence to support the view that, even when the amount excreted is less than that filtered, the potassium in the urine is derived largely from tubular secretion (Berliner, 1961)

The bulk of potassium reabsorption occurs in the proximal tubule The process in this segment if probably passive since the potassium concentration in the convoluted portion does not differ appreciably from that in plasma Reabsorption continues beyond the convoluted portion of the proximal tubule since only a small fraction of the filtered potassium remains when the fluid enters the distal convoluted tubule

The potassium secretory process begins in the distal convoluted tubules and continues into the collecting system The process is, in effect, an exchange of potassium ions for sodium ions, the reabsorption of sodium setting up an electrical gradient with the lumen of the

tubule strongly negative This electrical gradient causes potassium ions to diffuse into the lumen through the distal tubule lining which has a high permeability to potassium Thus sodium reabsorption provides the driving force for potassium secretion This driving force is opposed by active transport of potassium out of the lumen, the actual amount of potassium at any point along the distal system being determined by the balance of these two processes When the supply of sodium is exhausted before the end of the nephron, the driving force provided by sodium reabsorption falls off and potassium is reabsorbed sometimes to very low levels

The rate of potassium excretion is determined by several factors *1)* The concentration of potassium in cells, particularly the renal tubule cells The concentration of potassium in the plasma has little influence on potassium excretion except insofar as cell potassium concentration tends to vary with plasma concentration Such an arrangement is highly reasonable since potassium is primarily an intracellular ion, and it is, therefore, the cell potassium to which excretion should be related *2)* The amount of sodium remaining as the end of the distal tubule system is reached (Davidson et al , 1958) Thus, paradoxically, since sodium is reabsorbed as potassium is secreted, sodium and potassium excretion frequently vary in parallel rather than inversely *3)* The acid-base status In general, alkalosis increases the secretion of potassium and acidosis depresses it The effect, in all probability, is upon the initial step in potassium secretion, the uptake of potassium into the cells at their contraluminal cells (Malnic et al , 1971) The uptake of potassium into cells generally is enhanced by alkalosis and decreased by acidosis *4)* Tolerance to potassium For reasons that are not entirely clear potassium excretion is facilitated by repeated administration of potassium (Thatcher and Radike, 1947)

RENAL REGULATION OF ACID-BASE BALANCE

Under normal conditions the diet provides a number of sources of potential acid The organic phosphorus of proteins and phospholipids is converted to phosphoric acid, the sulfur of the sulfur-containing amino acids is converted to sulfuric acid When ammonium chloride is ingested, the ammonium ion is converted to urea and hydrogen ion leaving hydrochloric acid as the end product If calcium chloride is ingested, the calcium may be excreted in the stool as the insoluble salts of organic acids (such as fatty acids), and hydrochloric acid is absorbed Under abnormal conditons (starvation, diabetic ketosis) large amounts of organic acid may be produced, well beyond the capacity of the body to oxidize this acid to carbon dioxide

In the usual dietary circumstances the dietary sources of acid predominate over the sources of alkali, but the latter may be in excess with certain intakes Fruits and vegetables abound in the salts of organic acids The organic anions are oxidized to CO_2 leaving the bicarbonates of sodium and potassium In addition the intake may include sodium or potassium bicarbonate as such

Acid or alkali entering the body fluids react with the buffers of these fluids and the pH change which occurs is thereby minimized The most abundant buffer system of extracellular fluid is that made up of bicarbonate and carbonic acid and the bulk of the extracellular buffering is therefore involved with this system Because it must provide the major part of the alkali to neutralize any acid gaining access to the extracellular fluid, the bicarbonate concentration has been designated the *alkali reserve* and can be considered a measure of the degree of acidosis or alkalosis (even though, by respiratory compensation, changes of bicarbonate concentration may be accompanied by only minimal changes in pH)

Acid added to extracellular fluid reacts chiefly with bicarbonate to yield carbonic acid and the salt of the acid The carbonic acid in turn yields CO_2 which is excreted in the lungs

$$H^+A^- + Na^+HCO_3^- \rightleftharpoons Na^+A^- + H_2CO_3 \Downarrow H_2O + CO_2$$

The result is the replacement, in the extracellular fluid, of one equivalent of bicarbonate with one equivalent of the anion of the acid The anion (A^-) will eventually be excreted in the urine If it is excreted as the sodium salt, the form in which it exists in plasma, the overall result will have been the disappearance from the extracellular fluid of 1 mole of sodium bicarbonate for each mole of HA added

The buffer capacity of the extracellular fluid can be restored only by regaining a mole of

sodium bicarbonate This might be done if instead of excreting the sodium salt (NaA) in the urine the kidney were able to dispose of the free acid HA thus regenerating sodium bicarbonate This would amount to a reversal of the reactions above

$$H_2O + CO_2 \rightarrow H_2CO_3 + Na^+A^- \rightarrow$$
$$Na^+HCO_3^- + HA \rightarrow (\text{urine})$$

This, in fact, the kidney is able to do by virtue of its capacity to produce urine considerably more acid (down almost to pH 4) than the blood (pH 7 4) Thus to the extent that any acid is un-ionized at the pH of the urine, that acid may be disposed of directly, with regeneration and recovery of the bicarbonate by which it was temporarily buffered in the extracellular fluid

The extent to which an acid is un-ionized at a given pH can be deduced from the Henderson-Hasselbalch equation

$$pH = pK + \log [A^-]/[HA]$$

This may be rearranged in the form pK – pH = log [HA] – log [A^-] to indicate more clearly that when the pH is lower than the pK of the acid concerned there will be more un-ionized acid than salt Thus, any acid which has a pK higher, *or not much lower* than the pH of the urine,[12] can be excreted to an appreciable extent in un-ionized form Acids with pK's high enough to appear in the urine in undissociated form to an appreciable extent are monobasic phosphate ($H_2PO_4^- \rightleftharpoons HPO_4^= + H^+$), pK 6 80, β-hydroxybutyric acid, pK 4 7 and creatinine ($CrH^+ \rightleftharpoons Cr + H^+$), pK 5 0

For most acids which enter the extracellular fluid, excretion as the undissociated acid is impossible Hydrochloric and sulfuric acids are completely dissociated at all pH's At a urine pH as low as 4 0, the concentration of hydrochloric or sulfuric acid would be only 10^{-4} N or 0 1 mEq /liter Even *weak* acids having pK's much below 5 must be excreted almost entirely as salts In the excretion of such acids, then, some other mechanism is required if bicarbonate is to be regained to replace that originally lost in neutralizing them This is accomplished by the generation of ammonium ion from neutral precursors and the substitution of ammonium ion for sodium ion in the urine The acids are excreted as ammonium salts, the sodium is returned to the extracellular fluid as sodium bicarbonate The overall reaction may be considered to be the following

$RNH_2 + HOH \rightarrow NH_3 + ROH$ (which may then be oxidized to CO_2 and H_2O)

$$NH_3 + Na^+A^- + H_2CO_3 \rightarrow$$
$$NH_4^+A^- \text{ (to urine)} + Na^+HCO_3^-$$

Neither of these reactions nor those indicated above should be interpreted as indicating the actual processes which take place in the kidney They represent the net results of a series of reactions

Thus acids are disposed of without loss of alkali reserve *1)* by excretion of weak acids in their un-ionized form and *2)* by the substitution of ammonium ion for sodium ion in the excretion of their salts The disposal of excess alkali is more direct Alkali appears in the extracellular fluid as bicarbonate ($B^+OH^- + CO_2 \rightleftharpoons B^+HCO_3^-$) and is excreted in the urine as that bicarbonate which escapes reabsorption in the tubules This background concerning the nature of the overall processes will serve as an introduction to the renal mechanisms that determine the excretion of acid or alkali

Three processes are important in regulating the amount of acid or alkali excreted *1)* the filtration of bicarbonate at the glomeruli, *2)* the transport mechanism by which bicarbonate is reabsorbed and the urine rendered acid, and *3)* the synthesis of ammonia by the cells of the renal tubule

The glomerular filtrate contains bicarbonate at a concentration essentially identical to that in plasma [13] Micropuncture studies have shown that there is some variation in the pH and bicarbonate concentration as the fluid flows through the proximal convoluted tubule Under normal conditions in the dog, the bicarbonate concentration, and hence the pH, is close to that in plasma When plasma bicarbonate is reduced by acidosis, the bicarbonate concentration falls in the proximal tubule to

[12] Although more acid urine *can* be formed, the urine pH is not often below 5 0 and is more commonly around 6

[13] Because the plasma proteins are nonfilterable anions, a Donnan equilibrium is set up across the glomerular membrane, and all monovalent filterable anions, including bicarbonate, are about 5 per cent more concentrated in glomerular filtrate than in plasma water All monovalent filterable cations, including H^+, are about 5 per cent less concentrated

levels one-half to one-quarter that in plasma Since the tubule has a very high permeability to CO_2, the carbon dioxide tension and, hence, the carbonic acid concentration in the lumen are very close to those of plasma Thus the denominator in the Henderson-Hasselbalch equation,

$$pH = 6.1 + \log([HCO_3^-]/[H_2CO_3]),$$

remains constant and pH varies directly with the log $[HCO_3^-]$ It should be noted that even though the bicarbonate concentration may change but little in the proximal tubule, most of the filtered bicarbonate is usually reabsorbed in this segment as a consequence of the reabsorption of a large fraction of the filtered volume

In the distal tubule the urine is further acidified, and the process continues into the collecting ducts The major reduction in pH occurs in the distal parts of the nephron (Montgomery and Pierce, 1937), but this does not necessarily indicate that the reabsorption of base occurs predominantly in the latter segments As bicarbonate is removed from the tubule lumen, changes in the pH of the remaining fluid will depend upon the changes in volume of the remaining fluid If bicarbonate removal proceeds more rapidly than volume decreases, the bicarbonate concentration falls and the pH likewise falls since the concentration of carbonic acid remains constant (see above) If the volume of the remaining tubular fluid diminishes more rapidly than does the amount of bicarbonate remaining, the pH of the fluid will rise Thus, the degree to which the urine is acidified depends not only upon the rate of bicarbonate removal, but on the relationship of the removal rate to the rate of removal of water Consequently, the production of urine more alkaline than plasma requires only that a greater fraction of the filtered water than of the filtered bicarbonate be reabsorbed

MECHANISM OF URINE ACIDIFICATION

Secretion of Hydrogen Ions Largely as the result of the studies of Pitts and his associates, (1945, 1946, 1948, Sartorius et al , 1949, Pitts, 1948), the process by which bicarbonate removal is effected is generally accepted as being one in which hydrogen ion is secreted by the cells of the renal tubule in exchange for sodium ions The mechanism may be conveniently depicted as follows (Fig 5 10) In the renal tubule cell, as a result of energy-requiring processes, hydrogen ion and hydroxyl ion are generated from water in spatially separated loci The hydrogen ion enters the tubule lumen in exchange for a sodium ion which is taken into the cell Meanwhile the hydroxyl ion is buffered within the cell by reacting with carbonic acid to yield bicarbonate ion and water The bicarbonate and sodium ions are extruded into the extracellular fluid The carbonic acid is regenerated by the hydration of carbon dioxide, the latter may be derived from either the metabolic processes within the cell or from the carbon dioxide of the blood and extracellular fluid

The regeneration of the carbonic acid proceeds rapidly only in the presence of the enzyme *carbonic anhydrase* and this step may become rate-limiting in the overall process When the production of carbonic acid is impaired by inhibition of the enzyme, the concentration of carbonic acid in the cell falls and with it the hydrogen ion concentration (Hober, 1942) Since the rate at which hydrogen ion is extruded in exchange for sodium ion is related to the hydrogen ion concentration in the cell, the rate of secretion of hydrogen ion is diminished Thus *inhibition of carbonic anhydrase diminishes the secretion of hydrogen ion* and all of the processes dependent upon the secretion of hydrogen ion

It should be noted that in the above process, for each hydrogen ion extruded, one equivalent of sodium as the bicarbonate is added to the extracellular fluid and this result is independent of the fate of the hydrogen ion in the

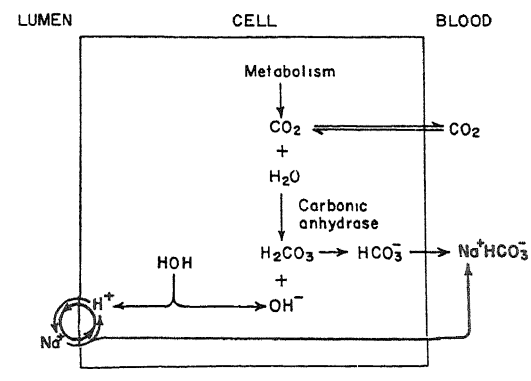

Fig 5 10 Hypothetical cellular processes in the secretion of hydrogen ion in exchange for sodium

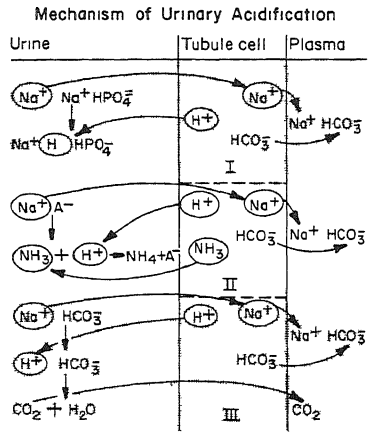

Fig 5 11 Fate of hydrogen ion secreted into tubule lumen in exchange for sodium *a)* Formation of titratable acid *b)* formation of ammonium ion *c)* reabsorption of filtered bicarbonate Modified from figure of Orloff 1956

tubule lumen (Fig 5 11) The fate of the hydrogen ion that enters the lumen in exchange for a sodium ion depends upon the composition of the fluid that it enters

Acid added to any buffered solution is distributed among the buffers of that solution in a predictable way depending upon the relative concentrations of the buffers and their pK values Any change in hydrogen ion concentration must affect all the buffers present since all must satisfy their ionization constants The amount of hydrogen ion distributed to each buffer will be directly proportional to the concentration of the buffer and inversely related to the difference between the pH of the solution and the pK of the buffer

We may consider as an example the secretion of hydrogen ion into the proximal renal tubule The buffers contained in the glomerular filtrate may be considered to be bicarbonate (pK′ 6 1) at a concentration of about 27 mmoles/liter and phosphate (pK 6 8) at a concentration of about 1 5 mmoles/liter Because it is present in much higher concentration, bicarbonate will take up most of the hydrogen ion secreted even though the pH of the fluid (7 4) is closer to the pK of phosphate Thus, in the proximal tubule most of the added hydrogen ion reacts with bicarbonate

$$H^+ + HCO_3^- \rightleftarrows H_2CO_3 \rightleftarrows H_2O + CO_2$$

The result of hydrogen ion addition, then, is the conversion of bicarbonate ion to CO_2 and water, and the CO_2 diffuses out of the tubule lumen to extracellular fluid Thus the exchange of a mole of sodium ion for a mole of hydrogen ion has resulted in the removal of a mole of sodium bicarbonate from the glomerular filtrate even though no bicarbonate ion has crossed the membrane separating lumen from tubule cell Instead, the bicarbonate ion that enters the extracellular fluid is generated independently in the tubule cell

In the distal tubule the situation may be quite different Suppose that the proximal tubule's capacity for phosphate reabsorption has been saturated so that half of the filtered phosphate has escaped reabsorption and reaches the distal tubule At the same time the volume of the fluid flowing through the tubule has been greatly diminished by the processes of reabsorption, so that we may assume that at some point in the distal tubule only 5% of the glomerular filtrate remains The phosphate concentration in the fluid will then have reached a value ten times that in the glomerular filtrate or 15 mmoles/liter Now the hydrogen ion secreted into the fluid will to a very considerable extent react with dibasic phosphate, converting it to monobasic phosphate

$$H^+ + HPO_4^- \rightleftarrows H_2PO_4^-$$

As the pH falls, the concentration of bicarbonate diminishing rapidly, a greater proportion of the hydrogen ion will be taken up by other buffers At pH 6 1, the bicarbonate concentrations will be only about 1 4 mEq /liter, at 5 1 about 0 14 mEq /liter

It is important to note that as hydrogen ion reacts with bicarbonate the resulting undissociated acid (H_2CO_3) disappears from the urine (as CO_2) The hydrogen ion that reacts with other weak acids, however, remains and can be detected in the final urine in the form of *titratable acid* The amount of the latter can be determined as the amount of alkali required to titrate the urine back to the pH of plasma, and is equal to the amount of hydrogen ion expended and sodium bicarbonate regenerated in the conversion of the buffer salt (as it existed in plasma) to the buffer acid as it appears in the urine The titratable acid, therefore, is a very poor measure of the amount of hydrogen ion secreted by the renal tubules since most of the acid produced by this secretion is carbonic acid which is dissipated

However, from the standpoint of the regulation of the acid-base balance of the body, the

situation is reversed That part of the secretion of hydrogen ion which is expended in reabsorbing bicarbonate from the glomerular filtrate serves an important conservative role in preventing loss of bicarbonate from the body, but its overall effect is only to return to the extracellular fluid that which it previously had lost for a time into the glomerular filtrate The excretion of titratable acid, however, represents the addition of extra sodium bicarbonate to the extracellular fluid, replacing the neutral salt (Na^+A^-) which it had previously contained This, then, is an addition to the alkali reserve and as such can be used to balance off the acid products of ingestion and metabolism

The excretion of titratable acid is a process in which there is a net gain of alkali reserve, but it is a process of limited potentiality, limited by the capacity of the kidney to reduce the pH of the urine and by the amount of weak acid of suitable pK excreted in the urine This process alone would be unable to maintain the alkali reserve against the continued addition to extracellular fluid of even most of those acids that can be excreted to a considerable extent in un-ionized form Thus, β-hydroxybutyric acid can be excreted about half as the free acid, half as the salt The excretion of titratable acid can therefore diminish the attrition of body buffer by about one-half, but the continued production of this acid would eventually exhaust the extracellular bicarbonate supply Of course, the production of titratable acid contributes nothing to balancing off the effects of the ingestion or production of strong mineral acids The latter effects are overcome by the production and excretion of ammonium ion in place of so-called "fixed cation" (largely sodium and potassium)

Excretion of Ammonia. The source of urinary ammonia was the subject of debate for many years That the ammonia is produced in the kidney was established by the studies of Nash and Benedict (1921) who showed that more ammonia left the kidney in renal venous blood than entered in the arterial blood The experiments of Van Slyke and his associates (1943) demonstrated that a major fraction of the urinary ammonia was derived from the amide nitrogen of glutamine

$$\text{Glutamine} \rightarrow NH_3 + \text{glutamic acid}$$

The more recent work of Pitts (1964) has shown that much of the remainder is derived from the amino group of glutamine Ammonia can also be produced by the oxidative deamination of a number of amino acids (glycine, alanine, leucine, aspartic acid) but under ordinary conditions the urinary ammonia appears to be derived from glutamine and asparagine with smaller contributions from glycine, citrulline, tryptophan, and proline

Ammonia, produced in the cells of the renal tubules, enters and accumulates in the renal tubules by simple diffusion The nature of the process by which this accumulation takes place may be understood from a consideration of the nature of cell membranes and the solubility characteristics of weak electrolytes (Orloff and Berliner, 1956)

Most cell membranes that have been studied have the characteristics of lipid layers permeated by aqueous pores which occupy only a very small part of the total surface area Substances that are highly soluble in lipid can penetrate the entire surface of the cell, while those that are highly water-soluble and lipid-insoluble can penetrate only through the aqueous pores Lipid soluble materials, therefore, diffuse in and out of cells very much more rapidly than water-soluble substances Among the latter are most ions, ionized compounds are, in general, highly water-soluble and poorly soluble in lipid On the other hand, many un-ionized substances are highly soluble in lipids (provided they are not highly polar compounds, e g , sugars, urea, short-chain alcohols, etc) In accord with these generalizations, the ammonium ion (NH_4^+) is highly water soluble and would be expected to penetrate cell membranes poorly, on the other hand, free ammonia (NH_3) is highly lipid-soluble and penetrates cells quite readily

Now suppose we have two aqueous solutions of different pH separated by a membrane having the characteristics of the lipid layer discussed above To such a system ammonia is added The ammonia, being highly lipid-soluble, will penetrate the membrane readily and will reach equilibrium when the concentration of the free ammonia (NH_3) is the same on both sides of the membrane However, in each solution ammonia will react with hydrogen ion to yield ammonium ion

$$NH_3 + H^+ \rightleftharpoons NH_4^+$$

This reaction will be continuously at the equi-

librium required by the dissociation equation

$$K_A = [H^+][NH_3]/[NH_4^+]$$

or

$$pH = pK_A + \log [NH_3]/[NH_4^+], \qquad pK_A = 8.9$$

Since $[NH_3]$ is the same on both sides of the membrane, the numerator of last term may be considered a constant and the log $[NH_4^+]$ will vary inversely with the pH Thus, a decrease in pH of one unit will yield a 10-fold increase in ammonium ion concentration Since the free ammonia constitutes a very small part of the total ($NH_3 + NH_4^+$) the total will vary pretty much as the concentration of ammonium ion

This model may be considered to approximate the situation in the kidney where the solution on one side of the membrane represents the contents of the renal tubule cells in which ammonia is produced and the other side of the membrane, the fluid in the lumen We may consider the pH of the intracellular fluid and its ammonia concentration to be maintained relatively constant and ammonia to accumulate in the lumen until the free ammonia concentration is approximately the same on both sides and the ammonium ion concentration in the lumen that required by the urinary pH The concentration of ammonium ion will therefore increase as urine pH decreases

Because several assumptions involved in this model are only approximations, the actual ammonia excretion varies with pH appreciably less than would be predicted (Orloff and Berliner, 1956) A urinary pH change of two to two and a half units is required to yield a 10-fold change in ammonia excretion (The idealized model would indicate a tenfold change with each pH unit) It should be noted that as NH_3 diffuses into the urine, hydrogen ion is titrated and the pH of the urine tends to become elevated, the pH difference would disappear if it were not maintained by the continuous secretion of hydrogen ion

Ammonia appears in the tubule lumen wherever the tubule fluid has a pH low enough to permit the trapping of ammonia as ammonium ion It thus appears in the proximal tubule when the pH falls appreciably below that of plasma (normally in the rat, in metabolic acidosis in the dog) As urine pH approaches its minimum in the distal nephron, each hydrogen ion secreted into the lumen must be neutralized by capture of NH_3 to form an ammonium ion before another hydrogen ion can be secreted

The excretion of ammonia like the excretion of titratable acid represents replenishment of the body's alkali reserve Quantitatively it represents, under most conditions, the more important contribution to the maintenance of the acid-base balance of the body The sum of titratable acid and urinary ammonium ion represent the net gain of sodium bicarbonate for the body fluids as a result of the process of urine formation (In estimating body balance, it is necessary to subtract from this total any bicarbonate excreted in the urine)

A striking and unique feature of ammonia formation and excretion is the phenomenon of *adaptation* If an individual is given an acidifying regimen (such as the administration of ammonium or calcium chloride or the feeding of a strongly acid-ash diet), there is a gradual increase, over a period of three to five days, of the excretion of ammonia in the urine This increase is independent of changes in urinary pH (which occur very much more rapidly) and the amount of ammonia in the urine is eventually greater at each pH than it was before the acidifying stimulus was started The administration of alkali has an effect exactly the reverse of the administration of acid Neither the nature nor the immediate stimulus to this adaptation are too clearly established It undoubtedly involves a modification in the enzymatic mechanism by which ammonia is produced and presumably a rise in the concentration of ammonia in the cells in which it is produced

In the rat, but not in the dog, it can be shown that glutaminase activity is increased (Davies and Yudkin, 1952, Rector and Orloff, 1959) The overall behavior of ammonia excretion in man resembles that in the dog more closely than in the rat For instance, if acidosis is produced by the administration of inhibitors of carbonic anhydrase which cause massive loss of bicarbonate in the urine, ammonia excretion and glutaminase activity increase markedly in the rat, but ammonia excretion remains at a level related only to urine pH in both man and dog There is no evidence of adaptation of the sort produced by the administration of acidifying salts

The stimulus to adaptation is also not clear

It is obviously in some way related to the intake of acid, but it does not appear to depend on the degree of acidosis, ammonia excretion remaining high when, as a result of the adaptation, plasma bicarbonate has been restored essentially to normal

Quantitative Aspects of Urine Acidification As with all processes of urinary excretion, the urinary acidification is dependent upon the balance between glomerular filtration and tubular reabsorption In this case, the important characteristic of the filtrate is its bicarbonate concentration We will postpone consideration of those factors which modify the secretion of hydrogen ion by the renal tubules and consider first the effect of changes in plasma bicarbonate concentration

We must first take note of the fact that for reasons that have not been determined, the capacity of the tubules to reabsorb bicarbonate varies with the rate of glomerular filtration but not with the plasma bicarbonate concentration The concentration of bicarbonate in the glomerular filtrate is therefore a far more important determinant of bicarbonate excretion than the total amount of bicarbonate filtered To take this into account and to present the reabsorption and excretion of bicarbonate as an orderly, predictable phenomenon, it is the practice to divide the amounts filtered, reabsorbed and excreted by the rate of glomerular filtration and to present the data as the amount reabsorbed, etc , per 100 ml or per liter of glomerular filtrate

When the plasma bicarbonate concentration is low, the urine is acid and essentially free of bicarbonate, all of the filtered bicarbonate is reabsorbed As the plasma bicarbonate concentration is increased, the urine remains essentially free of bicarbonate until the concentration approaches approximately 28 mEq /liter Bicarbonate then begins to appear in the urine and as the plasma concentration increases further bicarbonate reabsorption remains virtually constant at 28 mEq /liter of glomerular filtrate, and the excess is excreted in the urine This is illustrated in Figure 5 12 This tends to produce stabilization of the plasma bicarbonate concentration at its normal level of 27 to 28 mEq /liter When the plasma bicarbonate falls below this level, the filtered bicarbonate is completely reabsorbed and conserved If the plasma bicarbonate rises appreciably above 28 mEq /liter, the excess is excreted and the plasma bicarbonate tends to return rapidly to normal

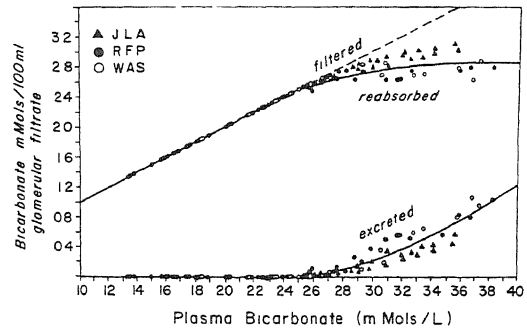

Fig 5 12 Relationship between plasma bicarbonate and reabsorption and excretion of bicarbonate in man (Pitts Ayer and Schiess 1949)

It should be noted that, to the extent that the capacity of the tubule to secrete hydrogen ion is expended in the reabsorption of bicarbonate, no appreciable amount is available to appear as titratable acid or ammonia Thus, when the plasma bicarbonate is close to 28 mEq /liter, essentially all of the filtered bicarbonate will be reabsorbed but there will be little titratable acid and ammonia in the urine (reflecting the fact that the urine pH will not be very low) However, when the plasma bicarbonate drops lower the bicarbonate of the glomerular filtrate may be exhausted before the capacity to secrete hydrogen ion is fully utilized, and a variable part of the remaining capacity will appear as titratable acid (depending on the rate of excretion of buffer acid) or as ammonium ion (depending upon the rate of production of ammonia)

It is also noteworthy that the amount of titratable acid and ammonia in the urine is a poor indication of the capacity of the tubules to secrete hydrogen ion because, if plasma bicarbonate is low, hydrogen ion secretion stops when the urine pH gets too low and before all the capacity for hydrogen-sodium exchange is utilized Thus, the *capacity* to secrete hydrogen ion can be evaluated only when there is bicarbonate left over from the process—that is, when the urine is alkaline

Factors Modifying the Rate of Secretion of Hydrogen Ion. Under ordinary conditions of acid-base balance, with a normal carbon dioxide tension in the blood, a normal cell potassium concentration, etc , the capacity to secrete hydrogen ion in exchange for sodium is

about 28 mEq /liter of glomerular filtrate as indicated in the preceding discussion This tends to maintain the plasma bicarbonate concentration at about 28 mEq /liter The capacity to secrete hydrogen ion may be varied in response to several factors

Carbon Dioxide Tension When the carbon dioxide tension is increased (respiratory acidosis) the plasma bicarbonate concentration increases by titration of the blood buffers, and the pH change attributable to the increased carbonic acid concentration is minimized The elevated plasma bicarbonate concentration persists, and the maintenance implies an increase in bicarbonate reabsorption (hydrogen ion secretion) by the renal tubules Indeed, such an increase in bicarbonate reabsorption is demonstrable immediately upon elevation of the carbon dioxide tension (Relman et al , 1953, Brazeau and Gilman, 1953) If elevation of the carbon dioxide tension is maintained for extended periods there is a further increase in the capacity to secrete hydrogen ion, the nature of this further adaptation is unknown (Sullivan and Dorman, 1955) Decreases in carbon dioxide tension (respiratory alkalosis) have exactly the opposite effects, reducing renal bicarbonate reabsorption (hydrogen ion secretion) and causing stabilization of the plasma bicarbonate concentration at a reduced level

The effects of changes in carbon dioxide tension on hydrogen ion secretion are readily interpreted in terms of the hypothesis that the rate of secretion of hydrogen ion is directly related to the hydrogen ion concentration of the tubule cells The concentration of dissolved CO_2 is directly related to the carbon dioxide tension (P_{CO_2}) and the concentration of carbonic acid (H_2CO_3) is directly proportional to the P_{CO_2} Since cell membranes have a very high permeability to CO_2, all changes in extracellular P_{CO_2} are reflected by similar changes in intracellular P_{CO_2} Thus intracellular pH falls when extracellular P_{CO_2} is elevated and vice versa (On the other hand, changes in extracellular bicarbonate concentration are probably *not* regularly reflected by parallel changes in intracellular bicarbonate and pH)

Potassium Metabolism The secretion of hydrogen ion is depressed when potassium is administered so that the urine frequently becomes alkaline even though the plasma bicarbonate concentration is low Conversely, in the presence of potassium depletion the rate of secretion of hydrogen ion is enhanced so that the plasma bicarbonate concentration becomes stabilized at an elevated level

The effects of potassium on hydrogen ion secretion presumably reflect the fact that the rate of secretion of hydrogen ion is dependent upon the pH of the secreting cells and that when cells lose potassium they become more acid while when they gain potassium they become less acid (Orloff et al , 1953)

Chloride Balance When loss of chloride has been incurred in the course of elevation of the plasma bicarbonate, the excretion of the excess bicarbonate must lead to a contraction of extracellular fluid volume unless chloride is available from the intake to replace the bicarbonate In the absence of such chloride intake, urine acidification continues at a high level

Carbonic Anhydrase The role of carbonic anhydrase and the effect of inhibition of this enzyme have been discussed earlier Under normal conditions the activity of carbonic anhydrase is not rate-limiting in hydrogen ion secretion although it may become so when inhibited There is no evidence that adaptation to acid loads involves an increase in kidney carbonic anhydrase

Adrenal Steroids The secretion of hydrogen ion participates in the enhancement of sodium reabsorption produced by aldosterone and other steroids with similar effects on electrolyte metabolism

PASSIVE REABSORPTION THE EXCRETION OF UREA

Because passive reabsorption is the result of the active reabsorption of other constituents of the glomerular filtrate, it is appropriate to consider this relatively simple mechanism last The reabsorption of urea has long been considered a typical example of this process [14] Certainly as the most abundant constituent of the urine and as one which fits in unique fashion

[14] There is evidence that in ruminants (sheep, camel) there is some sort of active renal conservation of urea when the animal receives a low protein intake Active reabsorption from the collecting duct has also been demonstrated While it has also been suggested that there is a similar mechanism in man, the evidence is not convincing, and for the sake of didactic clarity, any such process will be disregarded

into the formation of highly concentrated urine (Gamble et al, 1934), urea requires separate consideration

Cell membranes generally have a high permeability to urea It is therefore not surprising that as the filtrate is reabsorbed from the renal tubules, tending to concentrate the urea in the remaining fluid, urea tends to diffuse out of the lumen What is more remarkable is the very considerable extent to which the urea concentration can be raised in the urine This appears to be due to two factors *1)* an unusually low permeability to urea of the cells lining some segments of the renal tubules (it is to be remembered that much of the tubule lining membrane also has a uniquely low permeability to water, especially in the absence of antidiuretic hormone), and *2)* a mechanism for maintaining a high urea concentration in the interstitial fluid (of the medulla) surrounding those portions of the nephron that contain fluid with the highest urea concentrations (the collecting ducts), in the latter case the concentration gradient driving the diffusion of urea out of the urine is minimized (Levinsky and Berliner, 1959)

As is characteristic of substances excreted by mechanisms involving passive reabsorption, the fraction of the filtered urea excreted in the urine varies with the urine flow (Moller et al, 1929, Shannon, 1936) The fraction of the filtered urea excreted is given by the ratio of the urea clearance (C_U) to the glomerular filtration rate At urine flows in excess of about 2 ml/min in individuals with normal renal function, there is relatively little further increase in the urea clearance with further elevation of urine flow up to the limits of *water diuresis* At this time the urea clearance averages about 60 to 70% of the inulin clearance, i e, about 30 to 40% of the filtered urea is reabsorbed If *osmotic diuresis* is superimposed, the urine flow can be further increased, and under these conditions the excreted fraction of filtered urea increases further along a curve which may be extrapolated to suggest that no urea would be reabsorbed when no water was reabsorbed (Shannon, 1938) Conversely, as urine flow decreases in antidiuresis the excreted urea diminishes to what may be only 15 or 20% of the filtered These phenomena are illustrated in Figure 5 13 from the data of Shannon obtained in the dog

As was noted earlier, in the discussion of water excretion and reabsorption, the change from the low flow of concentrated urine to the high flow of water diuresis involves primarily modifications in the flow in the distal portions

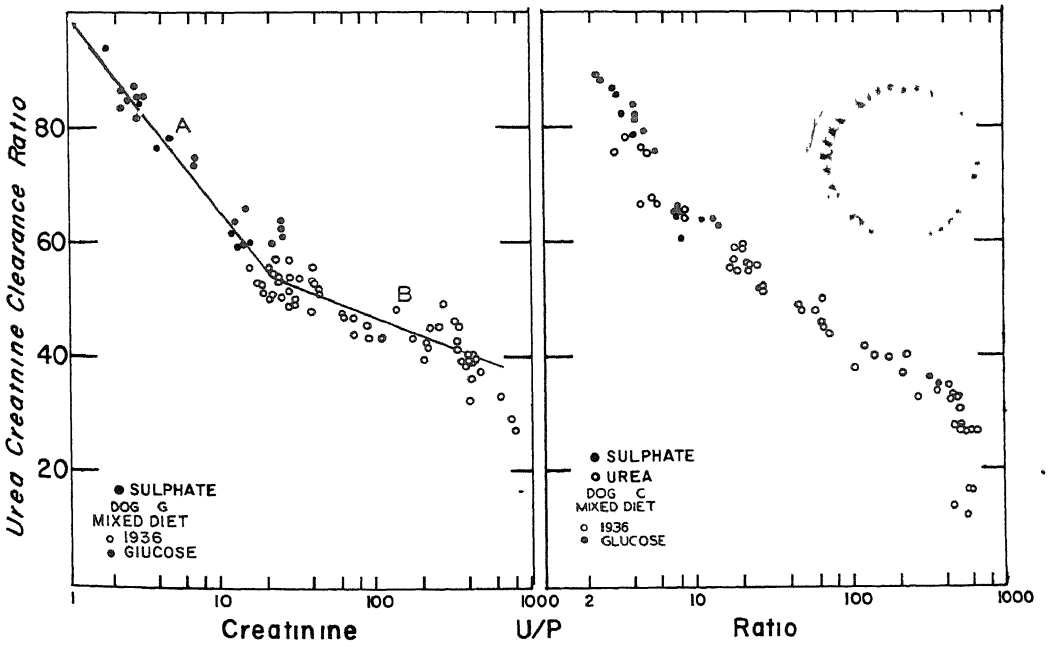

Fig 5 13 The ratio of urea clearance to creatinine clearance (Fraction of the filtered urea excreted in relation to the reabsorption of water as indicated by the U/P ratio of creatinine (Shannon 1938)

of the nephron The reabsorption of water that occurs in the proximal tubule is relatively unaffected Thus, the additional urea that is reabsorbed when water diuresis is interrupted is logically considered to be reabsorbed in the distal tubule and collecting system Furthermore, since in the absence of antidiuretic hormone these portions of the nephron have a low permeability to water, they may be expected to have a low permeability to urea as well It is thus logical to attribute the reabsorption of some 30 to 40% of the filtered urea to losses from the proximal tubule as water is reabsorbed from that segment and to consider the losses from the distal portions of the nephron to be negligible in water diuresis As the fraction of the filtrate reabsorbed in the proximal tubule is diminished in *osmotic* diuresis, the urea is concentrated to a lesser extent and less than the usual 30 to 40% is reabsorbed

In antidiuresis, the reabsorption of water in the distal segments of the nephron system is markedly increased, at the same time, the permeability of the collecting duct to urea is also enhanced Both of these factors lead to an increase in the diffusion of urea out of the urine in the distal portions of the nephron and account for the rapid falling off of the urea clearance as urine flow decreases to low levels

Because the arrangement of the blood supply in the medulla constitutes a countercurrent exchanger, urea escaping from the collecting ducts is not easily carried away in the blood, as it is in the cortex Instead, even a relatively slow leak of urea from the collecting ducts is sufficient to yield a high urea concentration in the peritubular region As a result, the urea concentration in the interstitial space of the papilla is almost as high as in the urine This has several important consequences *1*) The amount of urea lost from the urine is reduced because the concentration gradient is small *2*) The osmotic effect of the urea in the collecting duct urine is counterbalanced largely by urea in the interestitial space, the sodium chloride of the interstitial space, which initiates the urine concentrating process can be utilized to balance the osmotic effect of the non-urea solute, the urea being simply added to both sides of the intervening membrane Consequently, the urine can be made considerably more concentrated when urea is a major part of the excreted solute, and urea, the major product of protein catabolism, and, in fact, by far the most abundant product of metabolism requiring urinary excretion, can thus be excreted largely in water already obligated for the excretion of other urinary solutes *3*) Some of the urea enters the descending limb of the loop of Henle and recirculates through the distal tubule and collecting system In fact, the micropuncture studies of Lassiter, Gottschalk, and Mylle (1961) have shown that, in the antidiuretic rat, the urine flowing through the loops of Henle gains an amount of urea equivalent to about half of the amount filtered so that it would appear that a large part of the urea that escapes the collecting ducts recirculates through the distal tubule and that very little can leave the medulla via the blood in the vasa recta

Because the level of the blood urea and the urea clearance are frequently used for the clinical evaluation of renal function, a brief discussion of these clinical indices is warranted Since the concentration of urea in red blood cell water is the same as in the plasma, the concentration of urea in whole blood is only slightly lower than in plasma, the difference being due to the larger fraction of solids in the red cells Consequently, it has been the usual practice to base the clinical estimation of urea clearance on the measurement of urea in whole blood (although glomerular filtration operates only on plasma) Because of the variation of urea clearance with urine flow some account must be taken of this factor The convention which has been adopted has been to arbitrarily divide urea clearances into two classes When the urine flow exceeds 2 ml /min the clearance of urea is calculated in the conventional fashion except for the substitution of B, the concentration in whole blood, for P, the concentration in plasma The figure (UV)/B obtained is called the *maximal urea clearance* and a value of 75 ml /min is accepted as the average normal It is sometimes the practice to divide the clearance obtained by 75 and express the result as a per cent of normal

When the urine flow is less than 2 ml /min, some correction is necessary to take into account the marked effect of urine flow change on urea excretion It has been found empirically that, in normal individuals, if the clearance is divided by the square root of the urine flow ($\sqrt{V}$) the value obtained is relatively independent of urine flow provided the latter is less than 2 ml /min This figure is referred to

as the *standard urea clearance* and is equal to

$$(UV/B) \times (1/\sqrt{V}) = U\frac{\sqrt{V}}{B}$$

It has an average normal value of 54 and, again, the result obtained is often expressed as a percent of the normal value

When urea clearances are measured, every attempt should be made to assure a urine flow in excess of 2 ml /min since the maximal urea clearance is more clearly related to the value which one wishes to estimate, the rate of glomerular filtration

The blood urea concentration is also, in a rough way, related to the rate of glomerular filtration However, it is subject to modification by factors that do not affect the urea clearance, namely the intake and metabolism of protein and other nitrogen sources For this reason the urea clearance is a much more reliable index of renal function

For the individual in nitrogen balance, almost the entire nitrogen intake is excreted in the form of urea The excretion of urea is in the long term equal to the formation of urea Therefore, if we were to consider the daily excretion of urea as a sort of 24-hr determination of urea clearance we would have

$$C_U = UV/B = \text{rate of nitrogen turnover}/B$$

and

$$B = \text{rate of nitrogen turnover}/C_U$$

Thus, we see that the blood urea is inversely related to the filtration rate to the extent that the urea clearance is related to the filtration rate, but in addition it is also directly proportional to the nitrogen turnover The latter factor is eliminated when the urea clearance is determined

NON-IONIC DIFFUSION

The excretion of weak electrolytes is frequently modified by diffusion dependent upon the dissociation characteristics of the substance concerned The phenomenon is entirely analogous to that involved in the entrance of ammonia into the urine, a process which was discussed in some detail above It was pointed out that un-ionized weak electrolytes frequently penetrate cell membranes very much more readily than their ions As a result when cell membranes separate two aqueous phases of differing pH, the weak electrolyte accumulates in that phase in which the pH requires that the ratio of ionized to un-ionized weak electrolyte is higher The same considerations apply to a number of other weak electrolytes, not only weak bases such as ammonia but weak acids as well Most of the substances the excretion of which has been shown to involve this type of mechanism are foreign to the body, but it is highly probable that a number of normal constituents are also involved although they have not been studied in detail Some of those drugs which have been shown to be excreted by mechanisms involving processes of nonionic diffusion are bases (quinine, atabrine, neutral red, mecamylamine) and acids (salicylates, phenobarbital) As opposed to the situation with respect to ammonia, which is produced in the tubule cells, the two phases of differing pH involved in excretion of these foreign materials are the urine and the peritubular interstitial space

The effect of pH on the excretion of weak acids is exactly the opposite of its effect on that of weak bases This is due to the fact that the ratio of ion to un-ionized fraction increases with pH in the case of weak acids, as indicated by the equation

$$pH = pK_A + \log [A^-]/[HA]$$

while in the case of weak bases the ratio of ionized to un-ionized decreases with rising pH as indicated by the dissociation equation for a base

$$pH = pK_A + \log [RNH_2]/[RNH_3^+]$$

The effect of pH on the excretion of weak bases is appreciable only when the pH of the urine is lower than the pK_A of the base, since it is only when pH is less than pK that the amount of ion is the major fraction of the total For similar reasons pH change has an appreciable effect on acid excretion only when the urine pH is higher than the pK of the acid

The bases and acids noted above as being excreted by mechanisms involving non-ionic diffusion are each secreted into the proximal tubule by active transport processes and escape to a variable extent, depending on urine pH, by non-ionic diffusion in the more distal segments of the nephron

2 / PATHOLOGICAL PHYSIOLOGY OF THE KIDNEY. MICTURITION

Clinical Evaluation of Renal Function

EXAMINATION OF THE URINE

Ordinarily, the first step in the evaluation of the functional status of the kidney, and frequently the source of the first clue to the presence of renal disease, is the clinical pathological examination of the urine This has the unique advantage of extreme simplicity, requiring only a minimum of time and the simplest of equipment Furthermore, the presence of renal disease is usually manifested by some abnormality of the urine However, it is important to note that an apparently normal urine does not exclude the presence of certain diseases of the kidney nor impairment of renal function of even very marked degree

Although the full routine examination of the urine includes several other tests usually intended to detect nonrenal metabolic abnormalities (diabetes, ketosis, etc), those particularly related to disease of the kidney itself are tests for protein and examination of the urinary sediment In addition, determination of the specific gravity and acidity may, under certain conditions, be revealing of disorders of kidney function Certain specific defects of renal function may be detected by analysis of urine for amino acids

TESTS INVOLVING EXAMINATION OF THE BLOOD ONLY

The most commonly used test intended to evaluate the functional state of the kidney is the determination of the blood urea (The results of this determination are commonly reported as the blood urea nitrogen, since nitrogen makes up just under half of the molecular weight of urea, the blood urea concentration is approximately twice the concentration of blood urea nitrogen) The concentration of urea in the blood is directly proportional to the nitrogen turnover and inversely proportional to the renal clearance of urea Its relationship to the nitrogen turnover and to glomerular filtration are fully discussed in the preceding chapter

Since the blood urea concentration is only partially related to the rate of glomerular filtration and to the functional status of the kidney, it is hardly surprising that there is a wide range of normal values for the blood urea concentration and it is likely to be unequivocally elevated only when renal function is reduced by about half or more

Nonprotein Nitrogen Under normal conditions urea contributes about half of the nonprotein nitrogen of plasma (or serum) The remainder is made up of the nitrogen of a heterogeneous group of substances creatine, creatinine, uric acid, amino acids, etc As renal function is depressed the nonprotein nitrogen concentration of plasma rises, largely because of increasing urea concentration, though some of the other components also accumulate The nonprotein nitrogen determination is thus subject to very much the same interpretation and qualifications as the blood urea analysis

Creatinine The plasma creatinine concentration is a somewhat more reliable index of renal function than the blood urea concentration because the rate of formation of creatinine in the body is much more stable than the formation of urea However, some reservation is required because the usual analysis of plasma for creatinine involves a chemical method affected by other constituents of the plasma, this is a more important consideration when the concentration of creatinine is at or near a normal level than when it is substantially increased

TESTS INVOLVING COLLECTION OF URINE

A general comment and caution concerning these tests as a group is warranted These tests (except for the concentration test) involve determination of the rate of excretion of some substance They thus require a *timed collection of urine* and can be no more accurate than the timing and completeness of collection In the case of substances such as urea or creatinine which are normal constituents of the urine, the urine formed before the actual period of the test will contain the test substance and it is, therefore, just as important that the bladder be completely emptied at the start of the test period as that all of the urine be collected at the end Failure to empty the bladder

before the test period will give a result that is misleadingly high just as failure to empty at the conclusion of the test will give an erroneuosly low value Failure to give due care and consideration to this point frequently vitiates the usefulness of what is fundamentally a valuable method for assessing kidney function

Urea Clearance The mechanism of urea excretion has been considered in detail in the preceding chapter, and little need be added here The test is useful for the information it gives concerning the level of glomerular filtration In contradistinction to the simple determination of blood urea, the urea clearance is not dependent upon the rate of formation of urea so that this source of variation is eliminated The urea clearance depends only upon the rate of glomerular filtration and the urine flow When the test is carefully performed it is a very useful index of glomerular filtration rate

Creatinine Clearance The clearance of endogenous creatinine is frequently a valuable index of glomerular filtration As compared with the urea clearance it has the advantage of being unaffected by the rate of urine flow [1] However, for reasons that have not been fully elucidated, the clearance of endogenous creatinine is sometimes considerably greater than the glomerular filtration rate and sometimes lower This is particularly true in the presence of renal disease The creatinine clearance can, therefore, be considered only a rough approximation of the rate of glomerular filtration

Excretion of Phenosulfonphthalein (PSP, Phenol Red) Phenolsulfonphthalein (PSP) is one of that group of organic acids rapidly secreted into the urine by the renal tubules (see preceding chapter) In contrast to some of the other substances in this group, PSP is *not* completely removed from the blood which perfuses the kidney Nevertheless, the rate at which it is excreted by the kidney is determined largely by the rate at which PSP is delivered to the kidney by the flow of blood The excretion of PSP is, therefore, reduced when the renal blood flow is diminished The greatest virtue of the test is its simplicity, PSP is a dye which, in alkaline solution, has an intense red color, and its concentration in the urine is easily estimated

A number of different procedures for the performance of the PSP test have been used, involving various routes of administration of the dye and varying time periods for the collection of the urine Procedures involving intravenous administration of the dye and relatively short periods for the collection of the urine are to be preferred as most sensitive to changes in kidney function Low results can be obtained because of retention of PSP in the bladder as well as because of poor renal function

Concentration Test The concentration test is a measure of the ability of the kidneys to form hypertonic urine Because the test as usually performed involves determination of the urine specific gravity, it can be considered only a rather crude index of this particular function [2] The determination of specific gravity is, however, such a simple procedure that it is unlikely that it will soon be replaced by an estimation of osmolality by the determination of the freezing point depression

In the performance of the test, it is usual to determine the specific gravity of the urine formed after all fluids have been withheld for 10 to 24 hr Normally the specific gravity should be greater than 1 025 although a specific gravity between 1 020 and 1 025 can not be interpreted as a clear indication of abnormality

Clearances of Inulin and *p*-Aminohippurate. Properly performed these measurements yield accurate estimates of glomerular filtration rate and renal blood flow and hence are highly valuable in accurately defining the status of renal function The theoretical basis of the measurements is discussed in the preceding chapter Unfortunately the determination of inulin and *p*-aminohippurate clearances requires the administration of continuous intravenous infusions at constant rate The desired and attainable accuracy can be achieved only with meticulous care in the collection of the urine, usually with bladder catheterization and washout of the bladder at the termination of each collection period Finally, the chemical analysis, particularly that for inulin, is relatively involved For these reasons these tests are rarely used for routine clinical purposes, for most such situations one or more of the approximation procedures may be used

Although the development of isotopically labeled inulin (^{14}C or ^{3}H) and Diodrast (^{131}I) has eliminated many of the problems of chemical analysis in the measurement of filtration rate and blood flow, the other inconveniences remain The precision possible with these methods, properly applied, is rarely needed for clinical purposes and the approximation methods generally suffice Additional approximation methods based upon the disappearance of substances labeled with radioactive markers have been developed The disappearance of a suitable substance (one excreted only by the kidneys and susceptible to la-

[1] However, as in any test involving the collection of urine, the *errors* due to incomplete or inaccurate collection of the urine are minimized if the rate of flow is high

[2] In the formation of hypertonic urine the nature of the urinary solute is more or less a matter of indifference, the process being involved with modifying the urine osmotic pressure to which each solute particle, independent of its nature, contributes equally However, each solute particle does not modify the specific gravity in the same way, one molal solutions of different solutes may vary widely in specific gravity

being with a radioisotope) can be followed by measuring its concentration in serially collected blood samples or, in some instances, even by external counting

MEASUREMENT OF TUBULAR REABSORPTIVE AND SECRETORY CAPACITY

These indices of renal function determined respectively, as the maximum capacity to reabsorb glucose (Tm_G) and to secrete *p*-aminohippurate (Tm_{PAH}) are, like the measurement of inulin and PAH clearances, more or less definitive measurements of renal function (see preceding chapter) Like the latter determinations, the procedures are involved, poorly suited to routine use, and rarely performed for purely clinical purposes

Classification of Renal Diseases

Disturbances of renal function may be separated into two groups—those due to disease of the kidney itself and those due to nonrenal disturbances In the latter group fall abnormalities of renal function due to circulatory disorders and to disturbed hormonal balance with loss or excess of endocrine factors that modify the function of the kidney Among disturbances due to disease of the kidney itself two groups may be recognized *1*) disorders due to specific abnormalities of one or more of the transport mechanisms of the renal tubule, although these are particularly interesting from the point of view of clinicophysiological correlations, they are neither as frequent nor as important as 2) the inflammatory and degenerative diseases which involve the kidney more diffusely, affecting entire nephrons or nephron segments and their functions

In the group of diseases that produce such diffuse involvement of the kidney, a few warrant brief discussion here to provide a background for some of the correlations between disturbances of physiology and renal disease By far the most important of these from the standpoint of frequency of occurrence are glomerulonephritis, arteriolar nephrosclerosis, and pyelonephritis

GLOMERULONEPHRITIS

Glomerulonephritis is a diffuse inflammatory disease involving primarily the glomeruli and secondarily, with loss of glomerular function, degeneration of the conjoined tubules A number of classifications of glomerulonephritis, based largely on pathological distinction, have been proposed and a number of variants are recognized by some workers For present purposes it is sufficient to note that glomerulonephritis can be divided into two forms which may or may not represent different stages of the same disease

Acute glomerulonephritis is characterized by a more or less sudden onset with proteinuria and hematuria, and varying degrees of edema, hypertension and renal insufficiency The onset of the disease can usually be related to an antecedent infection most often with group A, β-hemolytic streptococcus Glomerulonephritis is generally believed to be a disease, involving, in some still obscure fashion, an antigen-antibody reaction which produces damage to the glomerular capillaries Acute glomerulonephritis has a relatively low mortality The great majority of cases recover completely, with no residual evidence of renal disease or of significant functional loss A small proportion do not recover, but show persisting evidence of active renal disease and progressive loss of renal function with an eventually fatal outcome

Chronic glomerulonephritis is a progressive disease characterized by proteinuria, hypertension and diminution of renal function Whether or not it is the progressive form of the same disease recognized as acute glomerulonephritis is disputed In most patients with the chronic form no episode of acute glomerulonephritis is recognized The rate of progress of the disease is extremely variable, some patients have a rapid downhill course with a precipitous decline in renal function Others may, for years, have proteinuria as the only evidence of smoldering disease

THE NEPHROTIC SYNDROME

The nephrotic syndrome is characterized by massive proteinuria leading to a marked reduction of the plasma protein (particularly albumin) concentration, with edema, frequently massive, and generally a marked increase in the concentration of lipids, particularly cholesterol, in the plasma Hematuria and hypertension are usually not prominent A small proportion of instances of the nephrotic syndrome are clearly due to recognizable causes such as *amyloidosis* of the kidney, *lupus erythematosus*, *syphilis*, etc., but in most cases the underlying cause is not recognizable. No unanimity exists as to whether or not the idi-

opathic nephrotic syndrome represents a stage of chronic glomerulonephritis A certain number of patients with the nephrotic syndrome do not recover, but show progressive loss of renal function with the development of hypertension and renal insufficiency in a fashion not distinguishable from chronic glomerulonephritis On the other hand, with antibiotic treatment and prevention of intercurrent infection and with control of the disease with adrenocortical steroids, a considerable proportion of patients with the idiopathic nephrotic syndrome recover completely

Whereas it was formerly believed that in true nephrosis the glomeruli were normal and the disease limited to degenerative changes in the tubule epithelium, this is now recognized as being the exact reverse of the true situation The primary defect is in the capillary basement membrane, permitting the escape of protein into the glomerular filtrate The striking changes in the appearance of the tubule cells on microscopic examination are probably secondary to the high concentration of protein in the glomerular filtrate with protein uptake from the tubule lumen

ARTERIOLAR NEPHROSLCEROSIS

Arteriolar nephrosclerosis is the manifestation of renal damage due to hypertension It is characterized by thickening and hyalinization and sometimes necrosis of the renal arterioles There is progressive loss of glomeruli and the function of the tubules to which they are attached Clinically it is characterized by proteinuria and progressive impairment of renal function which in some instances ("malignant nephrosclerosis") may be remarkably rapid Some degree of nephrosclerosis occurs in most cases of hypertension of long-standing The progressive form leading to renal insufficiency occurs in some 5 to 10% of patients with so-called "essential" hypertension if not treated with drugs that lower blood pressure

In contrast to the diffuse involvement of the kidney in *arteriolar*sclerosis (arteriolar nephrosclerosis) *arterio*sclerotic involvement of the larger vessels may lead to patchy ischemic degeneration of portions of the kidney This type of involvement is relatively benign and rarely leads to significant functional disturbance, except when, occasionally, marked stenosis of the main renal artery or its major branches produces sufficient renal ischemia to lead to hypertension

PYELONEPHRITIS

Pyelonephritis is an inflammatory disease of the kidney resulting from infection of the urinary tract with invasion of the kidney interstitium Single acute attacks may subside without significant sequelae, but repeated or long-standing infections lead to scarring and contraction of the kidney and what may be extensive loss of renal tissue The loss of renal function may be accelerated as changes due to hypertension (itself initiated by the chronic pyelonephritis) are superimposed on the results of infection and scarring Proteinuria is usually not prominent and may be absent

Disturbances of Function in Diffuse Renal Disease

PROTEINURIA (ALBUMINURIA)

Perhaps the commonest manifestation of renal disease is the presence of increased amounts of protein in the urine Normally only traces of protein are present in the urine, less than 100 mg being excreted in a 24-hr period In the presence of renal disease the amounts excreted may vary widely and reach figures of many grams Whereas protein may gain access to the urine with exudation or bleeding into any part of the urinary tract, the glomeruli are the most pertinent source of urinary protein Among the proteins of the urine, albumin predominates, but despite the fact that urinary protein is frequently referred to as albumin, the other plasma proteins are also represented However, it is true that the relative abundance of albumin is greater in the urine than the plasma

An increased concentration of protein in the glomerular filtrate, the result of an abnormal increase in the permeability of the glomerular capillaries to plasma protein, is generally accepted as the cause of proteinuria in most instances of renal disease and is one of the major features of the nephrotic syndrome, of glomerulonephritis and of arteriolar nephrosclerosis

It is worth noting that decreased reabsorption of normally filtered protein has been seriously considered as a possibly significant factor in producing proteinuria This possibility is based on the uncertainty concerning the amount of protein normally contained in the glomerular filtrate in man At a concentration of only 10 mg/100 ml, some 18 g/day might be excreted in the urine if none were

reabsorbed It may be dangerous to assume that the concentration in human glomerular filtrate is the same as that in the dog but it is worth noting that recent micropuncture studies in the dog revealed albumin concentrations in the proximal tubule averaging less than 5 mg /100 ml

On the other hand, there is good evidence not only that there is an increased filtration of protein when proteinuria is present, but that there is also an increase in the reabsorption of protein by the tubules under these conditions and that, in all probability, it is this increased protein uptake that is responsible for the histological changes in renal tubule cells in such disorders as the nephrotic syndrome

Aside from its importance as a clue to the presence of renal disease, proteinuria may, when of sufficient intensity, lead to significant depletion of the plasma proteins In the nephrotic syndrome, largely as a result of urinary losses, the plasma albumin concentration may be reduced to 20% or less of its normal value This is a significant factor in the development of nephrotic edema

The presence of proteinuria is not always a sign of significant organic disease of the kidney It may be produced in otherwise normal individuals, for example, by fever or by violent exercise Particularly likely to be misleading is the benign condition known as *orthostatic albuminuria* or *postural proteinuria* This is characterized by the occurrence, especially in young people, of proteinuria when the individual assumes the upright position The urine, after a night's rest in bed, is protein free The production of proteinuria is presumably attributable to some sort of circulatory disturbance associated with the erect posture It is important chiefly because it is frequently mistakenly interpreted as indicating the presence of latent glomerulonephritis

CYLINDRURIA

Casts are collections of protein that has precipitated in the tubules or ducts of the kidney and has been molded in the form of the structure in which it was precipitated. Cylindruria or the presence of increased number of casts in the urine is commonly associated with proteinuria of glomerular origin Aside from the diagnostic information derivable from the nature of the casts, the detection of casts is most significant as an indication that the protein in the urine has arisen from the nephrons The casts may consist of protein only (hyaline casts) or may have incorporated into them red or white blood cells, epithelial cells, etc The normal urine does not contain more than 2000 casts/24 hr

HEMATURIA

Red blood cells may be present in the urine in increased numbers (normal less than 130,000/24 hr) because of bleeding anywhere into the urinary tract Of greatest importance in the present context is that, with inflammatory disease of the glomeruli, red cells as well as protein may penetrate the glomerular capillaries Marked hematuria of renal origin is particularly characteristic of acute glomerulonephritis

IMPAIRMENT OF URINARY CONCENTRATION POLYURIA NOCTURIA

Two types of impairment of urine concentrating capacity are recognizable *1*) due to impairment of the process by which water is removed to produce urine hypertonic to plasma and *2*) due to the excretion of increased amounts of solute per functioning nephron Both types of defect contribute to the impairment of urine concentrating power observed in the presence of renal disease Specific defects in the process that renders the urine hypertonic are present in *potassium depletion* and *hypercalciuria* Since the processes responsible for rendering the urine more concentrated than plasma are located in the renal medulla, disease that disrupts the structure and/or function of this portion of the kidney, such as pyelonephritis and hydronephrosis, may be expected to have particularly marked effects on the concentrating process

On the other hand, as renal function becomes progressively impaired by any nephron-destroying disease process, impaired ability to produce concentrated urine must inevitably result Indeed, it has been shown experimentally that removal of one kidney and part of the other results in impaired ability of the remaining kidney to produce concentrated urine The situation here is quite analogous to that observed as solute excretion is markedly increased (osmotic diuresis) in the individual with normal kidneys (see previous chapter, Fig. 5 9*B*) As renal function becomes progres-

sively diminished, the rate of excretion of solute must, over the long run, remain essentially unchanged reflecting the maintenance of salt balance and the excretion of products of metabolism However, as the number of nephrons involved in urine formation becomes smaller, the amount of solute excreted by each of those remaining becomes greater in proportion Thus, the volume of isotonic fluid in each nephron reaching the site of formation of hypertonic urine is increased, and even the removal of a normal amount of water changes the concentration only to a limited extent

As the ability to form concentrated urine is impaired, the volume of urine excreted must increase The formation of increased volumes of urine is known as *polyuria*, a common manifestation of impaired renal function The production of excessive amounts of urine may cause the patient to awake at night to void, a symptom designated as *nocturia* (Of course, the ingestion of large volumes of fluid may lead to polyuria and nocturia in the absence of renal disease)

OLIGURIA ANURIA

Oliguria is the excretion of a markedly reduced volume of urine, anuria is the complete suppression of urine formation Oliguria may, at times, be physiological—that is, a normal response to dehydration and the characteristic manifestation of the formation of highly concentrated urine A particularly low urine flow is found when dehydration is accompanied by a low rate of solute excretion This combination is likely to be encountered in the individual who is excreting very little salt because of a low salt intake, because of antecedent salt loss (sweating, diarrhea, vomiting, induced diuresis) or because salt excretion is suppressed for other reasons as in the individual who is developing edema (see discussion of edema)

On the other hand, oliguria or its extreme, anuria, may be a manifestation of a severe disorder of renal function. It may occur as a complication of severe acute nephritis or as a terminal event in chronic glomerulonephritis or other chronic renal disease Most often, however, anuria or severe oliguria is a manifestation of some acute renal insult—a circumstance commonly known as *acute renal insufficiency* or *acute renal failure* Such severe acute damage may be produced by a variety of injuries and nephrotoxic substances, particularly with traumatic shock (in which circumstance it has been called the *crush syndrome*), hemorrhagic shock, incompatible blood transfusion, and mercury or carbon tetrachloride poisoning This list is far from inclusive, and acute renal insufficiency may be caused by any condition which produces prolonged hypotension and/or intense renal vasoconstriction Renal ischemia becomes a major factor in the production of acute renal insufficiency in those situations in which chemical nephrotoxins can not be implicated

The methods by which glomerular filtration is measured are not applicable in the presence of anuria, so that it is not possible to say with certainty whether, in acute renal failure, glomerular filtration ceases, or whether it continues but that complete reabsorption of the filtered fluid occurs through disrupted tubule walls Both theories have their supporters In either case, it is clear, *effective* glomerular filtration is zero

It has also been proposed that in the anuria following trauma the renal blood flow is not reduced, but actually increased, the blood being shunted away from the cortex and through the juxtamedullary and medullary regions by dilation in the latter areas This concept has been largely discredited In the presence of anuria there is a marked reduction in the renal blood flow The preferential injection of the juxtamedullary circulation which can be demonstrated under these conditions (Trueta et al , 1946) is due to the lesser involvement of this part of the renal circulation in the generally intense renal vasoconstriction

EDEMA

The accumulation of sufficient excess of extracellular fluid to produce detectable swelling of distensible tissues (edema) is a common feature of many renal diseases Since edema fluid is extracellular fluid, it has the composition of plasma except for its lower protein concentration. Like plasma, then, its major constituents are sodium chloride and water Except for localized and limited amounts of edema which can be produced by redistribution of the normal volume of extracellular fluid, the production of edema requires that an excess of both salt and water be retained within the body and, conversely, edema may be produced by any circumstance that yields a sufficient

increase of the salt and water content of the body Actually in the production of edema, it is the salt retention which is primary, water being retained to maintain the normal osmotic pressure of body fluids, and, further, in the salt, it is specifically the sodium ion which plays the predominant role, in the edematous individual, edema is increased by sodium bicarbonate (or, of course, sodium chloride) but not by ammonium or potassium chloride

In patients with renal disease, edema may be traced to three types of distrubance *1)* to *impairment of sodium excretion* due to the direct effect of disease on renal processes involved in salt excretion, *2)* to *hypoproteinemia*, and *3)* to *cardiac insufficiency*, a common complication of renal disease particularly in the presence of long-standing hypertension

1) The edema of acute glomerulonephritis is primarily of the first type, due to the effect of disease on the renal processes involved in salt excretion, salt intake exceeds the capacity of the kidney to excrete it, and edema results The predominant mechanism is probably a sudden and sharp reduction in the rate of glomerular filtration without an equivalent impairment of the capacity of the tubules to reabsorb sodium salts, a condition frequently called "glomerulotubular imbalance " Through much of the course of chronic glomerulonephritis, a new balance is struck so that, despite reduction of the rate of glomerular filtration, sodium reabsorption by the tubules is reduced to an equivalent extent, and adequate excretion of salt is maintained In the course of chronic glomerulonephritis, edema may appear as a result of any of the mechanisms noted above, because of the development of hypoproteinemia or, particularly late in the course of the disease, because glomerular filtration is reduced to such low levels that it is no longer possible to maintain more than a very low rate of salt excretion, and finally because cardiac insufficiency may be superimposed

In acute renal insufficency the capacity to excrete salt may be entirely lost Thus, any salt and fluid intake is retained in the form of edema, except to the extent to which they may be lost by extrarenal routes This situation represents the extreme of edema formation due to impairment of the renal processes for salt excretion

2) The classic example of edema resulting primarily from hypoproteinemia is that which characterizes the nephrotic syndrome In this disorder the continuous loss of large amounts of protein, particularly albumin, in the urine taxes the capacity of the body mechanisms to synthesize albumin and the plasma protein concentration falls As the plasma protein concentration is reduced, the colloid osmotic pressure is lowered, particularly since most of the colloid osmotic pressure of plasma is normally attributable to its albumin concentration The lowering of the plasma colloid osmotic pressure favors redistribution of fluid volume from plasma to interstitial space in accord with the Starling hypothesis (see sect 4, chap 12) It is important to note that although this series of events favors expansion of the interstitial fluid volume at the expense of the intravascular volume, no significant quantity of edema can be attributed to this series of events *alone*, the intravascular volume is not large enough to yield a significant volume of edema without disastrously compromising the circulation The production of hypoproteinemic edema, then, requires, as does all edema formation, retention of excess salt and water The reduced intravascular volume favored by the reduction of colloid osmotic pressure is, in all probability, the stimulus for renal salt retention mediated in part by the secretion of salt retention steroid (aldosterone) by the adrenal cortex and, probably to a major extent, by the as yet poorly understood system which controls the reabsorption of salt by the tubules A low rate of glomerular filtration may be a contributory factor

That hypoproteinemia alone is not a sufficient cause of edema in the nephrotic syndrome is indicated by the results of steroid treatment in this disorder. When fully successful, treatment with large doses of adrenocortical steroids produces disappearance of proteinuria, restoration of the plasma protein concentration, and diuresis with disappearance of the edema However, in a number of instances in which the steroid is without apparent effect on proteinuria or plasma protein concentration, withdrawal of steroid therapy is accompanied by diuresis and loss of the edema, although the plasma protein concentration remains at its previous low level Spontaneous diuresis without increase of the plasma protein concentration may also occur

3) The edema of cardiac failure, whether a complication of renal disease (hypertension) or not, depends on renal retention of excess salt

Thus, edema of any origin is a manifestation of disordered kidney function, in the case of heart failure secondary to an abnormality of cardiac function Although the sequence of events leading to edema in heart failure is disputed, the salt retention which occurs is the result of a complex of factors including increased secretion of salt-active adrenocortical steroids, some reduction of renal blood flow and glomerular filtration in many instances, and, almost certainly, the poorly understood factor or factors mentioned above The latter is manifested by the following observations The administration of salt-active steroids to normal experimental animals leads to only very little retention of sodium (much of which replaces potassium which is lost) and no edema If, however, because of borderline cardiac insufficiency or elevation of venous pressure in a major segment of the circulation, the experimental animal is prone to the development of edema, sodium will be retained and edema will form—without reduction of the rate of glomerular filtration The difference between edema formation and no edema formation in these two experimental situations is neither in glomerular filtration nor the amount of adrenocortical steroid administered, indicating involvement of the additional unidentified factors

ACIDOSIS

Inability to maintain a normal level of plasma bicarbonate (alkali reserve) in the face of an acidifying intake is a common feature of advanced renal disease of any type The most important factor responsible for the acidosis is deficient ability to form and excrete ammonia and thus maintain the plasma bicarbonate concentration in the face of the acid load provided by the acififying components of the normal diet Usually there is no defect in the ability of the kidney to render the urine acid and highly acid urines are frequently observed in even the most advanced renal failure Since there is no major change in the excretion of weak acids, the output of titratable acid is not depressed However, the reduced number of nephrons is not adequate to form and put out ammonia at a normal rate in the face of even the usual, much less any increased, demands Thus, the strong acids derived from dietary sources are excreted as the sodium or potassium, rather than the ammonium salt and the blood bicarbonate (alkali reserve) is depleted In some cases an additional factor may contribute to the acidosis in the form of a deficient ability to reabsorb bicarbonate completely when the plasma bicarbonate concentration is at normal or only slightly lowered levels

If bicarbonate is added to render the intake effectively neutral, the acidosis of renal failure may be absent In fact, if bicarbonate intake is much more than that necessary for a neutral intake, alkalosis may be relatively easily produced since the capacity to excrete bicarbonate at a rapid rate is limited as a consequence of the reduction of the rate of glomerular filtration

As opposed to the tendency to the development of acidosis, which is almost universal in advanced renal disease of any type, acidosis of renal origin may occur as the result of a more or less specific defect of renal function with renal function remaining relatively intact in other respects This relatively uncommon condition is known as *renal tubular acidosis* In contrast to the acidosis of renal insufficiency, it appears to be due specifically to an inability to render the urine normally acid and not to a deficient capacity to form ammonia In some such cases the maximum capacity to secrete hydrogen ion in exchange for sodium can be shown to be normal, since there is a normal maximum rate of bicarbonate reabsorption when bicarbonate is administered Under these conditions of bicarbonate loading, the urine is alkaline and the secretion of hydrogen ion which effects bicarbonate reabsorption occurs against only a very limited concentration gradient (see chap 1, p 5-29ff) However, as the bicarbonate concentration is reduced to normal or below, the tubules are unable to effect the complete removal of bicarbonate, this requiring that the urine be rendered highly acid Hence, bicarbonate escapes in the urine The defect appears to be in the ability to secrete hydrogen ion against any considerable concentration gradient Since the urine does not become acid, the excretion of ammonia remains low despite what is probably a normal ability to produce ammonia in the renal tubules (see p 5-31)

RENAL INSUFFICIENCY, UREMIA

Renal insufficiency is the general term for reduction of the function of the kidney It is manifested by many of those physiological disturbances already described—impaired con-

centrating capacity, polyuria, nocturia, acidosis, and a general loss of flexibility in the maintenance of normal body composition in the face of the stress of departure of the intake from ideal *Uremia* is the complex of symptoms and signs that accompany advanced renal insufficiency It is characterized by anemia, nausea, vomiting, weakness, twitching, frequently convulsions, and, terminally, stupor and coma Although it derives its name from the elevated blood urea concentration, which is a universal finding in the presence of the syndrome, the urea retention is not primarily responsible for the symptoms

That urea itself is not responsible for the abnormalities associated with uremia is shown by several observations Urea may be administered to normal individuals without producing significant disturbances In the uremic individual, the blood urea can be considerably reduced by restriction of the protein intake without otherwise affecting the course of the disorder The improvement which can be produced in the uremic patient by dialysis with the "artificial kidney" is not lost when urea is included in the dialysis bath so that the blood urea is not removed by the dialysis

Disturbances of acid-base balance and fluid and electrolyte metabolism are also commonly present in uremia, and may, at times, contribute to or be responsible for certain of the symptoms Nevertheless, these electrolyte imbalances can not be considered to be the major contributor to the picture of uremia, and the factor or factors primarily responsible for the symptoms and signs remains unidentified It is generally believed that noxious products of metabolism may, in the presence of depressed renal function, accumulate in the body fluids till toxic concentrations are reached These substances, if they exist, have never been adequately identified

INTRINSIC DEFECTS OF RENAL TUBULAR FUNCTION

As opposed to the disturbances of renal function attributable to diffuse inflammatory or degenerative kidney disease, there are a number of abnormalities due to deficiency of certain transport mechanisms or groups of transport mechanisms Many of these defects are familial or congenital though some may be acquired They are for the most part uncommon, but warrant brief mention because of their unusual physiological interest

One such defect, *renal tubular acidosis*, has been mentioned above and the impairment of sodium-hydrogen ion exchange described The disorder is, at least in some instances, familial It is frequently associated with nephrocalcinosis and pyelonephritis, but these are quite probably secondary rather than the cause of the renal abnormality

Nephrogenic diabetes insipidus is a rare congenital familial disorder most often encountered in males and characterized by the continuous obligatory excretion of dilute urine, and consequently intense polyuria and secondarily polydipsia The abnormality is apparently due to inability of the distal portions of the renal tubules to respond to pituitary antidiuretic hormone by an increase in the permeability to water Thus, the urine, diluted by salt removal in the distal portions of the nephron, fails to give up the excess of water in the tubules, and the water is lost in the urine True or *pituitary diabetes insipidus* is characterized by the same symptoms and signs but is due to a lack of antidiuretic hormone secretion The tubules are normally responsive to antidiuretic hormone in this disorder, which is much more frequent than the nephrogenic type Pituitary diabetes insipidus is usually an acquired abnormality secondary to injury to the pituitary and/or hypothalamus

Renal glycosuria is characterized by the excretion of glucose in the urine when the concentration in the plasma is normal or low The abnormality is a defect in the mechanism by which glucose is reabsorbed in the proximal tubule, other functions of the proximal tubule may be normal The specific nature of the derangement is not known There is some depression of the maximum capacity to reabsorb glucose (Tm_G), but there is also considerable excretion of glucose when the concentration is below that required to saturate the reabsorptive mechanism The possible interpretations of this "splay in the titration curve" are discussed on page 5-12 of the preceding chapter

Renal Hypophosphatemia (or Vitamin D resistant rickets) is a familial disorder characterized by excretion of phosphate in the urine when the plasma concentration is low It is attributable to a defect of the phosphate reabsorptive mechanism analogous to that for glucose in renal glycosuria

Amino-aciduria. Defects of amino acid reabsorption occur as specific defects of certain transport mechanisms and as part of more generalized disorders of renal tubular function An example of the specific type is that known as *essential cystinuria* in which the abnormality is limited to diminished reabsorption of cystine, lysine, arginine and ornithine The chief hazard derives from the formation of stones from the poorly soluble cystine Abnormalities involving certain other specific amino acids or groups of amino acids are also known In addition

defects of amino acid reabsorption may occur in several other disorders including, among others, Wilson's disease (fundamentally a disturbance of copper metabolism), heavy metal poisoning, and the Fanconi syndrome in which amino-aciduria is associated with defective reabsorption of glucose and phosphate and sometimes with renal tubular acidosis

Disturbances of Renal Function of Extrarenal Origin

The function of the kidney is dependent, for the maintenance of glomerular filtration, on the adequacy of the circulation The effect of shock, leading, as it may, to sustained damage to the kidney, has already been discussed In addition several of the renal transport systems for electrolytes and water are regulated by the activity of endocrine organs The function of these systems is therefore subject to disturbance through abnormal activity of the endocrine organs in the form of either deficient or excessive secretion of hormones acting on the kidney Two such abnormalities have already been described in relation to intrinsic renal disorders which they resemble or to which they are related

1) *Pituitary diabetes insipidus* in which, because of deficiency of antidiuretic hormone secretion, renal water reabsorption is diminished and a dilute urine is continuously formed The converse of this disorder may occur and a concentrated urine be formed when a reduced osmotic pressure of body fluids would ordinarily lead to the formation of dilute urine, most often this is due to the induction of antidiuretic hormone secretion by nonosmotic stimuli, occasionally to ectopic secretion of vasopressin by tumors

2) The excessive reabsorption of salt that characterizes *edema formation* and the contribution of hypersecretion of aldosterone have been discussed in relation to edema Excessive secretion of aldosterone leads to accumulation of edema only in the presence of factors predisposing to edema formation In the absence of such factors, the increased sodium reabsorption is limited, and the major manifestation of hypersecretion of aldosterone is *potassium loss* resulting from stimulation of secretion of potassium ion in exchange for reabsorbed sodium If potassium loss due to intrinsic renal disease with defective potassium reabsorption exists, it has not been demonstrated, and excessive renal potassium excretion appears to be due to excessive secretion of potassium by the renal tubules, generally stimulated by excess adrenocortical hormone

In the absence of adrenocortical hormones (*adrenal insufficiency*, Addison's disease) reabsorption of sodium and secretion of potassium by the renal tubules are defective Sodium loss in the urine proceeds despite contraction of the extracellular fluid volume, which may become markedly reduced The potassium concentration of body fluids becomes elevated Abnormal loss of sodium in the urine despite sodium depletion may occasionally result from renal disease, and may be produced by inhibitors of sodium reabsorption (diuretics)

The reabsorption of phosphate by the renal tubules is regulated by parathyroid hormone Excessive secretion of parathyroid hormone (*hyperparathyroidism*) is associated with loss of phosphate in the urine, loss of parathyroid function (*hypoparathyroidism*) leads to elevation of the plasma phosphate concentration without an equivalent increase in urinary excretion

THE URINARY BLADDER

ANATOMIC CONSIDERATIONS

Urine leaving the tips of the renal papillae passes through three functionally distinct divisions of the urinary tract in its course to the exterior The first of these, termed the upper urinary tract, is made up of the minor and major calyces of the two kidneys, the renal pelves, and the ureters It functions as a low-pressure, actively propulsive conduit with a small, fixed capacity, transmitting urine rapidly to the urinary bladder by peristaltic wave motion The second division, the urinary bladder, acts as a reservoir, storing urine at low pressures and periodically discharging it at much higher pressures The third division, comprising the male urethra below the urogenital diaphragm, serves as a passive conduit for the urinary stream and, except for the intrinsic resistance offered to the flow of fluid, plays no part in the mechanics of voiding This structure has no homologue in the female, a fact which underscores its role as an essential male genital organ, associated anatomically rather than functionally with the urinary tract

The entire urinary tract is lined by transitional epithelium as far distally as the membranous urethra This epithelium, 5 to 7 cells thick when the urinary organs are empty, rests on a fibroelastic lamina propria which is com-

monly but incorrectly designated the submucosa (A muscularis mucosae is not present in the urinary system, and, therefore, a true submucous coat which by definition lies deep to this muscular layer cannot be present The term "submucosa" will nevertheless be retained, since it is honored by long and extensive usage) Transitional cells have the ability to slide over one another, thereby increasing their surface area at the expense of the thickness of the cell layer without breaking the continuity of the epithelium Deep mucosal folds or rugae are present in the collapsed ureter and bladder, which, together with the unique properties of the epithelial coat, permit the considerable dilatation which these structures undergo in the course of urine transportation and storage The submucosa rests on a smooth muscle coat, the muscularis, and is in turn surrounded by a loose areolar adventitia which in no way limits distensibility

Anatomic adaptation to function resides chiefly in the muscularis of the urinary tract It was formerly believed that the smooth muscle of the upper tract and bladder was disposed in three layers of unvarying thickness, an inner longitudinal, a middle circular, and an outer longitudinal This concept is not supported by anatomic microdissections, and fails to explain the pattern of motility of these organs The muscularis of the upper urinary tract is now believed to be arranged as interlacing bands of smooth muscle fibres, spiralling in both a clockwise and counterclockwise direction from the necks of the minor calyces to the trigone of the bladder In the calyces and renal pelvis, the majority of spirals have a shallow angle of ascent, and the majority of the muscle in this area appears circular Near the ureteropelvic junction and in the upper few centimeters of the ureter, the spirals wind much less sharply and the muscle bundles appear predominantly longitudinal The major length of the ureter is again supported mainly by tightly wound spirals with only a few longitudinally arranged bundles, but, in the lowermost portion of the ureter, where it passes through the bladder wall, the muscular spirals disappear and the intramural ureter is surrounded only by a thin coat of entirely longitudinal muscle These fibers are continued beyond the ureteral orifices, where they fan out and mingle with their opposite numbers to form the bulk of the trigonal muscle

The individual smooth muscle cells of the upper urinary tract are linked by intercellular bridges, forming a syncytium capable of conducting an action potential without the necessity of extrinsic nervous mechanisms The force and direction of the resulting muscular contraction depends on the predominant directional arrangement of the muscle bundles at any given level

The lower ends of the ureters enter the posterolateral angles of the bladder wall and, pursuing an oblique course, first through an hiatus in the vesical muscle, and then within the vesical submucosa, terminate in orifices at the lateral angles of the trigone The total length of ureter enclosed by the bladder in the adult is approximately 2 cm , with an average diameter of 3 5 mm Terminally, the ureter is anchored firmly to the trigone by continuation of its longitudinal muscular coat, and by fusion of its roof with the mucous membrane of the bladder Where is passes through the ureteral hiatus, however, there is only the loosest of areolar connections between vesical and ureteral muscle (Waldeyer's space) in order that the bladder may "slide up" around the ureter as it fills with urine Externally the ureter is invested by the reflection of fascicles of the detrusor musculature onto the lower several centimeters (Fig 5 14) There is thus no anatomical basis of a circular muscular sphincter in this area, known as the ureterovesical junction, which might prevent reflux of urine from the bladder to the upper urinary tract The ureterovesical junction nevertheless remains closed except when urine is flowing into the bladder Reflux is prevented by the oblique course of the ureter through the bladder wall, which is in turn maintained by the firm terminal anchoring of the ureter to the trigone of the

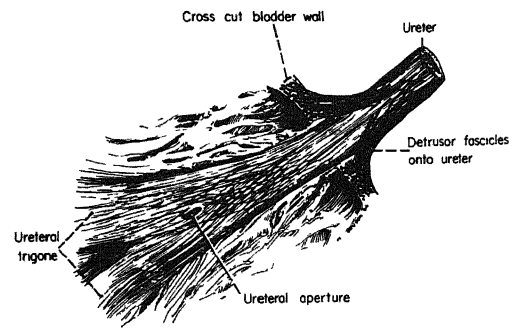

Fig 5 14 Reflectance of fascicles of muscle from bladder onto lower portion of ureter Source Woodburne, 1964

bladder and the firm support of its posterior wall by the detrusor muscle of the bladder When intravesical pressure exceeds ureteral pressure, as in voiding, the flexible anterior wall of the submucosal ureter is collapsed against the firm posterior muscular supports while fixation to the trigone maintains its length The resistance to flow through a tube of zero diameter is infinitely high, and reflux cannot occur

The bladder, when distended, consists of a spherical portion called the fundus and a cylindrical portion called the posterior urethra (Fig 5 15) The male posterior urethra includes the prostatic and membranous urethra, and in the female it includes the entire proximal three-fourths of the urethra The fundus and posterior urethra should be considered as one unit, both anatomically and functionally, as both are derived embryologically from the urogenital portion of the cloaca

The muscularis body of the urinary bladder, known as the detrusor muscle, is composed of an interwoven network of decussating smooth muscle bundles, coursing in random fashion in all directions, and at all depths in the bladder wall There is no evidence for the three concentric layers of fibers formerly believed to be present At the vesical neck and in the posterior urethra the orientation of these muscle bundles is primarily longitudinal To stress the longitudinal orientation of the smooth muscle in the posterior urethra is not to deny that other components of the bladder wall continue into the urethra in spirally and circular directions external to the inner longitudinal muscle A true annular sphincter has never been demonstrated at the vesical neck, although there is

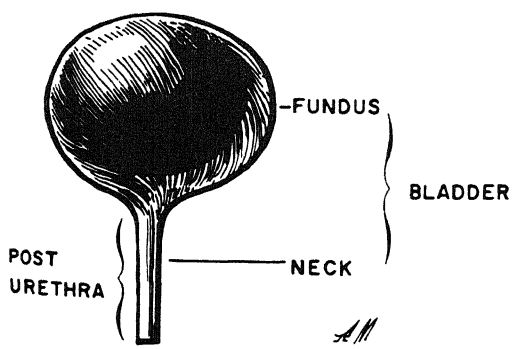

Fig 5 15 The bladder when distended consists of a spherical portion called the fundus and a cylindrical portion called the posterior urethra Source Lapides 1970

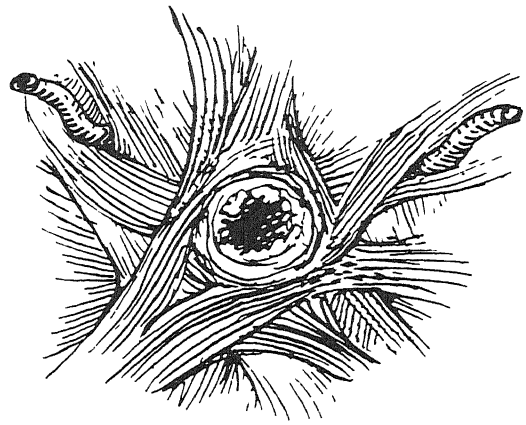

Fig 5 16 Dissection of musculature at vesical neck of bladder Source Woodburne 1960

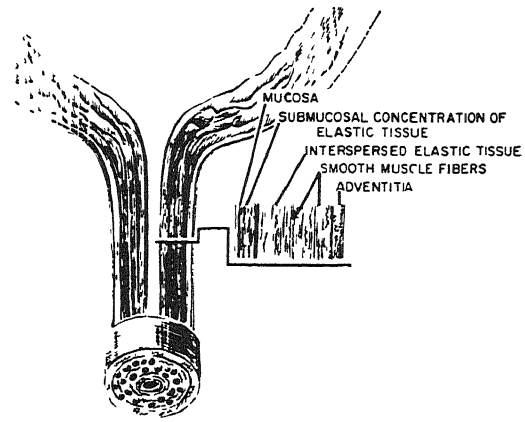

Fig 5 17 Disposition of elastic tissue in posterior urethra Source Lapides 1970

a minor accumulation of muscle fibers in this area In dissection of the vesical neck it has been noted that fascicles of smooth muscle arch toward and then away from the vesical neck and their pull would be in a diverging rather than in a constricting motion, hence, constituting an opening mechanism (Fig 5 16)

In addition there is a considerable amount of elastic tissue found in the bladder and in the posterior urethra The amount of elastic tissue is most prominent at the vesical neck and along the posterior urethra This elastic tissue is in the submucosa and intermingled with the muscle bundles (Fig 5 17)

The structure of the external sphincter and its role in voluntary compression of the urethra has been briefly considered Urethral compression is also exerted to a minor extent by the levator ani muscles, and the small muscles of

the perineum, notably the bulbocavernosus, which is also capable of stripping the male urethra following micturition

Neuroanatomic Considerations

THE UPPER URINARY TRACT

Nerve fibers and ganglion cells are present in the adventitia, muscular and submucosal coats of the ureter, originating from the sympathetic and parasympathetic divisions of the autonomic nervous system The presence of this innervation is unnecessary for the maintenance of muscular tone, or for the initiation, maintenance and variation of pelviureteric contractions. Drugs affecting the autonomic nervous system at all synaptic levels have no effect on ureteral motility in pharmacologic doses, whether administered systemically or applied directly to the ureteral wall Ureteral denervation, likewise, has no effect The best available evidence indicates that ureteral motility is an autonomous function, dependent on normal ureteral metabolism, and coordinated via the intercellular smooth muscle bridges of the muscularis The stimulus to contraction is stretching of the muscle fibres The ureter is richly supplied with visceral afferent fibres terminating in the L1 and T12 segments of the spinal cord Acute ureteral distension is the adequate stimulus, giving rise to ureteral pain, referred along the corresponding cutaneous dermatomes This pain may be abolished by section of the ureteral nerves without interfering in any way with peristalsis or tone

BLADDER BLADDER NECK AND EXTERNAL SPHINCTER

These structures function as a unit in the maintainance of continence and the act of micturition Their nerve supply is, therefore, functionally integrated, and can be logically considered under a single heading Innervation is both motor and sensory, derived from the somatic and autonomic nervous systems, with integration on both segmental reflex and suprasegmental levels

Motor Innervation Sympathetic white rami arising from the lowest thoracic and upper two lumbar segments of the intermediolateral column of grey matter of the spinal cord pass through the sympathetic chain to synapse in the celiac and mesenteric ganglia, from which grey rami flow into the pelvis as part of the superior hypogastric plexus (presacral nerve) At the promontory of the sacrum the plexus bifurcates, to form the right and left inferior hypogastric plexi (hypogastric nerves) which run deep into the pelvis to form the pelvic plexus From here, fibers pass to smaller plexi surrounding the bladder, prostate and posterior urethra These efferents, contrary to previous teaching, have no known effect on vesical and bladder neck function, through their action on the trigone and urethral crest, however, they may close the bladder neck during ejaculation

Parasympathetic motor fibers to bladder and bladder neck arise in the intermediolateral column in the second, third and fourth segments of the sacral cord, and travel as medullated fibers in the pelvic nerves (*N erigentes*) to the pelvic plexus Synapses occur with postganglionic neurons either here, or with ganglion cells within the bladder wall, with grey rami taking a short, direct course to the vesical muscle The parasympathetic division is the sole motor supply of the detrusor, both fundus and posterior urethra The time-honored theory of dual antagonistic innervation of the body and neck of the bladder, in which sympathetic impulses relaxed the detrusor and constricted the internal sphincter (syn = bladder neck), and parasympathetic impulses produced the reverse, is not supported by experimental evidence Presacral nerve section in the human has no effect on micturition, nor do sympathomimetic drugs Bilateral pelvic nerve section causes complete detrusor paralysis, with urinary retention and overflow incontinence, while their stimulation causes immediate detrusor contraction

The somatic motor supply of the striated muscles of the perineum, including the external sphincter, is carried via the pudendal nerves from the anterior horn cells of sacral segments 2, 3, and 4 These fibers maintain tonic contraction of the external sphincter except when reflexly inhibited during micturition Their bilateral section causes total relaxation and degeneration of the external sphincter muscle Continence is not affected, but rather, the ability is lost rapidly and voluntarily to arrest the urinary stream, once initiated.

Sensory Innervation. Afferent fibers, both visceral and somatic, follow the three routes taken by the efferent fibers of bladder, urethra, and perineum

Some sensory fibers arising from bladder and posterior urethra follow sympathetic efferent pathways to cell stations in the dorsal root ganglia The lower limit of their central connections is at L2, while their upper limit has been variously placed from T11 to as high as T6, following clinical observations on patients with transections of the spinal cord The exact role of these fibers is obscure They probably carry pain and some proprioceptive and temperature sensation, but their section produces no significant deficit They are said to account for the vague, often painful sensations due to vesical overdistension and spasm experienced by paraplegics with spinal cord transections below T12

All the important afferent fibers of the bladder, and posterior urethra, especially those associated with sensation of fullness and desire to void but which are also useful thresholds of pain and temperature sensation, follow the pelvic nerves to the dorsal root ganglia of S2–4 Section of these nerves results in the loss of all useful vesical sensation

The pudendal nerves carry superficial and deep somatic sensation from the distal bladder neck, and adjacent perineal structures

Reflex Centers and Suprasegmental-Pathways. Centers for the control and integration of micturition are situated in sacral spinal cord, brainstem, and cerebral cortex

A spinal center for the reflex control of micturition exists in the second, third, and fourth segments of the spinal cord (Fig 5 18) Two

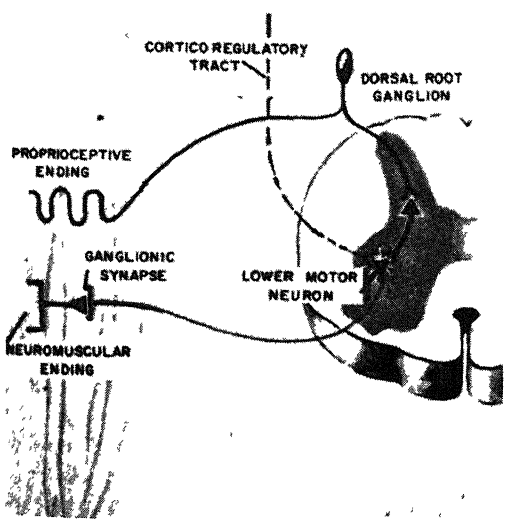

Fig 5 18 Spinal reflex arc in sacral cord concerned with micturition Source Lapides 1970

important reflexes are served Visceral afferent impulses from stretch receptors in the bladder wall travel via the pelvic nerves to the micturition center, which, unless inhibited by higher centers, sends efferent impulses via the pelvic nerves resulting in detrusor contraction This has the effect of forcing urine into the posterior urethra, initiating a second reflex Visceral afferent endings in the posterior urethra, stimulated by the presence of urine, send impulses via the pelvic nerves to the spinal micturition center, which transmits inhibitory impulses to the anterior horn cells of S2–4, decreasing the frequency of impulses in the pudendal nerve, and thereby causing relaxation of the external sphincter

The activity of the spinal micturition center is modified by a higher reflex center in the brainstem, and by cortical activity under the control of the will Pain and temperature afferents reach these centers via the crossed spinothalamic tracts after synapse in the dorsal horn cells at the appropriate segmental level Proprioceptive sensations, especially the desire to void and the feeling of fullness, turn into the ipsilateral funiculus gracilis without synapse, reach the medulla where they effect synapse in the nucleus gracilis, and then cross the midline to join the spinothalamic tracts and follow the great sensory pathways to the brainstem and cortical centers for micturition Regulatory pathways descend from these centers, via the crossed and uncrossed pyramidal and extrapyramidal tracts, to modify the activity of the spinal micturition center

The location of the brainstem center for micturition is uncertain in man, but probably resides in the pons It exerts both facilitory and inhibitory effects of the spinal center It is responsible for sustaining detrusor contraction and external sphincter relaxation until the bladder is completely emptied, this is necessary because, after partial emptying of the bladder, proprioceptive afferent impulses to the spinal center fall below the threshold necessary to maintain the micturition reflex The brainstem probably also inhibits the spinal micturition reflex at an unconscious level, even when the bladder is adequately filled

The cerebral cortex receives vesical representation at the extreme medial aspect of the sensory-motor strip (paracental lobule) Here the degree of fullness of the bladder, the slight burning felt on initiating voiding, and the pain of vesical spasm are consciously appreciated

Here too, voluntary control is exerted over the lower micturition centers Thus, although micturition can proceed normally in the absence of cortical control, the cortex inhibits lower centers until a suitable time and place for voiding can be found Voiding is then allowed to proceed automatically by removing cortical inhibition Micturition can also be voluntarily initiated by the cerebral cortex in the absence of a desire to void or, once begun can be interrupted at any time

Mechanical Considerations

The urinary system is a series of pipes and reservoirs transmitting and storing fluid, and as such is subject to the laws of fluid mechanics Most important of these is LaPlace's law, which states

$$P = 2T/R \text{ in a sphere,}$$

and

$$P = T/R \text{ in a tube,}$$

where

P = intraluminal pressure (sphere), resistance to flow (tube), (provided external pressure is constant)

T = tension on the wall of the sphere or tube (i e , the sum of the force of active tension developed by muscular contraction plus the passive tension exerted by the elastic properties of the wall)

R = radius of the tube or sphere

These relationships hold good, regardless of the characteristics of the wall of the viscus, provided the system is at equilibrium

Certain corollaries of this law provide a mechanical explanation for the behavior of the upper urinary tract and bladder, and will be emphasized in the appropriate sections below One example will be recalled, namely, the absence of reflux when the intravesical ureter is collapsed Under these conditions, the radius (R) is very small, so that for any given tension on the ureteral wall, the resistance to flow (P) in the ureter is extremely high, certainly higher than the intravesical pressure

Urinary Transport in the Upper Urinary Tract

Distension is the adequate stimulus to contraction throughout the entire upper urinary tract. Urine flowing into the minor calyces creates distension, triggering a calyceal contraction which, because of the predominantly circular muscle in the area, causes narrowing of the calyx and forces urine into the renal pelvis Calyceal contractions occur independently of one another and of renal pelvic contractions Calyceal pressures follow renal pelvic pressures, because the two are in free communication at all times

The renal pelvis is relatively indistensible beyond its fairly low capacity of 3 to 5 ml Like the calyces it undergoes rhythmic dilatation and contraction, referred to as diastole and systole, respectively It fills passively from the calyces under very low pressures during diastole, and then contracts, expressing only a small percentage of its volume into the upper end of the ureter The normal intrapelvic pressure seldom exceeds more than a few centimeters of water, even in systole, but tends to be higher in the narrow, ureter-like pelvis than in the large, ampullary-type pelvis—a direct result of LaPlace's law

Efforts to locate a pelviureteric pacemaker have failed, but the contraction wave begins somewhere in the region of the pelvicalyceal junction and sweeps distally at a relatively constant rate of about 3 cm /sec The pelvis is comprised of both circular and longitudinal muscle, and in systole, therefore, it decreases in volume and approximates itself toward the kidney

The upper end of the ureter is in communication with, and fills with, the renal pelvis during diastole, the ureteropelvic junction remaining open during this phase, and the pelvis and upper together forming the functional renal pelvis Contraction of the renal pelvis and closure of the ureteropelvic junction occur almost simultaneously, trapping urine within the renal pelvis, above, and within the uppermost ureter below the ureteropelvic junction The ureteropelvic junction may be defined, physiologically, as the most proximal point of closure of the ureter during systole of the renal pelvis, and its localization varies somewhat with the volume of urine flow

The ureteral cone is the segment of ureter in open communication with the renal pelvis during diastole Its proximal limit is the pelviureteric junction, but its size, shape, and distal limit depends on the rate of urine flow and the body position, filling being reduced in the supine position

The frequency of pelviureteric contractions ranges from 1-5/min at normal rates of flow, tending to occur at regular intervals, although at different rates on the two sides Sudden reduction of urine formation may or may not result in a transient decrease in the frequency of contractions, following which the rate returns to its normal frequency, even in the presence of complete anuria Higher than normal rates of urine flow increase the amplitude of contractions, provided the ureteral cone is capable of coping with the increased volumes If, however, renal pelvic distension occurs, the frequency of contractions increases At the highest flow rates, the entire pelvis and ureter remain open, urine transport being a function of the pelvivesical pressure gradient

The closure of the pelviureteric junction marks the origin of a peristaltic wave which sweeps down the ureter, transporting the urine trapped in the ureteral cone ahead of it A single peristaltic wave rarely strips the ureter of urine completely, but leaves behind from one to four tapered columns of urine of varying length, called urine spindles, separated by lengths of contracted, empty ureter Spindles tend to be formed under conditions causing resistance to urine flow, such as recumbency, high urine flow rates, and high intravesical pressure, which lead to retention of urine in the upper tract Small spindles fill from above and empty from below as the peristaltic wave sweeps over them, but large spindles can contract as a unit, rapidly expelling urine toward the bladder Spindle formation is a more efficient method of emptying the ureter than peristalsis, the transition from the latter to the former method of urine propulsion occurs smoothly, and is a function of the volume retained in the upper tract

Circular muscle is absent in the intravesical ureter, which, therefore, plays a passive role in urine transport Urine is forced in intermittent jets through this portion of the upper tract, ahead of the contraction waves descending from above Just as the spurt of urine ceases, the longitudinal muscle of the submucosal ureter contracts, drawing the lateral angle of the trigone slightly upwards and outwards

Pressures in the ureter rise progressively as the bladder is approached being normally about 15 cm of water in the upper ureter, and 30 cm in the pelvic ureter during systole These pressures are not transmitted to the kidney as long as the ureter distal to the ureteral cone remains closed, and are quite sufficient to maintain a ureterovesical pressure gradient under normal conditions

Vesical Physiology

FILLING OF THE BLADDER

The normal bladder is completely empty at the end of micturition, the intravesical pressure is equal to the intra-abdominal pressure As the bladder fills, it adjusts its tone to its capacity, so that minimal alterations of intravesical pressure occur over a wide range of intravesical volumes This phenomenon, sometimes called adaptation, is an inherent property of the smooth muscle of the detrusor, and is not dependent on nervous mechanisms It is, therefore, present in denervated bladders, but not after death The adaptation is not to a constant pressure, but always to a pressure slightly higher than existed before the addition of the fluid increment

In the adult, direct measurements show a gradual smooth increase in intravesical pressure to about 10 cm of water at a capacity of approximately 400 ml (Fig 5 19) The first sensation of bladder filling generally occurs at a capacity of 100 to 150 ml , and the first desire to void at between 150 and 250 ml The physiological capacity of the bladder, that is, the maximum intravesical volume tolerated without undue discomfort and at which micturition is normally effected, ranges between 250 and 450 ml

Filling of the bladder beyond its physiological capacity is associated with progressive

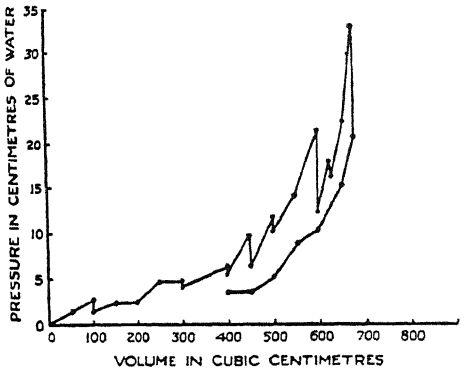

Fig 5 19 Curve of pressure changes in human bladder during filling and emptying Involuntary contractions and sharply rising pressures above 450 to 500 ml indicate filling beyond physiologic capacity

failure of adaptation, and intravesical pressure rises much more sharply relative to the increase in intravesical volume Despite strong cortical inhibition, efferent impulses reach the detrusor, causing involuntary contractions At first these are of low pressure and not associated with conscious sensation, but, as filling continues, they are associated with sharp rises in pressure, and felt consciously as an acute urge to void

The physiological bladder capacity varies greatly with age and psychic factors At birth it ranges from 20 to 50 ml, increasing four times during the 1st year of life In the adult it can be as high as 600 ml, especially in persons whose occupations make access to lavatory facilities difficult In all cases, the capacity is about twice that at which the first desire to void is felt The anatomic capacity of the bladder—the capacity just before rupture occurs—is well above 1 liter, and is never approached under physiological conditions

CONTINENCE

In addition to accepting urine from the ureters, and periodically discharging urine under voluntary control, the bladder must also retain urine As the bladder fills with urine, continence is maintained by the proximal 3 cm of the urethra This is accomplished by the continuous tone of the smooth muscle augmented by the rich elastic tissue in this area, both mechanisms tending to compress the lumen of the urethra The urinary sphincter is thus a tube of smooth muscle and elastic tissue with its greatest resistance in the mid urethra and least resistance at the vesical neck (Fig 5 20)

The external sphincter is not normally necessary to continence, and its paralysis does not cause leakage of urine, provided the posterior urethra is intact Under conditions of sudden increase of intra-abdominal pressure, such as occur with coughing, intravesical pressure may reach 50 to 80 cm of water, forcing urine into the bladder neck Leakage is prevented under these circumstances by reflex contraction of the external urethral sphincter and levator ani muscles

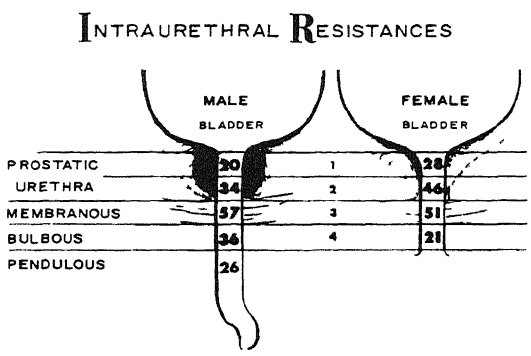

Fig 5 20 Intraurethral pressures in the male and female posterior urethra Source Lapides 1970

MICTURITION

Micturition may be defined as the periodic complete emptying of the urinary bladder, under voluntary control except in infancy The nervous, muscular and mechanical factors essential to the act have all been discussed, and must now be integrated

At the end of voiding, the bladder is empty, the bladder neck is closed, and the intravesical pressure is close to zero The bladder slowly fills as ureteral peristalsis forces jets of urine through the aperistaltic intramural ureter Despite a rising intravesical volume, the intravesical pressure remains low, due to the phenomenon of accommodation inherent in the smooth muscle of the vesical wall, and at no time does it exceed either the intraureteral pressure at the ureterovesical junction, or the urethral resistance provided by the closed posterior urethra

As the bladder radius increases, the tension on the vesical wall increases, even though the intravesical pressure remains almost constant (Laplace's law) Tension is the adequate stimulus for the proprioceptive end organs in the vesical wall which send visceral afferent impulses via the pelvic nerves to terminate in the spinal reflex center for micturition (S2-4), and also in the fasciculus gracilis to the reflex center for micturition in the brain step (pons?) and in the voluntary center for micturition in the paracentral lobule of cerebral cortex The first feeling of filling of the bladder is generally appreciated at a capacity of 100 to 150 ml, and the first desire to void, accompanied by a vague feeling in the penis or perineum, at 150 to 250 ml At this stage, the spinal reflex center for micturition is inhibited by impulses from the brainstem center via the corticoregulatory tracts, preventing efferent impulses from leaving the spinal center If micturition is unduly postponed, a feeling of fullness, then discomfort, and finally pain results The latter

sensation is transmitted to the cortex via the lateral spinothalamic tracts Under these conditions, voiding is inhibited by cortical impulses blocking the discharge of the spinal center

When an opportunity is found to empty the bladder, the voluntary restraint placed upon the spinal micturition center is lifted, and micturition proceeds automatically The cessation of inhibitory impulses from the cerebral cortex (in the case of a full bladder), or the facilatory impulses from the cortex (in the case of low intravesical volume), permit the discharge of parasympathetic efferent impulses along the pelvic nerves to synapses in the pelvic plexi and bladder wall, and thence via postganglionic rami to the body of the detrusor muscle and the posterior urethra A voiding contraction of the detrusor results, generating intravesical pressures of 50 to 150 cm of water At the same time, the detrusor contraction shortens and widens the posterior urethra (Fig 5 21) The effect is to increase intravesical pressure and decrease urethral resistance, and a bolus of urine is forced into the posterior urethra Urine in the posterior urethra stimulates parasympathetic visceral afferents which send impulses via the pelvic nerves to the spinal center This reflexly relaxes the external sphincter by decreasing the frequency of efferent impulses which normally travel from the anterior horn cells of S2–4 via the pudendal nerves to keep the external sphincter in a state of tonic contraction Urine flows through the urethra and, in the male, through a passive conduit, the penile urethra, to the exterior

Certain muscular movements not essential to micturition commonly accompany the act At the onset of micturition the levatores ani and perineal muscles are relaxed, thereby shortening the posterior urethra and decreasing urethral resistance At the same time the glottis closes, the diaphragm descends, and the abdominal wall muscles contract, accelerating the flow of urine by raising intra-abdominal pressure which in turn secondarily increases intravesical pressure

A voiding contraction, once initiated, is normally maintained until all the urine has been discharged from the urinary bladder This is a function of facilitory impulses from the brainstem The bladder contracts in all directions like a toy balloon deflating from its neck When the bladder and posterior urethra have emptied, the external sphincter closes, the detrusor relaxes, and finally the posterior urethra closes gradually

Arrest of the voiding stream, once initiated, is accomplished by a powerful voluntary contraction of the external sphincter and perineal muscles, and is associated with a sense of burning and urgency due to stimulation of somatic afferents in the region of the membranous urethra If the contraction is sustained, urine is forced backwards into the bladder by collapse of the posterior urethra, associated with gradual relaxation of the detrusor muscle

Micturition begins in the 5th intrauterine month with the onset of urinary secretion It remains a reflex act until approximately 2½ years of age, at which time it begins to come under cortical control Complete continence is usually achieved by the age of three

Uninhibited contractions of the bladder occur in young children up to a variable age, and may be attributed to an underdeveloped control of the spinal reflex arc by the upper brain center that control micturition in the adult

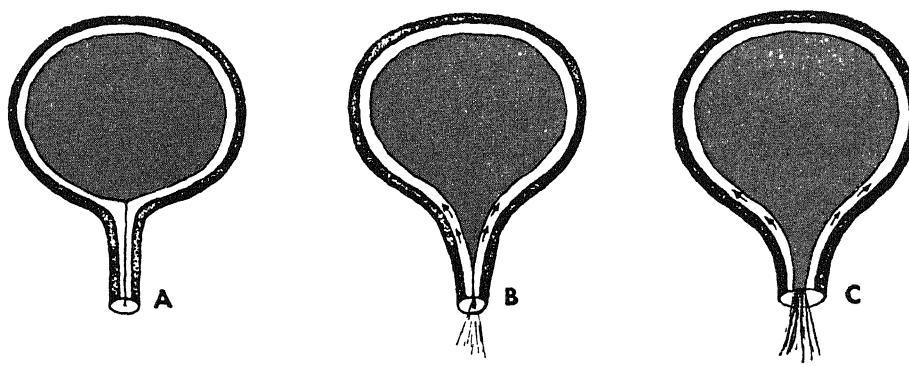

Fig 5 21 The bladder neck in continence and micturition Detrusor contraction decreases urethral resistance by shortening and widening the bladder neck Source Urology ed M F Campbell 1963 (See Lapides 1970)

Respiration

1 / UPTAKE AND DELIVERY OF THE RESPIRATORY GASES

The cells of higher animals continually use oxygen and produce carbon dioxide as a waste product Breathing movements promote the transfer of oxygen from the atmosphere into the lungs and the removal of carbon dioxide from the lungs Oxygen diffuses into the blood in the pulmonary capillaries to be carried to all parts of the body, where it diffuses from the capillary blood into the interstitial fluid and on to the cells Carbon dioxide diffuses from the cells through the interstitial fluid to the blood in the systemic capillaries, and then is carried to the lungs where it diffuses into the alveolar air The continual processes of respiration, regulated by a complex of "feed-back" and other mechanisms, play a major role in the maintenance of homeostasis Under constant conditions, the respiratory processes tend to attain a condition which may be called a "steady state," but not an "equilibrium with the environment," since at equilibrium all reactions would be at a standstill

The major problems to be considered under the heading of respiratory physiology are *1*) the uptake of oxygen from alveolar air and its delivery to the tissues, *2*) the uptake of carbon dioxide from tissues and its delivery to the alveolar air, *3*) the mechanism of rhythmic inspiration and expiration, and *4*) the mechanisms by means of which the amount of air breathed per minute is adjusted to the needs of the body The actual chemical processes by which oxygen is utilized in the cells (cellular respiration) will not be discussed, since this subject is considered in detail in biochemistry texts Some of the derangements of respiration are considered under the appropriate major headings, while others of a more general nature are described in the final chapter of this section

It is assumed that the reader already will have knowledge of elementary biochemistry and human anatomy Further, it is essential that the relation of carbon dioxide to the acid-base balance (sect 4, chap 11), the physiology of nerve, muscle, and reflex action (sect 9, chap 4) and the physiology of the autonomic nervous system (sect 9, chap 3) should be studied in advance in order to understand the chemical and neural control of respiration

A system of notation for use in respiratory physiology, summarized in Table 6 1, was agreed on by a group of physiologists meeting in Atlantic City in 1950 This system is now generally accepted, and will be followed in this section

THE KINETIC THEORY OF GASES

A quantity of gas when placed in a container of any size expands until it fills the confining vessel This fact is explained upon the theory that the gas molecules are in continuous motion, moving through space at high velocity and being deflected from their course only upon coming into collision with other gas molecules or with the boundaries of the space itself which they strike and from which they rebound repeatedly Such movements constitute a bombardment upon the confining walls which is responsible for the pressure of the gas The greater the number of molecules in any given space, and the higher their mean velocity, the more frequent will be the impacts

Boyle's Law If the volume of a given mass of gas is reduced, the molecules are brought closer together and the rate of bombardment upon a unit surface increases, the increase becoming manifest as a rise in pressure Robert Boyle first noted the quantitative relationship between pressure and volume *at a constant temperature the pressure of a given mass of gas is inversely proportional to its volume*, i e , the product of the pressure and the volume remains constant

Avogadro's Law states that *equal volumes of different gases at the same temperature and pressure contain the same number of molecules* Thus a gram-molecule of any gas at STPD occupies a volume of 22 4 liters Since the force of an impact is related to the mass of the molecule as well as to its velocity, it follows that at a given temperature the molecules of a gas of low molecular weight are traveling faster than are those of a heavier gas The mean kinetic energy of the gas molecules has a certain value which is related to temperature alone

Table 6 1[a]

Symbols and abbreviations used by pulmonary physiologists (based on report in Federation Proceedings 9 602-605 1950)

SPECIAL SYMBOLS

—Dash above any symbol indicates a *mean* value
Dot above any symbol indicates a *time derivative*

For Gases				For Blood			
Primary Symbols (large capital letters)		Examples		Primary Symbols (large capital letters)		Examples	
V	= gas volume	V_A	= volume of alveolar gas	Q	= volume of blood	Qc	= volume of blood in pulmonary capillaries
$\dot{V}$	= gas volume/unit time	$\dot{V}o_2$	= O_2 consumption/min	$\dot{Q}$	= volume flow of blood/unit time	$\dot{Q}c$	= blood flow through pulmonary capillaries/min
P	= gas pressure	$P_{A\,O}$	= alveolar O_2 pressure	C	= concentration of gas in blood phase	Ca_{O_2}	= ml O_2 in 100 ml arterial blood
$\bar{P}$	= mean gas pressure	$\bar{P}c_{\bar{Q}_2}$	= mean capillary O_2 pressure	S	= % saturation of Hb with O_2 or CO	Sv_{O_2}	= saturation of Hb with O_2 in mixed venous blood
F	= fractional concentration in dry gas phase	$F_{I_{O_2}}$	= fractional concentration of O_2 in inspired gas				
f	= respiratory frequency (breaths/unit time)			Secondary Symbols (small letters)		Examples	
D	= diffusing capacity	D_{O_2}	= diffusing capacity for O_2 (ml O_2/min/mm Hg)	a	= arterial blood	Pa_{CO_2}	= partial pressure of CO_2 in arterial blood
R	= respiratory exchange ratio	R	= Vco_2/Vo_2	v	= venous blood	$P\bar{v}_{O_2}$	= partial pressure of O_2 in mixed venous blood
Secondary Symbols (small capital letters)		Examples		c	= capillary blood	Pc_{CO}	= partial pressure of CO in pulmonary capillary blood
I	= inspired gas	$F_{I_{CO_2}}$	= fractional concentration of CO_2 in inspired gas	b	= blood in general		
E	= expired gas	V_E	= volume of expired gas	s	= steady state		
A	= alveolar gas	V_A	= alveolar ventilation/min				
T	= tidal gas	V_T	= tidal volume				
D	= dead space gas	V_D	= volume of dead space gas				
B	= barometric	P_B	= barometric pressure				
STPD	= 0°C, 760 mm Hg, dry						
BTPS	= body temperature and pressure saturated with water vapor						
ATPS	= ambient temperature and pressure saturated with water vapor						

[a] After Comroe et al (1962)

Law of Charles (or Gay-Lussac) A rise in temperature increases the velocity and kinetic energy of the gas molecules The force of the impacts is thus increased, and at constant volume the rate of bombardment also is increased For each rise in temperature 1° C a gas kept at constant volume increases its pressure by $\frac{1}{273}$ of its pressure at 0° C If, instead, the pressure is held constant, the volume increases by a corresponding amount Taking −273° C as the absolute zero, it follows that *the pressure of a gas at con-*

stant volume (or the volume at constant pressure) is proportional to the absolute temperature

The ideal gas law is a quantitative expression of the foregoing principles

$$PV = nRT$$

where P is the pressure, V is the volume, n is the number of gram-molecules of the gas, R is the "gas constant," and T is the absolute temperature When the units employed are atmospheres, liters and centigrade degrees, $R = 0.082$ For any real gas this expression is subject to small corrections related to the actual volume of the molecules themselves and the attractive forces between them

Diffusion In all circumstances the gas molecules, as a result of their movement, will distribute themselves evenly throughout the space in which they are confined, and consequently the pressure will become equal throughout all parts of the space This tendency of a gas to pass from a point of higher pressure to a point of lower pressure, and to distribute itself throughout the available space is called diffusion However, the term applies equally to the distribution of dissolved molecules or ions in solution, and to the transfer of molecules across gas-liquid interfaces The rate of diffusion of a *gas* at a given temperature is inversely proportional to the square root of its density Thus hydrogen diffuses four times as rapidly as does oxygen

Dalton's Law of Partial Pressures If we should deal with a mixture of two or more gases, it would be found that each component of the mixture behaved as though present alone Its molecules would become distributed evenly throughout the mixture, although its rate of diffusion would be retarded by collisions with other molecules *Each gas in a mixture exerts a pressure according to its own concentration, independently of the other gases present* The pressure of each constituent is referred to as its *partial pressure* or *tension* and the total pressure is the *sum of the partial pressures* of all the gases present

Henry's Law When a gas is brought into contact with water, gas molecules bombard the surface of the liquid and pass into it, but the dissolved gas molecules also tend to escape from the liquid After a time their rate of escape equals their rate of entry When this equilibrium is reached, the solution is said to be saturated Each gas has its own characteristic solubility at a given temperature and pressure If no chemical reaction is involved, but only physical solution, Henry's Law states that *the concentration of a gas in solution at equilibrium is directly proportional to its partial pressure in the gas phase* The solubility of oxygen, for example, is described by the expression

$$Co_2 = \alpha O_2 \, Po_2$$

where Co_2 is its concentration in aqueous solution, Po_2 is its tension, and αO_2 is a constant which is characteristic of oxygen If Co_2 is expressed in milliliters (STPD) per milliliter of solution and Po_2 in atmospheres, αO_2 represents the solubility in milliliters of oxygen gas per ml of water and per atmosphere This is called the solubility coefficient or absorption coefficient of oxygen

The solubility of a gas is not affected by the presence of other gases, each gas in a mixture dissolves in accordance with its own partial pressure and absorption coefficient The solubility is decreased slightly, however, by the presence of salts or other solutes Hence the absorption coefficients are slightly lower for solution in blood plasma than for solution in water (Table 6 2) The values for whole blood are influenced also by the presence of the erythrocytes In general, the solubility of a gas is decreased by an increase in temperature

Although carbon dioxide in solution combines with water to form H_2CO_3, this reaction does not cause deviations from Henry's Law The two forms are present in a constant ratio, and the equilibrium is such that only one part in 680 is in the hydrated form at 38° C (Roughton, 1943-1944)

When the absorption coefficient is known, it is a simple matter to calculate the tension from the milliliters of gas per milliliters of solution and vice versa Hence it is often convenient to use the value representing tension (in atmospheres or, more commonly, in mm Hg) as a measure of the concentration of physically dissolved gas in a solution If the liquid after equilibration were separated from the gas phase, this would not change the tension of the dissolved gas, hence the use of this measure does not require the presence of a gas phase If the solution were subsequently exposed to a vacuum or to an atmosphere of other gases, however, the dissolved gas would tend to diffuse out of the solution Hence the tension of a dissolved gas can be regarded as a measure of its tendency to escape from solution

Aqueous tension Water itself, when exposed to a vacuum or to an atmosphere of other gases, tends to evaporate until an equilibrium is reached between the gas phase and the liquid Although it is common to speak of the air becoming saturated, the tension or vapor pressure of water attained at equilibrium is not

Table 6 2

Absorption coefficients of gases in water blood plasma and whole blood in milliliters per milliliters and per atmosphere

	αO_2	αCO_2	αN_2

affected by the presence or absence of other gases It depends simply upon the temperature At body temperature (37° C) the aqueous tension of water is 47 mm Hg Substances in solution reduce the aqueous tension by small amounts

The Exchange of Gases in the Lungs

CONCEPT OF TENSION GRADIENTS

Oxygen from the air in the alveoli enters the blood in the pulmonary capillaries by diffusion through the alveolar and capillary membranes, while carbon dioxide diffuses in the reverse direction The transfer of a quantity of gas by diffusion can occur only from a place of higher to a place of lower concentration, i e , in the direction of a *concentration gradient* Strictly speaking, such a gradient would be defined as a decrease in concentration per unit of distance However, the actual distance traversed may not be precisely known and may not be of major interest It is customary to refer to the total difference in oxygen tension between alveolar air and pulmonary blood plasma as the oxygen diffusion gradient The direction of this gradient is from the higher (alveolar) toward the lower (capillary) tension The carbon dioxide gradient, stated in the same terms, is in the opposite direction Similar gradients exist between the blood plasma and the interstitial fluid, and in turn between the interstitial fluid and the interior of the respiring cells In each case, the tension gradients are to be regarded as the driving forces for the exchange of gases Combined forms of oxygen and carbon dioxide existing in the blood play no direct role in these exchanges, they serve only as reservoirs which, by dissociation and the laws of mass action, replenish and maintain the tensions of the physically dissolved gases

The rate of diffusion of a gas through a liquid per unit of *tension* gradient is directly proportional to the solubility of the gas and inversely proportional to the square root of its molecular weight Hence, at a given tension gradient and at body temperature, the diffusion rate of carbon dioxide in solution is about 20 times that of oxygen

THE ALVEOLAR AIR

The mixture of gases in the alveoli consists of inhaled air from which oxygen is being removed and to which carbon dioxide and water vapor are being added Under resting conditions each inhalation brings into the respiratory system a volume of air representing less than 10% of the total lung capacity, and not all of this reaches the alveoli Hence the composition of the alveolar air shows only minor fluctuations with the respiratory cycle The composition is not exactly the same in all parts of the lung, since there are variations in the effectiveness of ventilation The average composition, however, is maintained approximately constant by the mechanisms regulating the respiratory rate and volume

A sample of expired air taken near the end of a normal expiration (end-tidal sample) is fairly representative of the average composition of alveolar air The *Rahn sampler* is a device which automatically collects end-tidal samples, permitting continuous analysis and recording of the alveolar air (Rahn and Otis, 1949) In the older technique of *Haldane and Priestley*, allowance is made for small differences occurring during the respiratory cycle by taking two samples one from the last part of a forced expiration following a normal inspiration, the other from a forced expiration following a normal expiration The average of the two is taken to represent the mean composition of the alveolar air (Rossier et al , 1960) The *"functional" alveolar oxygen tension* can be obtained by an indirect method based on the *"alveolar air equation"*, this calculation requires analysis of the expired air (collected over a period of about 5 min) and measurement of the arterial CO_2 tension It is assumed that the mean CO_2 tension of the alveolar air is equal to that of the arterial blood (Riley et al , 1946, Otis, 1964)

The air in the lungs has a temperature of about 37° C and is usually considered to be saturated with water vapor Its aqueous tension is therefore 47 mm Hg [1] When the air cools after exhalation, some of the water vapor condenses The tension of water vapor in room air at 22° C could be no higher than 20 mm Hg and is usually much lower

In the measurement of respiratory gases, the volumes are expressed dry (i e , less the aqueous vapor) and at standard temperature and pressure The individual gases are ex-

[1] Christie and Loomis (1932), from direct measurements, obtained a slightly lower value for the aqueous tension of alveolar air (45 mm Hg) They claim that the alveolar air is not fully saturated and that the temperature of the lung is lower than is usually assumed Hyperpnea reduced the aqueous tension by as much as 7 mm Hg Holding the breath increased it by 0 5 mm Hg

pressed as percentages of the dry volume In order to arrive at the *tension* of a gas from its percentage by analysis, the figure for the barometric pressure less the aqueous tension must be used in the calculation For example, if a sample of alveolar air (dry) is 5 6% CO_2, and the barometric pressure is 760 mm Hg, the *alveolar carbon dioxide tension* is calculated as follows

$$P_{ACO_2} = (5\ 6/100)(760 - 47) = 40 \text{ mm Hg}$$

In Table 6 3 the *average composition of alveolar air (at sea level) is compared with the known composition of dry atmospheric air* The latter does not show significant variations within the troposphere Values for oxygen, carbon dioxide and nitrogen tensions also are given

During voluntary hyperventilation the alveolar tension of CO_2 falls and that of oxygen rises When the breath is held or during periods of apnea, changes occur in the reverse direction At higher altitudes, the alveolar oxygen and nitrogen tensions are reduced along with the barometric pressure, but the alveolar P_{CO_2} does not show a proportionate decrease since it is controlled by the rate of ventilation of the lungs The *percentage* of CO_2 therefore increases as the barometric pressure decreases and the oxygen and nitrogen *percentages* must accordingly decrease When the P_{O_2} is reduced enough to reflexly increase the breathing, the P_{CO_2} begins to fall and the decrease in P_{O_2} is partially compensated

Although a small but constant amount of nitrogen is physically dissolved in the blood (in accordance with Henry's Law), gaseous nitrogen is neither used nor produced in metabolism Argon and other inert gases are usually included under "nitrogen," since no distinction need be made in discussions of respiratory physiology It will be noted that the percentage of nitrogen is slightly higher in alveolar air than in the inspired air This is due, not to any absolute increase in the quantity of nitrogen, but to the reduction of the total volume of the respiratory gases resulting from the fact that the oxygen consumption exceeds the CO_2 production

BLOOD GASES

Oxygen and Carbon Dioxide Tensions The mixed venous blood, which enters the pulmonary arteries and is carried to the lungs, has an oxygen tension of about 40 mm Hg The gradient in oxygen tension from alveolar air to the blood as it enters the pulmonary capillaries is therefore about 60 mm Hg With this gradient as the driving force, oxygen diffuses across the alveolar and capillary membranes Equilibrium is quickly established, and as the blood leaves the pulmonary capillaries it is nearly saturated with oxygen A sample of blood obtained from a systemic artery is found to have an oxygen tension slightly lower than that of the alveolar air, not because of failure to attain equilibrium across the pulmonary membranes, but for reasons to be discussed later

The venous blood has a CO_2 tension of about 46 mm Hg, hence at the entrance of a pulmonary capillary the diffusion gradient for the transfer of CO_2 to the alveolar air is only about 6 mm Hg However, since CO_2 is more soluble than oxygen, this gradient suffices for the removal from the blood of an amount of CO_2 almost equivalent to the oxygen absorbed, and equilibrium is reached before the blood leaves the pulmonary capillary Within the limit of error involved in alveolar air sampling, the CO_2 tension of arterial blood is found to equal that of the alveolar air [2]

The great rapidity with which these exchanges occur is evident from estimates of the time spent by an individual corpuscle in traversing a pulmonary capillary Roughton (1945) has estimated that the "transit time" is about 0 75 sec under resting conditions and is reduced to about half this value by strenuous exercise

[2] The end-expiratory CO_2 tension is measurably lower than the arterial value in shallow breathing and in pathological conditions characterized by significant alveolar dead space

Oxygen Content and Capacity The amounts of gases in blood are commonly expressed in terms of *volumes percent*, i e , milliliters of gas (STPD) per 100 milliliters of blood From the absorption coefficient of oxygen and the oxygen tension, it can be calculated that the physically dissolved oxygen in arterial blood amounts to only 0 3 volumes per cent If the transport of oxygen by the blood were dependent upon physical solution alone, an enormous cardiac output would be required to supply the amount of oxygen needed by the tissues Actually most of the oxygen is carried in combination with hemoglobin,[3] and the total *oxygen content* of the arterial blood is about 20 volumes per cent All of this oxygen can be removed from the blood by evacuation

The oxygen content of blood is dependent upon the oxygen tension, but the relationship between these two variables is not linear It is described by the *oxygen dissociation curve*, which will be discussed in detail in a later section If blood is equilibrated with air at 760 mm Hg, the hemoglobin becomes saturated The oxygen content of the blood, corrected by subtracting the small amount in physical solution, then represents the *oxygen capacity of the hemoglobin* The oxygen capacity is a measure of the active hemoglobin content, since 1 g of hemoglobin will combine with exactly 1 34 ml of oxygen (STPD) Hemoglobin values calculated from precise measurements of oxygen capacity are often used as a basis for standardizing colorimetric methods for the determination of hemoglobin, but it must be remembered that many blood samples contain traces of inactive hemoglobin compounds such as methemoglobin and carboxyhemoglobin

The ratio of the oxygen content (after correction for dissolved oxygen) to the oxygen capacity of the hemoglobin is a measure of the degree of saturation of the hemoglobin This ratio is usually multiplied by 100 to give the *per cent saturation* In arterial blood the hemoglobin is normally about 97% saturated The amount of oxygen given up by the blood as it passes through the tissues varies from one region to another and from time to time, depending upon the blood flow and the metabolic rate in the region concerned Under resting conditions the average arteriovenous difference is about 5 volumes per cent The mixed venous blood, then, has an oxygen content of about 15 volumes per cent and its hemoglobin is about 75% saturated Samples of mixed venous blood can be obtained from human subjects by cardiac catheterization

Average normal values for blood gases and hemoglobin content are summarized in Table 6 4

Carbon Dioxide Content The tension of CO_2 in the alveolar air is lower than that of oxygen, but the absorption coefficient of CO_2 is much the higher of the two The calculated amount of CO_2 present in *simple solution* in the arterial blood is 2 5 volumes per cent This is distributed between the red cells and the plasma

The total *carbon dioxide content* is the quantity of CO_2 that can be extracted from 100 ml of blood by exposure to a vacuum after the addition of acid In arterial blood this amounts to about 46 volumes per cent A large fraction of it exists in the form of *bicarbonate ions*, some of this is in the plasma and a smaller portion is inside the erythrocytes Another fraction is bound to hemoglobin in the erythrocytes as *carbaminohemoglobin*

These various forms of carbon dioxide exist in equilibrium with each other in the blood, and all are involved in the transport of CO_2 When CO_2 enters or leaves the blood, a rapid readjustment of the equilibrium occurs

Carbon Dioxide-Bicarbonate-pH Relationships The dissociation of a weak acid is described quantitatively by the *Henderson-Hasselbalch equation*, which is the logarithmic form of the law of mass action (see sect 4,

[3] See section 4, Chapter 4 for a discussion of the chemistry of hemoglobin

chap 11) As applied to the carbonic acid-bicarbonate system, this equation is

$$pH = pK + \log[HCO_3^-]/[H_2CO_3]$$

where pK is the negative logarithm of the dissociation constant of carbonic acid

Carbon dioxide forms carbonic acid by hydration

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

The hydrated and unhydrated forms reach an equilibrium, and the dissolved carbon dioxide is the sum of the two forms However, the equilibrium point is so far to the left that only about 0 15% is in the hydrated form at 38° C Hence the concentration of the unhydrated form, designated $[CO_2]$, can be considered equal to the dissolved carbon dioxide with only a negligible error The small concentration of H_2CO_3 is directly proportional to $[CO_2]$ Hence if an appropriate value for K is used, the equation can be written

$$pH = pK' + \log[HCO_3^-]/[CO_2]$$

The established value for pK′ in *blood plasma* is 6 10[4] at 37° C When the plasma pH is 7 4, therefore, the ratio of plasma bicarbonate to dissolved carbon dioxide is 20 1 The concentrations of CO_2 and HCO_3^- can be expressed either in millimoles per liter or in volumes per cent of CO_2, the value for pK′ is 6 10 in either case

The dissolved carbon dioxide can be calculated from the CO_2 tension and the absorption coefficient α as determined on acidified plasma (Table 6 2) The plasma $[HCO_3^-]$ can be obtained by subtracting the dissolved CO_2 from the total measured CO_2 content of the plasma Incorporating these considerations, the equation becomes

$$pH = 6\,10 + \log([CO_2 \text{ content}] - \alpha P_{CO_2})/\alpha P_{CO_2}$$

If concentrations are expressed in volumes per cent and P_{CO_2} in millimeters of mercury, the value for α becomes 0 0686 In terms of millimoles per liter and mm Hg, α is 0 0308 (since 1 mole of CO_2 at STPD occupies 22 26 liters)

This equation is very useful since if any two of the three variables are measured the third can be calculated Its application to whole blood, however, is complicated since the carbon dioxide content of blood includes a considerable portion present as carbaminohemoglobin and the intracellular and extracellular concentrations of H^+ and HCO_3^- are complexly related

[4] Calculated from precise measurements of P_{CO_2}, pH, and CO_2 content or bicarbonate in plasma K′ therefore is a composite constant including the true dissociation constant of H_2CO_3, the equilibrium constant for the hydration of CO_2, the activity coefficient of the bicarbonate ion, and a small correction for equating $[CO_2]$ with the dissolved carbon dioxide The pK′ value varies slightly with pH, probably because traces of carbonate and of plasma carbaminobound carbon dioxide are included in the measurements of bicarbonate (Severinghaus et al , 1956, Siggard Anderson, 1962a)

Measuring Respiratory Gases

For many years the most widely used methods for the measurement of respiratory gases were those developed by J S Haldane at Oxford and by D D Van Slyke and his associates at The Rockefeller Institute Numerous modifications of these methods have been described, and micro methods based on the sample principles have been introduced These methods depend upon the careful measurement of gas volumes and pressures and the selective absorption of carbon dioxide and of oxygen by appropriate reagents In the analysis of blood the gases are first released by chemical treatment and vacuum extraction

More recently, various electronic and other instruments have been devised for the measurement or continuous monitoring of oxygen, CO_2, and nitrogen in gas mixtures, and of oxygen tension, hemoglobin saturation, and CO_2 tension in blood Some of the more important methods now in use will be outlined briefly Detailed descriptions of these are available in a compilation by Consolazio et al (1963) or in other references cited

ANALYSIS OF GAS MIXTURES

Haldane Method The gas sample is held in a sampling tube over mercury or in an oiled syringe A 10-ml volume is drawn into the gas buret and measured at the prevailing atmospheric pressure and temperature CO_2 is absorbed by strong potassium hydroxide solution, and oxygen by an alkaline solution of potassium pyrogallate or of sodium hydrosulfite and sodium anthraquinone-β-sulfonate, the respective decreases in volume are recorded The percentage of nitrogen is calculated from the volume of gas remaining unabsorbed The inside of the buret is kept wet with dilute sulfuric acid to maintain a constant aqueous tension throughout, the results then represent percentages on a dry basis

Scholander Method This is a rapid micro adaptation of the Haldane method employing an apparatus of very different design A 0 5-ml gas sample is introduced into a small reaction chamber connected to a micrometer buret The buret is filled with mercury The pressure of the sample is balanced against that of air in a compensating chamber by means of an indicating drop of fluid in a capillary tube connecting the two chambers Absorbing solutions for CO_2 and oxygen can be tilted into the reaction chamber without altering the total volume While a gas is being absorbed, mercury is forced into the reaction chamber from the micrometer buret at a rate sufficient to maintain a constant pressure The volume of mercury introduced is then measured in terms of micrometer divisions

The Pauling Oxygen Analyzer This instrument measures the partial pressure of oxygen in a gas mixture Its operation depends on the fact that oxygen is paramagnetic while most other gases are diamagnetic, i e , the magnetic susceptibility of oxygen is very much greater than that of any other common gas A small glass dumbbell filled with nitrogen or oxygen (depending on the range of the instrument) is suspended between the poles of a magnet by attachment to a vertically stretched silica fiber By rotating around the fiber, the dumbbell can move in the magnetic field The incoming gas surrounds the dumbbell, and the oxygen is attracted to the strongest part of the magnetic field The dumbbell is subjected to a magnetic force depending on the difference between the magnetic susceptibility of its spheres and that of the gas which the spheres displace, and rotates as the spheres move farther into or out of the magnetic field An equilibrium position is reached at which the magnetic rotational force is balanced by the restoring force of the twisted fiber Thus the operation of the instrument is analogous to the measurement of the density of a liquid by weighing a solid body suspended in the liquid A small mirror attached to the dumbbell reflects a light beam onto a scale which is calibrated to indicate oxygen tension The Pauling analyzer has proved to be particularly useful for the analysis of expired air in studies of metabolism employing the open-circuit method

The Infrared CO_2 Analyzer CO_2 absorbs infrared radiation in proportion to its concentration Rapidly responding instruments based on this property can be used for continuous monitoring of carbon dioxide in the expired air. The gas mixture is exhaled through a mouthpiece connected to the sampling tube, or a continuous sample is drawn into the analyzer through a very small polyethylene catheter A beam of infrared radiation passes through the sample and then into a detector connected to an amplifier-recorder system The instrument registers the infrared absorption and can be calibrated in terms of per cent CO_2 (Collier et al , 1955)

The Nitrogen Analyzer Gases subjected to electrical excitation ionize and emit radiation The nitrogen analyzer contains an electrical discharge tube through which a slow, steady stream of the gas mixture is drawn at very low pressure A high potential is applied and the radiation at wavelengths characteristic of nitrogen is passed by a suitable filter and allowed to activate a photoelectric cell The signal is amplified and indicated on a meter or recorder calibrated in per cent nitrogen The response of the instrument is extremely rapid

Gas Chromatography This recently developed technique seems destined to largely supersede other methods for the analysis of individual gas samples The apparatus for respiratory gases employs gas-solid chromatography, and usually includes two columns connected in series or in parallel, each with its own thermal conductivity detector The gas sample is injected into a stream of helium entering the columns CO_2 is separated from the other respiratory gases in one column, and, as the CO_2-laden portion of the helium carrier passes through the detector, a variation in thermal conductivity is recorded as a peak, the size of which is proportional to the percentage of CO_2 in the injected sample Oxygen and nitrogen are separated and measured in the other column (Lysyj and Newton, 1963)

Other Methods The Van Slyke apparatus, the polarographic method for oxygen and the CO_2 electrode are applicable to gas mixtures, but more commonly are applied to the analysis of blood or plasma These methods are described in the next section The mass spectrograph also is sometimes used for the analysis of respiratory gases

GASES IN BLOOD OR PLASMA

Handling Blood Samples Blood for gasometric studies must be drawn and handled without exposure to air It is sometimes drawn under oil or over mercury, but more commonly into a syringe which is immediately closed by replacing the needle with a cap The syringe may then be stored briefly in ice water prior to the analysis The sampling tube or syringe must contain an anticoagulant, usually a drop of heparin solution When plasma is required, it is obtained by centrifuging the blood under a layer of mineral oil or, preferably, in a closed syringe with the plunger held in position by a plastic case fitted around its exposed portion (Peters and Van Slyke, 1932, Comroe, 1950)

Tonometers As originally defined, a tonometer is an instrument for measuring tension However, the first methods used for measuring gas tensions in blood required equilibration of the blood with a gas phase and analysis of the gas Hence the vessel in which the equilibration was brought about came to be called a tonometer Many forms of apparatus have

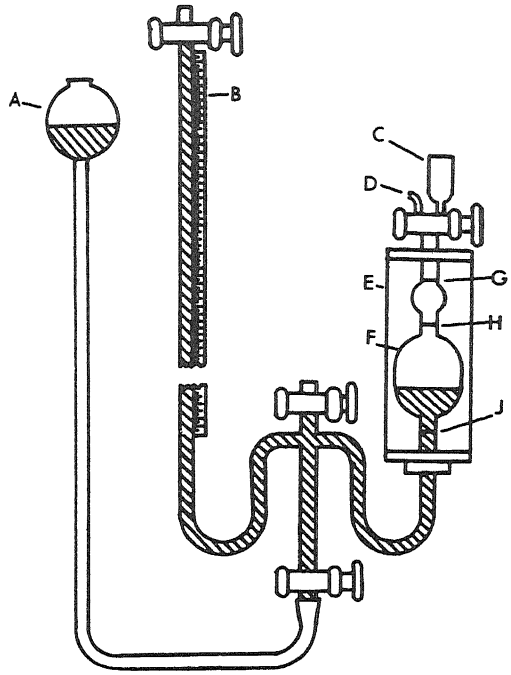

Fig 6 1 Van Slyke-Neill manometric apparatus *A* leveling bulb *B* manometer *C* cup *D* waste tube *E* water jacket *F* reaction chamber *G* 0 5 ml mark *H* 2 0 ml mark *J* 50 ml mark

been devised for this equilibration For example, in experiments to establish the oxygen dissociation curve it is desirable to expose small volumes of blood to large volumes of gas mixtures This can be done in a closed space, or a stream of gas can be passed over the blood On the other hand, in the "bubble" method for measuring gas tensions a relatively large volume of blood is exposed to a bubble of air so small that the exchange of gases has a negligible effect on the composition of the blood

The Van Slyke-Neill Manometric Apparatus (Fig 6 1) The analysis of blood or plasma is carried out by filling the reaction chamber with mercury and drawing in a 0 1 to 2 0-ml sample, preceded or followed by reagents to free the gases Carbon dioxide is released by lactic acid, and oxygen by potassium ferricyanide with saponin added to induce rapid hemolysis The gases are extracted by lowering the mercury to the 50-ml mark to create a vacuum and agitating the contents of the chamber with a shaking motor or a magnetic stirrer The volume of the extracted gases is then reduced to 0 5 ml or 2 0 ml and the corresponding pressure is read on the manometer A small amount of sodium hydroxide is introduced into the chamber to absorb the CO_2, and from the observed decrease in pressure at constant volume the CO_2 *content* of the sample is calculated The *oxygen content* is determined in the same way by absorption with a sodium hydrosulfite-sodium anthraquinone-β-sulfonate mixture

By this method the oxygen and carbon dioxide contents can be measured on a single blood sample *Oxygen capacity* is determined on a separate sample by first equilibrating the blood with air to saturate the hemoglobin and then measuring its oxygen content The *per cent saturation of hemoglobin* in the original sample can then be calculated The *oxygen tension* can be determined from the standard oxygen dissociation curve, provided the pH of the blood also is carefully measured and the necessary correction applied (Severinghaus, 1958) This method gives reliable values for oxygen tension in the range between 0 and about 60 to 70 mm Hg, but at higher levels the curve becomes too flat to allow accurate readings

The *carbon dioxide tension* and the *plasma bicarbonate*[5] can be calculated from the carbon dioxide content and the pH of the plasma by use of the Henderson-Hasselbalch equation Either plasma or whole blood may be used, but loss of CO_2 must be avoided The *plasma CO_2 content* may be measured on separated plasma or may be calculated from the analysis of whole blood However, if whole blood is used it is necessary to determine the hematocrit (or the oxygen capacity) and the per cent saturation of hemoglobin as well as the CO_2 content These data are needed since the CO_2 contained in the erythrocytes is proportional to the volume they occupy, and is influenced by the state of oxygenation of the hemoglobin as explained in a later section In practice the calculations are greatly simplified by the use of line charts, called nomograms, which graphically represent the Henderson-Hasselbalch equation and the relations between plasma and whole blood (Van Slyke and Sendroy, 1928, Singer and Hastings, 1948)

The Van Slyke volumetric apparatus operates on the same general principle as the manometric apparatus It is less accurate and less versatile than the

[5] The plasma bicarbonate represents the *alkali reserve* Van Slyke and Cullen introduced a determination of plasma carbon dioxide capacity or combining power which, although inexact, is often used clinically as a measure of the alkali reserve In this method the blood is drawn and centrifuged without strict anaerobic precautions, and the plasma is subsequently equilibrated with alveolar air at room temperature and analyzed for carbon dioxide content From this the bicarbonate concentration at 20° C is calculated The variable losses, being accompanied by shifts of bicarbonate into the cells, are not accurately replaced by the equilibration, but the method usually gives values somewhat higher than the original bicarbonate concentration since the solubility of carbon dioxide is higher at the lower temperature

manometric, but is simpler to operate, and is widely used for measuring blood gases in clinical laboratories After extraction, the gases are measured by observing the volume occupied at a fixed pressure (atmospheric), rather than the pressure exerted at a fixed volume (Peters and Van Slyke, 1932)

Ultramicro Gasometric Methods Natelson (1957) devised a manometric apparatus similar in principle to that of Van Slyke and Neill, but adapted for measurements on 0 03-ml quantities of blood or plasma More recently, Van Slyke and Plazin (1961) described a modification of the Van Slyke-Neill apparatus applicable to 0 025 to 0 030-ml samples Volumetric procedures on the same scale, developed by Roughton and Scholander, employ a device consisting of a capillary buret sealed to the nozzle of a 1-ml tuberculin syringe

Blood Gases by Gas Chromatography For the analysis of blood by this method it is only necessary to supplement the gas chromatograph (described previously) with a blood gas releasing system (Lenfant and Aucutt, 1966) The sample is mixed with releasing agents in a small chamber previously flushed with helium, and the evolved gases are carried into the chromatographic column by a stream of helium An analysis can be completed in 10 min or less

The "Bubble" Method for Oxygen and Carbon Dioxide Tensions A small bubble of air is equilibrated with blood at body temperature The bubble is then analyzed by micro methods, and from the percentages of oxygen and CO_2 the corresponding tensions are calculated If the volume of the bubble is kept very small in relation to the volume of blood, the amounts of oxygen and CO_2 exchanged during equilibration are insignificant and the results represent the original tensions in the blood This method was introduced by Krogh in 1908, and several appropriate forms of apparatus have been devised The Roughton-Scholander syringe analyzer is advantageous since it can be used for both the equilibration and the gas analysis (the "Riley technique")

Polarographic Measurement of Oxygen Tension If a platinum electrode in contact with a solution is made 0 6 to 0 7 volt negative to a chlorided silver electrode, dissolved oxygen molecules at the platinum surface receive electrons and are reduced to either H_2O_2 or OH^- The current passing from the platinum is linearly related to the availability of dissolved oxygen molecules at its surface When the platinum is in direct contact with the blood, however, the current flow is influenced by stirring and other factors which make adequate calibration difficult In the Clark electrode the electrical cell is separated from the blood by a thin polyethylene membrane that is permeable to oxygen (and CO_2) but impermeable to electrolytes and most other solutes If the platinum surface area is very small and the membrane is of the right thickness, this electrode shows a fairly rapid response, is insensitive to stirring, and can be calibrated to record *oxygen tension* in millimeters of mercury It can be used to analyze either solutions or gas mixtures, and for monitoring in vivo (Torres, 1963, Charlton et al , 1963)

The oxygen electrode has been applied to the measurement of *oxygen content* of blood by first mixing the sample with a ferricyanide reagent to release the oxygen into a known volume of solution The oxygen content is calculated from the tension observed and the solubility coefficient (Tucker, 1967, Cole and Hawkins, 1967)

The Carbon Dioxide Electrode This consists of a glass electrode, sensitive to pH changes, in contact with a thin layer of a solution containing a small concentration of bicarbonate ion and separated from the blood by a Teflon membrane Since the membrane is permeable to carbon dioxide but not to ions, the pH of the sample cannot affect the pH at the glass electrode surface The measured pH of the bicarbonate solution varies with the negative logarithm of the CO_2 *tension*, in accordance with the Henderson-Hasselbalch equation The electrode is calibrated against solutions of known CO_2 tension (Severinghaus and Bradley, 1958)

Interpolation Method for Carbon Dioxide Tension and Related Variables A graph showing the relation between log P_{CO_2} and the pH of a blood sample is a straight line By equilibrating a blood sample at two known P_{CO_2} levels and measuring the corresponding pH values, two points of the graph are determined and the curve for the sample can be drawn If the pH of the sample before equilibration is also measured, its P_{CO_2} can be found from the graph Carbon dioxide-oxygen mixtures are used for the equilibrations so that the hemoglobin will be fully oxygenated, a small estimated correction can be applied if the sample initially is not completely oxygenated Astrup (1961) described a capillary glass electrode and an equilibration unit, both thermostated at 38° C, with which the procedures can be carried out rapidly on a microscale

In addition to CO_2 tension, a number of other variables concerned with the acid-base balance can be calculated with the aid of a nomogram (Siggaard Anderson and Engel, 1960, Siggaard Anderson, 1962b) These include the standard bicarbonate of the plasma,[6] the buffer base and base excess (or deficit) of the blood, and the plasma bicarbonate, CO_2 content and CO_2 combining power The three pH values are the only measurements necessary

Photoelectric Oximetry An oximeter is a photoelectric photometer for measuring the fraction of he-

[6] Standard bicarbonate is defined as the bicarbonate concentration in the plasma of blood brought to a P_{CO_2} of 40 mm Hg at 38° C with the hemoglobin fully oxygenated This variable is useful in studies of nonrespiratory acid-base disorders since it is not influenced by variations in P_{CO_2} or oxygenation

moglobin in the oxygenated form Oxyhemoglobin absorbs less visible red light (620 to 770 mμ), and therefore transmits and reflects more in this waveband, than does reduced hemoglobin Infrared light of 805 mμ, however, is absorbed equally by oxygenated and reduced hemoglobin A transmission oximeter measures light transmitted by blood in both red and infrared regions, and the oxygen saturation is determined from the ratio of the two readings Some oximeters employ cuvettes in which the blood is contained or through which it is passed during either withdrawal from the body or diversion through an extracorporeal circuit Reflection oximeters also are available Instruments currently in use have been compared and evaluated by Cole and Hawkins (1967)

The ear oximeter is designed to record the oxygenation of the blood passing through the capillaries of the pinna The ear is warmed to some extent by the earpiece, with the result that a localized vasodilation occurs The capillary blood then is essentially arterial, since the oxygen utilization in this region is very small A transparent pneumatic pressure capsule is interposed between the light source and the ear so that allowance can be made for the light absorbed by the bloodless (pressurized) ear (Wood et al , 1960)

The Oxygen Dissociation Curve

The equilibrium between oxygen and hemoglobin is described by the oxygen dissociation curve, in which the per cent saturation of hemoglobin is plotted against the oxygen tension Since oxygen tension must be regarded as the *independent* variable, it is represented on the abscissa while per cent saturation (the *dependent* variable) is on the ordinate The equilibrium is influenced by electrolytes and other variables, hence curves determined on pure hemoglobin solutions differ in their exact shape and position from those determined on whole blood By equilibrating blood with known gas mixtures, Barcroft and Poulton (1913) determined the curves shown in Fig 6 2 For each curve the carbon dioxide was held constant while the oxygen tension was varied It is evident that increasing the CO_2 tension increases the dissociation, thus shifting the curve to the *right* (the "Bohr effect") This is due mainly to hydrogen ions produced by the dissociation of carbonic acid, but in part also to the formation of carbaminohemoglobin (Roughton, 1964) The hydrogen ion effect is related to the behavior of oxyhemoglobin and reduced hemoglobin as acids and the fact that the oxygenated form is a stronger acid than the reduced form, as discussed in a later section

An increase in temperature also shifts the curve to the right (increasing dissociation) Variations in blood electrolyte concentrations ordinarily are too small to have measurable effects on the oxygen dissociation curve

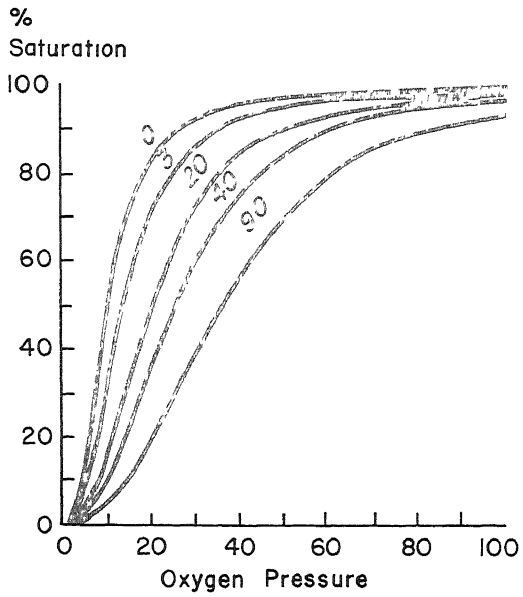

Fig 6 2 Dissociation curves of human blood exposed to 0 3 20 40 and 90 mm CO_2 Ordinates percentage saturation Abscissae oxygen pressure (After Barcroft and Poulton 1913)

With changing oxygenation it is not possible to hold both the P_{CO_2} and the pH constant (without adding acid or alkali), if P_{CO_2} remains constant the pH must shift slightly in the acid direction with increasing oxygenation since oxyhemoglobin is a stronger acid than reduced hemoglobin It is now customary to use the *standard oxygen dissociation curve* at 37° C and plasma pH of 7 40 (Fig 6 3) This has been established for human blood by careful measurements in several different laboratories, the observed values were subjected to pH and temperature corrections where necessary Severinghaus (1958) has prepared a nomogram from which the corrections can be calculated and from which dissociation curves for various values of plasma pH and temperature can be derived The reason for the sigmoid shape of the curve is discussed in section 4, chapter 4

Individual Variations and Species Differences The position of the oxygen dissociation curve is conveniently established by determining the point at which the hemoglobin is *half-saturated* On the standard curve (Fig 6 3) this occurs at an oxygen tension of 26 mm Hg The dissociation curve of the blood has been

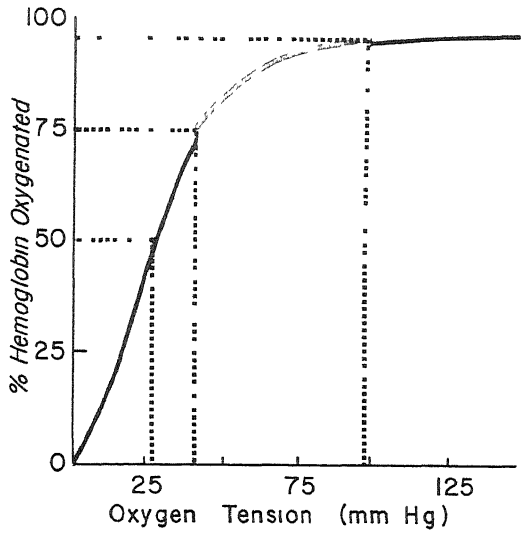

Fig 6 3 Standard oxygen dissociation curve of human blood at 37° C and plasma pH 7 40 Important points on the curve are the P_{O_2} at half-saturation (26 mm Hg) 75% saturation (40 mm Hg) and 97% saturation (99 mm Hg) The heavy line represents the normal working range between arterial and mixed venous blood It deviates slightly from the standard curve because the venous blood is 0 02 to 0 03 pH units more acid than the arterial blood

determined from time to time over a period of years in several persons and is found to be unaffected by age changes, but small variations occur in blood from different individuals In the cases of human and canine blood the tension required for half saturation at 37° C and at plasma pH 7 40 usually lies within the range of 25 to 30 mm Hg For blood from cats and sheep the value is about 1 5 times as large, indicating a lower affinity for oxygen The curve for blood of pigs, bullocks, and horses is similar to that of man Since the hemes in blood of all species are chemically identical, the variations in affinity for oxygen are attributed to differences in the globin part of the molecule The species differences in oxygen affinity are not correlated with the ability to withstand a lack of oxygen, indicating a preponderance of other factors in resistance to anoxia (Roughton, 1964)

Abnormal Hemoglobins Hemoglobin variants may modify oxygen exchange in man Hemoglobins with higher than normal affinity for oxygen occur, and are accompanied by compensatory polycythemia since they release oxygen to the tissues less readily than does normal hemoglobin There are also examples of hemoglobins with low oxygen affinity and associated anemia Alterations in the globin part of the molecule account for the variations in affinity (Lenfant et al , 1970)

Physiological Regulation of Oxygen Affinity Recent studies have revealed that the erythrocytes have an intrinsic adaptive mechanism for regulating the position of the oxygen dissociation curve (Benesch and Benesch, 1970, Lenfant et al , 1970, Rose, 1970) These cells contain a uniquely high concentration of 2,3-diphosphoglyceric acid (DPG), which tends to become reversibly bound to certain sites in the globin of reduced hemoglobin but does not bind to oxyhemoglobin The complex must dissociate for oxygen to be bound An increase in DPG therefore *shifts the oxygen dissociation curve to the right* DPG is formed by a side reaction of the glycolytic pathway, and its level is increased in response to low oxygen tension in the capillary or venous blood This adjustment requires only a day or two after ascent to a high altitude Calculations show that it would contribute to acclimatization, increasing the amount of oxygen released from the hemoglobin by possibly 10% at 15,000 ft , although at such an altitude the arterial oxygen values as well as the venous values are on a steep part of the dissociation curve In anemias and hypoxic states resulting from low cardiac output, the same adjustment occurs and, since the arterial blood is almost completely oxygenated, the shift of the curve to the right undoubtedly is an important aid in the delivery of oxygen

Alterations in the red cell DPG levels brought about by abnormal enzymatic activities are found to result in compensatory anemia or polycythemia These effects are comparable to those of hemoglobin variants previously mentioned

In blood stored for transfusions, a slow decrease in DPG brings about an increased oxygen affinity with the result that after transfusion of large quantities the release of oxygen to the tissues is subnormal This change in the blood is influenced by the preservative used, and can be retarded by the addition of inosine (Bunn et al , 1969)

Oxygen Dissociation Curve of Fetal Blood The curve for fetal blood at pH 7 40 lies to the left of the standard curve, while the curve for maternal blood is in the normal position or

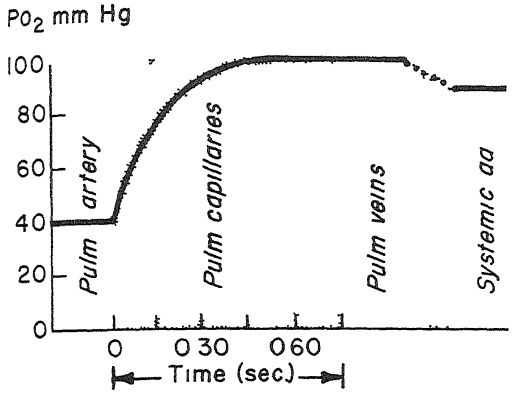

Fig 6 4 Changes in P_{O_2} of blood during its passage through the lungs (From Comroe et al 1962)

sometimes a little to the right (Darling et al , 1941) This means that the affinity for oxygen is higher in fetal than in maternal blood, a fact established for the human and several other species by various workers The difference in affinity is thought to aid in the transfer of oxygen from the maternal to the fetal circulation in the placenta Fetal hemoglobin differs in structure from adult hemoglobin, and its oxygen affinity is less influenced by DPG (Tyuma and Shimizu, 1970)

Oxygen and Carbon Dioxide Transport

OXYGENATION OF ARTERIAL BLOOD

Under normal resting conditions the blood passing through an alveolar capillary is thought to reach equilibrium with the air in the alveolus well before arriving at the end of the capillary, despite the brevity of the transit time (Fig 6 4) If this were not so, the great reductions in transit time and in venous blood oxygen content which occur during severe exercise would lead to a considerable decrease in oxygenation of the arterial blood Actually, severe exercise brings about only a very slight decrease in the oxygen tension of arterial blood while slightly increasing that of alveolar air, the alveolar-arterial P_{O_2} difference increases from 4 to 9 mm Hg under resting conditions[7] to about 13 to 18 mm Hg in severe exercise (Rossier et al , 1960)

The existence of a measurable P_{O_2} difference between alveolar air and arterial blood is attributed to two factors *1) admixture of small amounts of venous blood* with the oxygenated blood and *2) uneven effectiveness of ventilation* in relation to blood flow in different parts of the lungs Sources of venous admixture normally include the bronchial and coronary circulations, pathologically there may also be pulmonary arteriovenous shunts Blood from venous sources could decrease the arterial P_{O_2} significantly without causing a perceptible change in the P_{CO_2}, since the total difference between venous and arterial P_{CO_2} is only 6 mm Hg

Uneven ventilation relative to blood flow would not be expected to measurably influence the arterial P_{CO_2} since underventilation of some alveoli (as compared with the mean for all alveoli) would be compensated for by overventilation of others But an effect on arterial P_{O_2} occurs and is related to the shape of the oxygen dissociation curve Because of the flattening of the curve at its upper end, increasing oxygen tension above 95 mm Hg adds very little to the blood oxygen content, hence overventilated alveoli cannot supply extra oxygen sufficient to compensate for the effects of underventilated alveoli The alveolar-arterial P_{O_2} difference decreases when the alveolar oxygen tension is reduced to a level falling on a steeper part of the oxygen dissociation curve

Although the alveolar-arterial P_{O_2} difference is small and of little consequence in normal subjects, it becomes a matter of importance in certain respiratory disorders Methods have been developed to evaluate separately the effects of *1)* venous admixture, *2)* uneven ventilation-blood flow relationships, and *3)* impaired diffusion, since each of these may be a factor in respiratory dysfunction With regard to the second of these, ventilation and blood flow cannot be considered separately, the oxygen and CO_2 tensions in blood leaving the lungs are determined by the *ratio* between the ventilation of the alveoli and their capillary blood flow Alveoli that are relatively overventilated waste a fraction of their ventilation, and alveoli that are underventilated waste a fraction of their blood flow, and both types of alveoli contribute to differences in gas tensions between alveolar air and arterial blood In some disorders, ventilation blood flow ratios are uneven enough to cause anoxemia or to exacerbate anoxemia resulting from decreased alveolar

[7] Slightly higher values are found by many investigators, the method used for sampling the alveolar air is of critical importance

ventilation (Comroe et al , 1962, Rahn and Fahri, 1964, West, 1965)

The Working Range of Blood Oxygenation The normal range between arterial and mixed venous blood under resting conditions is shown in Fig 6 3 In arterial blood the hemoglobin is 96 to 97% saturated with oxygen In the tissue capillaries, outward diffusion of dissolved oxygen reduces the blood oxygen tension Accordingly, oxyhemoglobin dissociates, and the released oxygen diffuses away in the dissolved form When the tension has been reduced to 40 mm Hg, the level of saturation is about 75% A slight decrease in the blood pH occurs (0 02 to 0 03 pH units) due to the uptake of carbon dioxide, hence the physiological curve deviates slightly from the standard dissociation curve at pH 7 40

Depending upon the particular tissue and its activity at the moment, the blood in its passage through the capillaries loses from one-tenth to nearly all of its oxygen load The figure used to express the proportion of the total oxygen content given up to the tissue is called the *coefficient of utilization* Thus if the oxygen content of arterial blood is 19 5 volumes per cent and that of venous blood is 15 volumes per cent (i e , an arteriovenous difference of 4 5 volumes per cent) the coefficient is 4 5/19 5 or 0 23 As indicated above, the coefficient varies considerably for different tissues and for the same tissue in accordance with blood flow and metabolic activity During heavy exercise the overall coefficient of utilization increases to about 0 6, and that of active muscle to as high as 0 8

Certain features associated with the shape and position of the oxygen dissociation curve are of the utmost physiological importance At the normal oxygen tension of alveolar air at sea level, the hemoglobin in the blood passing through the lungs becomes almost completely saturated The flattening of the upper part of the curve means that relatively little reduction in the per cent saturation occurs until the alveolar Po_2 falls to about 60% of its value at sea level Such a decrease would occur on ascending to an altitude of about 10,000 ft , and at sea level is not uncommon in cardiopulmonary disease Within this range, wide variations in alveolar Po_2 can occur with minimal changes in the total oxygen load of arterial blood. This circumstance constitutes a considerable safety factor On the lower part of the curve, the steep slope means that in this region a given fall in oxygen tension causes the release of a relatively large volume of oxygen The relation between oxygen content and oxygen tension therefore is such as to favor a nearly maximum *uptake* of oxygen in the lungs as long as the tension is above 60 mm Hg and an adequate *release* of the gas at the lower tensions which prevail in the tissues The slope of the curve would favor release at still lower tensions, but at some point the diffusion gradient would become insufficient to support the rapid transfer of oxygen into the cells

The effects of increasing hydrogen ion concentration and Pco_2 on oxygen dissociation (shifting the curve to the right) tend to favor the release of oxygen to the tissues since carbon dioxide and sometimes lactic acid are produced by tissue activity A slight increase in temperature, such as may occur in working muscle, has a similar effect However, these shifts in the position of the curve are small and in working muscle are much less important than the great increase that occurs in the blood flow The influence of temperature is of some importance in hyperthermia, and requires particular consideration when patients are subjected to hypothermia for surgical procedures Estimates of oxygen tension from oximeter readings taken during hypothermia would be higher than the true values if the effect of temperature were disregarded

OXYGEN CONTENT–Po_2 CURVES

When *per cent saturation* is plotted against oxygen tension, as in Fig 6 3, the importance of the hemoglobin concentration is not evident, the curve for blood from an anemic patient appears the same as that for normal blood The difference becomes apparent if oxygen *content* is plotted against oxygen tension, as in Figure 6 5 Such a curve for blood of any hemoglobin concentration can be obtained from the standard curve by calculating the volumes per cent of oxygen combined with hemoglobin (per cent saturation × oxygen capacity) at each of a series of Po_2 values and adding the small concentration of dissolved oxygen present at that level It is evident from Figure 6.5 that a 50% decrease in hemoglobin, such as might occur in anemia, would halve the amount of oxygen delivered by 100 ml of blood if the working range were unaltered Partial compensation occurs by an increase in the coefficient of utilization, which in the diagram extends the working

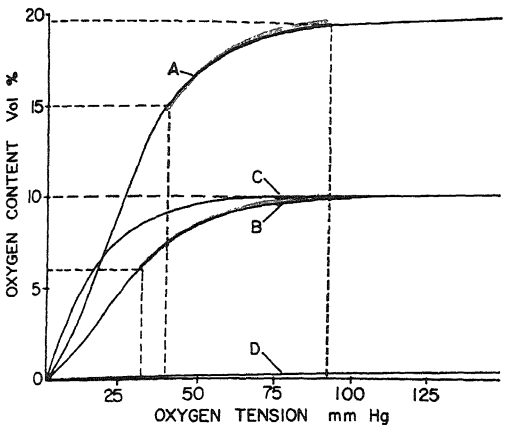

Fig 6 5 Effects of anemia and of carbon monoxide on the oxygen dissociation curve of blood at pH 7 40 and 37°C *A*) Normal blood hemoglobin 15 gm/100 ml *B*) Anemia hemoglobin 7 5 gm/100 ml *C*) Carbon monoxide poisoning hemoglobin 15 gm/100 ml half-saturated with CO *D*) Curve representing oxygen in physical solution Heavy lines indicate the working range in normal and anemic subjects

range downward to a tension of 32 mm Hg, but the oxygen delivered by 100 ml of blood is still not as much as in the normal subject Not shown in Figure 6 5 is a small shift of the anemic curve to the right induced by an increase in 2,3-diphosphoglyceric acid in the red cells Additional compensation is achieved by a rise in the cardiac output, which increases the oxygen delivery by increasing the volume flow of blood through the tissues The circulatory adjustments are aided by a decrease in blood viscosity (a consequence of erythrocyte depletion), which reduces the peripheral resistance

Effects of Carbon Monoxide Hemoglobin and carbon monoxide react reversibly to form *carboxyhemoglobin* As with oxygen, the hemoglobin becomes saturated in the proportion of one molecule of gas to one atom of iron, and the physicochemical aspects of the two reactions are very similar except that the affinity of hemoglobin for carbon monoxide is about 200 times its affinity for oxygen When both gases are present they compete for the hemoglobin

The presence of 0 1% of carbon monoxide in the inspired air over a period of a few hours (or a higher concentration for a shorter time) is sufficient to convert 50% of the hemoglobin in the blood to carboxyhemoglobin, and at about this level the effect becomes lethal By contrast, an anemic patient whose blood hemoglobin is reduced to 50% of normal shows little evidence of anoxia under resting conditions The major reason for this difference is shown in Figure 6 5 It will be seen that the position of the oxygen dissociation curve is shifted to the left by carbon monoxide, with the result that the ability to delivery oxygen to the tissues is greatly reduced In other words, as the per cent of carboxyhemoglobin increases, the remaining active hemoglobin holds more tightly to the oxygen with which it combines This is explained as follows in the hemoglobin molecule there are four hemes, each containing one atom of iron, and when one or more of the hemes is combined with carbon monoxide an interaction takes place which increases the affinity of the remaining hemes for oxygen (Roughton, 1964)

VARIATION OF BLOOD CO_2 CONTENT WITH P_{CO_2}

Figure 6 6 shows the manner in which the CO_2 *content* of the blood varies when the blood is exposed to gas mixtures of varying CO_2 *tension* In the physiological range, an increase in P_{CO_2} induces an almost proportional increase in CO_2 content, i e , the curve is nearly a straight line in this region A pH decrease, calculable from the Henderson-Hasselbalch equation, accompanies a P_{CO_2} increase but is very small in this range The exact position of the CO_2 content-P_{CO_2} curve depends upon the total buffering power of the blood Christiansen, Douglas, and Haldane (1914) first noted that the curve is higher for reduced blood than for oxygenated blood In other words, reduced blood has more buffering power than oxygenated blood and can carry more carbon dioxide at a given P_{CO_2} This suggested that oxyhemoglobin may behave as a stronger acid than reduced hemoglobin Thus oxygenation would cause the hemoglobin to release hydrogen ions, which would then be neutralized and would use up some of the buffer base (including some bicarbonate), and accordingly the position of the CO_2 content-P_{CO_2} curve would be shifted downward Titration curves for oxygenated and reduced hemoglobin supported this interpretation However, this mechanism is now known to be only a part of the explanation for the shift of the curve The other factor is the effect of oxygenation in diminishing the power of hemoglobin to combine directly with carbon dioxide

Transport of CO_2 as Carbaminohemoglobin Carbon dioxide combines with hemoglobin, not

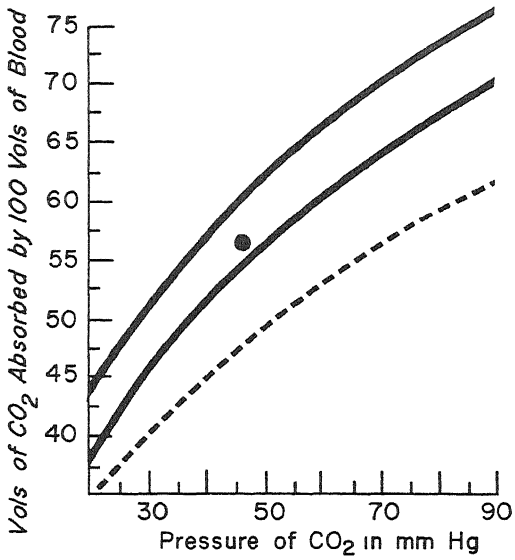

Fig 6 6 Carbon dioxide dissociation curves of fully reduced human blood (upper solid line) in presence of hydrogen and fully oxygenated human blood (lower solid line) in presence of air Volumes of CO_2 along the ordinate CO_2 tension along the abscissa Line AVB is the so-called physiological dissociation curve of CO_2 i e as a result of the reduction of hemoglobin the relation of volumes of CO_2 to CO_2 tension is indicated at points along this line and not along the lower curve for oxygenated blood At *A* (arterial point) are indicated the volume and tension of CO_2 in arterial blood Point *B* indicates the conditions in fully reduced blood Point *V* (venous point) represents the degree of reduction of hemoglobin which normally occurs in the body during the passage of the blood through the systemic capillaries The interrupted line below is the CO_2 dissociation curve for oxygenated dog s blood (Modified from Christiansen Douglas and Haldane 1914)

with the hemes as do O_2 and CO, but rather with free amino groups in the globin part of the molecule The reaction can be represented as follows

$$Hb—NH_2 + CO_2 \rightleftharpoons Hb—NHCOO^- + H^+$$

This occurs at a very rapid rate, requiring no enzyme, and the CO_2 does not go through the stage of H_2CO_3 The carbamic acid is almost completely ionized, but the pH change is minimized by the buffering power of the hemoglobin (which increases as the hemoglobin is desaturated, and vice versa)

Carbamino compounds of CO_2 with amino acids are well known, and the technique of estimating them was adapted to the measurement of carbaminohemoglobin by Ferguson and Roughton (1934) Hemoglobin solutions containing bicarbonate were equilibrated with suitable tensions of CO_2 and then were mixed very rapidly with alkaline barium chloride The alkali stabilized the carbamino compound, probably by inducing its complete ionization, and also converted the dissolved CO_2 and bicarbonate to carbonate which was then precipitated by the barium chloride The $BaCO_3$ precipitate was removed by centrifuging The carbaminohemoglobin, which remained in solution, could then be decomposed by acidification and the released CO_2 measured by the Van Slyke technique It was found that *oxygenation of the hemoglobin* greatly reduced the amount of carbamino-bound CO_2 Although an increase in P_{CO_2} would be expected to favor the formation of carbaminohemoglobin, a decrease in pH has an opposite effect (by converting $Hb—NH_2$ to $Hb—NH_3^+$, which does not react with CO_2), hence the dissociation curve of carbaminohemoglobin is practically flat over the physiological range, and the variation in P_{CO_2} between arterial and venous levels has little effect on the carbamino reaction The chief factor influencing the formation and breakdown of carbaminohemoglobin in the body is the variation in oxygenation It has been estimated that 20 to 30% of the carbon dioxide delivered to the alveolar air under resting conditions is transported as carbaminohemoglobin, although only 6 to 7% of the CO_2 content of the venous blood is in this form (Davenport, 1958, Roughton, 1964, Rossi-Bernardi and Roughton, 1967)

Only traces of carbamino compounds are formed by the plasma proteins, and the concentrations do not vary significantly between arterial and venous blood

Transport of CO_2 as Bicarbonate Carbon dioxide produced in the tissues diffuses into the blood in the capillaries as free CO_2 in solution In the blood, a large part of it is converted to carbonic acid·

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \qquad (1)$$

This reaction will take place in the absence of a catalyst, but the uncatalyzed reaction is much too slow to account for the rapid exchanges which take place in the body The reaction rate is accelerated enormously (in both directions) by an enzyme called *carbonic anhydrase*, which is found inside the erythrocytes but not in the

blood plasma [8] The formation and decomposition of H_2CO_3 therefore occur primarily in the red cells

The equilibrium point of reaction (1) lies far to the left However, the hydration of CO_2 is followed by the rapid dissociation of carbonic acid

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ HCO_3^-$$

It is obvious that, by the law of mass action, an increase in P_{CO_2} and the removal of hydrogen ions would tend to drive the two reactions to the right This is what happens as the blood is passing through the *tissue capillaries* CO_2 diffusing into the blood increases the P_{CO_2}, and hydrogen ions are removed by the buffers, especially by hemoglobin since oxyhemoglobin is being converted to the reduced form, a weaker (less dissociated) acid The opposite changes occur as the blood passes through the *alveolar capillaries* the diffusion of CO_2 out of the blood reduces the P_{CO_2}, and the hemoglobin becomes oxygenated and releases hydrogen ions, with the result that the equilibrium is shifted to the left

These interlocking reactions can be formulated as follows

$$CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$$

$$H^+ + HbO_2^- \rightleftharpoons HHb + O_2$$

[8] Carbonic anhydrase is a protein of comparatively low molecular weight (about 30,000) containing one atom of zinc per molecule It is present also in tissues such as gastric and intestinal mucosa, renal cortex, pancreas, brain, spleen, red muscle, liver, and salivary glands, and in the oviducts of hens where its function appears to be concerned in the deposition of calcium in the egg shell Its physiological significance in most of these situations is unknown The enzyme is inhibited by sulfanilamide, cyanide, heavy metals, sulfocyanate, and certain other ions Different sulfonamide drugs differ in their inhibitory potency The ones most commonly used therapeutically are weak inhibitors, but some have been developed for this special purpose Among these is acetazolamide (Diamox), which is used as a diuretic in cardiac insufficiency It acts on the kidney, decreasing the tubular reabsorption of bicarbonate and thus increasing the excretion of sodium and potassium as bicarbonates It also affects the brain (perhaps indirectly), and is used as an anticonvulsant In experimental animals, large doses of Diamox initially induce a fall in CO_2 output, with recovery to the normal rate in about an hour The compensation is brought about by a 40% increase in the P_{CO_2} of the venous blood and a doubling of the ventilation rate (Roughton, 1964)

Here oxyhemoglobin is represented as an ionized acid and reduced hemoglobin as unionized It must be recognized that neither is *completely* ionized or unionized, this formulation merely symbolizes the fact that oxyhemoglobin is the stronger acid of the two When the equilibrium shifts, hydrogen ions released by one reaction can be taken up by the other The overall equilibrium (the sum of the two reactions above) therefore is

$$CO_2 + H_2O + HbO_2^- \underset{\text{lungs}}{\overset{\text{tissues}}{\rightleftharpoons}} HCO_3^- + HHb + O_2$$

This is called the isohydric shift The reaction does not go to completion in either direction, but the equilibrium is shifted to the right by conditions in the tissues and to the left by conditions in the lungs Thus it can be said that CO_2 tends to drive out oxygen, and oxygen tends to drive out CO_2 The shift occurs with very little change in the plasma pH

The negative ions, HbO_2^- on the left and HCO_3^- on the right, are balanced by the presence of positive ions (mostly K^+) inside the red cells [9] However, the cations take no active part in the reaction, and the common statement that they have been "captured" by oxyhemoglobin on the one hand or by bicarbonate on the other is likely to introduce confusion It would be more accurate to consider that *hydrogen ions* are captured either by reduced hemoglobin or by the bicarbonate system

The "heme-linked" or "oxylabile" ionizing groups, i e , those that dissociate to release hydrogen ions more readily in oxygenated than in reduced hemoglobin, are believed to be imidazole groups of the amino acid histidine, a constituent of the globin part of the molecule

An over-simplification must be recognized in the above formulation The hemoglobin molecule contains 4 hemes (sect 4, chap 4) and each heme appears to be associated with one ionizable hydrogen Therefore, fully oxygenated hemoglobin should be represented as $H_4Hb_4(O_2)_4$, and there are intermediate forms such as $H_4Hb_4(O_2)_3$, etc However, the simpler formulation is qualitatively satisfactory if the

[9] The cation content frequently is referred to as "base," but in modern acid-base theory the term "base" is reserved for substances able to accept protons (sect 4, chap 11)

symbol Hb is understood to represent one heme and not a hemoglobin molecule

The Chloride-Bicarbonate Shift Chloride and bicarbonate ions pass freely through the red cell membrane, while cations traverse it only very slowly When the blood is in the tissue capillaries bicarbonate ions formed inside the red cells tend to diffuse out to the plasma Since they cannot be accompanied by cations the red cells are left with a positive electric charge which tends to draw anions into the cells Hence chloride ions, being the most abundant anions, migrate inward in exchange for bicarbonate The reverse movements occur when the blood is passing through the lungs and intracellular bicarbonate is being converted to CO_2 The intracellular-extracellular distribution of ions is described by Donnan's theory, which requires the following relations

$$\frac{[HCO_3^-]_{cells}}{[HCO_3^-]_{plasma}} = \frac{[Cl^-]_{cells}}{[Cl^-]_{plasma}} = \frac{[H^+]_{plasma}}{[H^+]_{cells}}$$

This "Donnan ratio" varies from about 0 72 in arterial blood to 0 75 in venous blood (Davenport, 1958) It follows that *1)* the greater portion of the bicarbonate is carried in the plasma, and *2)* the pH inside the cells is lower than that of the plasma by about 0 12 to 0 14 pH units With the redistribution of ions occurring between the arterial side and the venous side of the circulatory system there is an alteration of osmotic relationships such that some water enters the cells along with the chloride, and a slight swelling of the cells occurs

The exchanges occurring as the blood passes through the lungs are summarized in Roughton's diagram (Fig 6 7)

Gas Tensions in the Tissues

Oxygen Tension In the tissues, oxygen is being supplied by diffusion and consumed within the cells, hence diffusion gradients are present and a uniform Po_2 cannot exist At any given point within a tissue the Po_2 level represents a dynamic balance between oxygen supply and utilization The rate of *supply* is influenced by the following factors arterial Po_2 and oxygen capacity, blood flow, distance from a capillary, distance between capillaries, distance along the capillary, radius of the capillary, and the rate of diffusion of oxygen in the tissue The rate of oxygen *utilization* normally depends upon the energy requirement of the tissue, it varies with activity but is not limited by the availability of oxygen except when Po_2 is reduced to a very low level

Davies and Bronk (1957) used a microelectrode for the polarographic measurement of Po_2 at the surface of the cerebral cortex in cats, and were able to demonstrate the existence of steep downward diffusion gradients as the electrode was moved away from an arteriole or a venule Others have used modifications of this technique to record Po_2 in various parts of the brain and in other tissues (Payne and Hill, 1966)

The distribution of a gas in a tissue can be analyzed theoretically and its *average* tension estimated by calculation with the aid of a diffusion model originally suggested by Krogh It is assumed that the tissue is functionally divided into cylindrical segments, each supplied with a centrally situated capillary (Kety, 1957), Gleichmann et al (1962) applied this reasoning to estimate the mean oxygen tension in the cerebral cortex of the dog, and compared the results with polarographic measurements of Po_2 at the surface of the cortex The active surface of each electrode covered an area 2 to 4 mm in diameter, and large vessels were absent from the areas chosen The surface values agreed fairly well with those calculated for mean Po_2 in the tissue, and usually came close to the venous blood Po_2 The observed values were 25 to 42 mm Hg in animals with ventilation rates approximately normal

Other workers have reported lower Po_2 values from the surface of the cortex and from electrodes thrust into various parts of the brain For example, Meyer and Gotoh (1961) reported

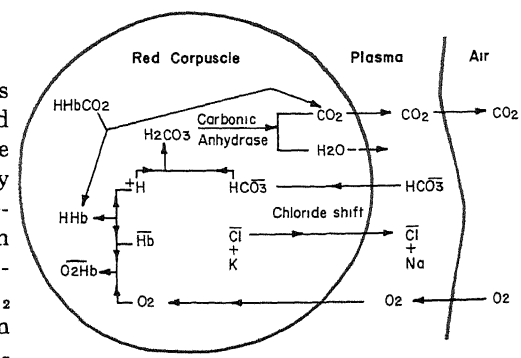

Fig 6 7 Showing main processes occurring in the blood during the output of carbon dioxide and uptake of oxygen in the lung (After Roughton 1961)

surface values of 10 to 20 mm Hg in cats and monkeys Cater et al (1961) made an extensive exploration of the rat brain, finding values of 33 to 60 mm Hg at the cortical surface, 20 to 38 in gray matter of the cortex, 6 to 16 in white matter of the cortex, and 10 to 15 in hypothalamic nuclei In rat muscle the values were 14 to 26, and in subcutaneous tissue there were wide variations from 8 to 62 Jamieson and Van den Brenk (1964) reported the following mean values for rat tissues cerebral cortex 34, liver 13, kidney 17, and spleen 17 mm Hg

In the various tissues studied, rapid variations in Po_2 occur in relation to metabolic, circulatory and respiratory changes induced by various means

CO_2 Tension Diffusion gradients of Pco_2 must be assumed to exist between the tissue cells and the blood in the capillaries With the aid of Krogh's diffusion model, Gleichmann et al (1962) calculated the *average* Pco_2 in the cerebral cortex of the dog in each of a series of experiments A statistical analysis of the data indicated that the average tissue Pco_2 is only about 0 7 mm Hg higher than the mid-capillary blood Pco_2 (i e , the average of arterial and cerebral venous values) CO_2 electrodes placed on the surface of the cortex gave values which in each experiment agreed closely with the estimated average tissue Pco_2 The values ranged from 31 to 58 mm Hg Meyer and Gotoh (1961) found that the Pco_2 of the cerebral cortex fluctuates rapidly in relation to metabolic, circulatory, and respiratory alterations

Adjustments in Metabolic Requirements

Increased activity of any tissue entails an increase in oxygen consumption and CO_2 production On the other hand, an increase in the oxygen supply above that which is adequate does not increase the oxygen usage There are two ways in which an increased demand for oxygen may be met *1*) by increasing the blood flow through the tissue, and *2*) by raising the coefficient of oxygen utilization Both of these factors come into play, but the extent to which each operates is different for different tissues The coefficient of oxygen utilization is increased by establishing a steeper Po_2 gradient between the capillary blood and the tissue cells, this is brought about by *1*) a decrease in the intracellular Po_2 as utilization increases, *2*) a shortening of the distance through which oxygen must diffuse, i e , the opening up of more capillaries so that the radius of the cylinder of tissue supplied by each capillary is reduced, and *3*) increased dissociation of oxyhemoglobin due to increased production of acids (carbonic and lactic) and a rise in temperature (Otis, 1963)

Total, Dead Space and Alveolar Ventilations

The lung is made up of tubes for airflow and alveoli for exchange of gases between air and blood At the end of a normal expiration, the airways and alveoli are filled with alveolar gas At the end of a normal inspiration, however, the airways are filled with moist room air and the balance of the inspired volume has been added to the volume of the alveolar spaces During the subsequent expiration, room air is washed out of the airways by alveolar air and the cycle begins again Therefore one expired breath (tidal volume) contains gas from two compartments, one filled with room air containing a negligible concentration of carbon dioxide, and the other filled with alveolar air with a partial pressure of carbon dioxide (P_{CO_2}) in equilibrium with arterial blood

The volume of the airways of an adult man is about 150 ml At a tidal volume of 500 ml and a respiratory frequency of 12/min , the total ventilation is 6 0 liters/min of which the airway ventilation is $150 \times 12 = 1\,8$ liters/min and the alveolar ventilation is $350 \times 12 = 4\,2$ liters/min It is customary to refer to airway ventilation as "dead space" ventilation because it is not associated with exchange of gases with capillary blood The terms "anatomical" and "physiological" dead space ventilation are used to distinguish simple airway ventilation from ventilation of airways together with alveolar spaces which do not participate in gas exchange A lung lacking its pulmonary artery, for example, would have only dead space ventilation despite its normal anatomical subdivision into airways and alveoli

Anatomical dead space can be measured postmortem by making casts of the airways from mouth to terminal bronchioles and measuring their volume It can also be measured approximately by the technique described in Figure 6.8 (Fowler, 1952) This requires measuring volume of expired air and nitrogen concentration in expired air simultaneously A subject breathing room air (79% nitrogen) takes in a breath of 100% oxygen and then exhales slowly The nitrogen meter records 0% nitrogen during the period of inspiration and during the first part of expiration as the dead space air is washed out The meter then samples a mixture of rising nitrogen concentration as dead space gas is mixed with alveolar gas Ideally, if the inspired oxygen is evenly distributed throughout the alveoli, the meter then records an unvarying nitrogen concentration The measurement of dead space is calculated to be the volume expired up to the time at which one-half the volume of the rising phase has been delivered Measurements so made in normal subjects indicate that anatomic dead space at the end of a maximal expiration is about one-half its value at the end of a complete inspiration This indicates the extent to which the airway volume is increased by elongation and widening as traction of airways by lung parenchyma increases with lung volume

Total ("anatomical" plus "physiological") dead space ventilation is readily measured provided the carbon dioxide content of alveolar air is known This can be measured by sampling alveolar gas as described in a previous chapter Since alveolar air is normally in equilibrium with arterial blood, the alveolar partial pressure can also be obtained from the arterial partial pressure Mixed expired air is a mixture of room air from the airways and nonperfused alveoli together with air from perfused alveoli Its carbon dioxide partial pressure is lower in proportion to the dilution of the alveolar fraction, in equilibrium with capillary blood, by the dead space fraction, containing virtually no carbon dioxide If, for example, the arterial P_{CO_2} is 40 mm Hg and the partial pressure of carbon dioxide in mixed expired air ($P_{E_{CO_2}}$) is 30 mm Hg, it must be concluded that alveolar gas was diluted one part room air (dead space) in three parts alveolar air

The equation for calculating the ratio dead space volume/tidal volume is

$$V_D/V_T = (P_{A_{CO_2}} - P_{E_{CO_2}})/P_{A_{CO_2}}$$

where V_D—dead space volume, V_T—tidal vol-

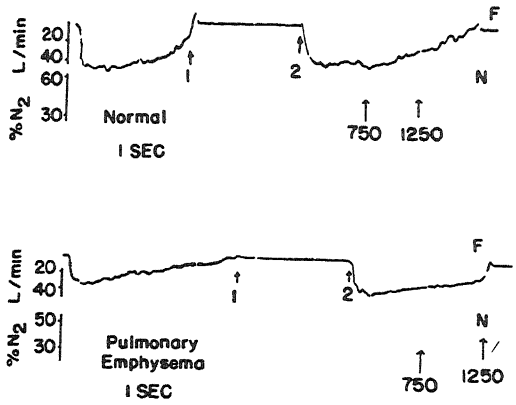

Fig 6 8 Single breath nitrogen dilution method for 1) measuring anatomic dead space and 2) detecting nonuniform distribution of inspired air F = respiratory flow N = nitrogen concentration Horizontal axis is time Integration of F would give volume Expiration after breathing room air is indicated to left of 1 Between 1 and 2 patient inspired one breath of oxygen and at 2 expiration began See text for description of nitrogen curve and its use for measuring anatomical dead space Nonuniform distribution of inspired oxygen is shown by continued increase of nitrogen concentration after rapidly rising phase The increase in concentration between expired volume of 750 and 1250 is 1% in the normal subject and 9% in the patient with emphysema indicating that mixing within the lung is less complete in the latter (From Comroe Jr and Fowler 1951)

ume, $P_{A_{CO}}$—the partial pressure of carbon dioxide in alveolar gas or arterial blood and $P_{E_{CO}}$ —the partial pressure of carbon dioxide in mixed expired air In the instance cited,

$$V_D/V_T = (40 - 30)/40 = 0\ 25$$

If the minute ventilation were 6 liters/min and the respiratory frequency 12/min, the tidal volume would be 500 ml and the dead space volume 500 × 0 25 = 125 ml. Dead space ventilation would be 125 × 12 = 1500 ml /min and the balance of 4½ liters/min would be alveolar ventilation V_D/V_T does not exceed 0 30 in normal subjects

The design of the lung is such that dead space ventilation is obligatory, i e, the proportion of a tidal volume delivered to the alveoli is whatever exceeds the volume of the dead space Table 6 5 shows how alveolar ventilation is affected by tidal volume when total ventilation and dead space volume are kept constant It shows that dead space ventilation increases at the expense of alveolar ventilation as tidal volume approaches dead space volume It is clear from this table that any increase in dead space, such as physiological dead space or anatomical dead space in the form of breathing equipment, decreases alveolar ventilation unless total ventilation is increased The patient with marginal ventilatory ability is therefore disadvantaged by any increase in dead space and may be assisted by decreasing his anatomical dead space Tracheostomy reduces the anatomical dead space about 50% by eliminating ventilation of the mouth, larynx, and pharynx One of its favorable aspects is the increase in alveolar ventilation which results from reducing dead space

Dead space ventilation is not altogether useless Inspired air is warmed, saturated with water vapor at 37° C and filtered Panting, which is primarily dead space ventilation, is an important temperature regulating mechanism in some animals The vital functions of ventilation, however, concern maintaining a sufficiently high partial pressure of oxygen in the alveoli and excreting carbon dioxide These are accomplished exclusively by alveolar ventilation

The Alveolar-Arterial Partial Pressure Difference for Oxygen

Alveolar air contains four gases (O_2, CO_2, N_2, H_2O) the sum of whose partial pressures equals the barometric pressure (see previous chapters) The partial pressures of two of these, N_2 and H_2O, is fixed, for the pressure of water vapor in saturated air at body temperature (37° C) is a constant (47 mm Hg) and the nitrogen inspired into the lung is neither taken into the blood stream nor is it added to from the blood stream The sum of the partial pressures of oxygen and carbon dioxide is therefore also a constant, approximately 150 mm Hg at sea level This means that the subject breathing room air can vary his alveolar P_{O_2} only by varying his alveolar P_{CO_2}

Alveolar P_{CO_2} is directly proportional to the

Table 6 5

Frequency per min	V_T *ml*	V_D *ml*	Ventilation (l /min)		
			Total	Dead Space	Alveolar
10	600	150	6 00	1 50	4 50
15	400	150	6 00	2 25	3 75
20	400	150	6 00	3 00	3 00
30	200	150	6 00	4 50	1 50
40	150	150	6 00	6 00	0

rate at which carbon dioxide is produced by the tissues and inversely proportional to alveolar ventilation

$$P_{A_{CO}} \cong \frac{\text{Production}}{\text{Excretion}} \cong \frac{\text{Metabolic rate}}{\text{Alveolar ventilation}}$$

Clearly, therefore, at any metabolic rate, alveolar ventilation is the key to alveolar P_{O_2} Insufficient alveolar ventilation causes hypoxia because carbon dioxide is produced more rapidly than it is excreted, alveolar P_{CO_2} rises and alveolar P_{O_2} must consequently fall Conversely, increasing alveolar ventilation at a time when the rate of CO_2 production is constant lowers alveolar P_{CO_2} resulting in an increase in alveolar P_{O_2}

Alveolar P_{O_2} ($P_{A_{O_2}}$) can be varied also by changing the total barometric pressure when the oxygen concentration (F) is kept constant (normally 0 2093), by changing the concentration in inspired air ($F_{I_{O_2}}$) or by changes in both pressure and concentration For example, the Himalayan mountain climber can compensate for the fall in $P_{A_{O_2}}$ resulting from low barometric pressure by breathing mixtures in which oxygen concentration is increased at the expense of nitrogen concentration

These factors upon which $P_{A_{O_2}}$ depend are included in the alveolar air equation, one form of which is as follows

$$P_{A_{O_2}} = (BP - 47)F_{I_{O_2}} - (P_{A_{CO}}/R) + [F_{I_{O_2}} P_{A_{CO}} (1 - R)/R]$$

For the derivation of this and other equations used in respiratory physiology, the interested student is referred to Rahn and Fenn (1955) or Comroe (1965) The critical terms in the equation are the barometric pressure (BP), the concentration of oxygen in inspired air (F_{I_O}) and the partial pressure of carbon dioxide in alveolar gas ($P_{A_{CO_2}}$) or arterial blood The final term

$$[F_{I_O}, P_{A_{CO}} (1 - R)/R]$$

is numerically small and is 0 when the gas exchange ratio or respiratory quotient (R) is 1 It should be clear from substituting normal values for $P_{A_{CO}}$ (40 mm Hg) and R (0 8) that $P_{A_{O_2}}$ can be increased to about 660 mm Hg at sea level (760 mm Hg) by breathing 100% oxygen and to more than one atmosphere by placing the subject in a pressure chamber where the barometric pressure can be raised to two or three atmospheres (hyperbaric oxygen chamber). $P_{A_{O_2}}$ can be raised relatively little by increasing alveolar ventilation, for normal $P_{A_{CO_2}}$ is only 40 mm Hg and $P_{A_{CO_2}}$ is rarely lowered to less than 20 mm Hg during hyperventilation On the other hand, CO_2 retention from alveolar hypoventilation can be sufficiently severe to double normal $P_{A_{CO}}$ thereby reducing P_{A_O} substantially Under normal circumstances, however, the regulation of respiration is such that increases in CO_2 production are attended by commensurate increases in alveolar ventilation, and a normal $P_{A_{CO}}$ and normal P_{A_O} are maintained

Alveolar P_{O_2}

The partial pressure of oxygen in alveolar gas ($P_{A_{O_2}}$) calculated from the alveolar equation is a mean value representative of all the alveoli This value is invariably higher than the partial pressure of oxygen in arterial blood (P_{A_O}) by about 13 mm Hg in normal individuals and by considerably greater amounts in certain abnormalities The reasons for this difference in oxygen tensions are as follows (Fig 6 9)

ANATOMICAL SHUNTS

Some blood passes from the venous to the arterial circulation without being exposed to the P_{A_O} calculated by the alveolar equation (Fig 6 9) Some of this blood bypasses the lung entirely, the best known examples being blood from the coronary circulation draining directly into the left heart through the Thebesian veins,

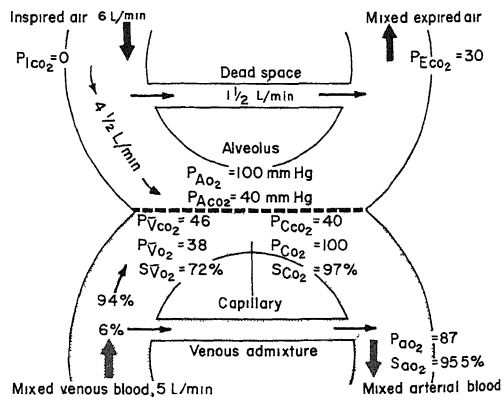

Fig 6 9 Idealized schema of lung Upper half represents ventilation lower half perfusion See text for meaning of symbols and concepts $P_{C_{O_2}}$, $P_{C_{O_2}}$, and $S_{C_{O_2}}$ are partial pressures of carbon dioxide and oxygen at the end of the pulmonary capillary and saturation of blood at the end of the capillary respectively

and venous blood in the bronchial veins draining into the pulmonary circulation distal to the capillary bed It is estimated that less than 6% of the cardiac output follows these anatomic shunts Clearly, they result in lowering the P_{O_2} of arterial blood below the P_{O_2} of pulmonary capillary blood in equilibrium with alveolar gas

It is instructive to calculate the magnitude of this effect under specified conditions Assuming, for example, that P_{A_O} equals 100 mm Hg, the oxyhemoglobin dissociation curve indicates that pulmonary capillary blood in equilibrium with this gas has an oxyhemoglobin saturation of 97% If the capillary-venous difference in saturation is 25%, a common value, the venous saturation will be 72% If venous shunts account for 6% of the cardiac output, leaving 94% to pass through the pulmonary capillaries, the resultant mixture will have a saturation of (0 06 × 72) + (0 94 × 97) = 4 32 + 91 18 = 95 50% The partial pressure of oxygen at this saturation is 87 mm Hg, 13 mm Hg lower than in pulmonary capillary blood There is normally, therefore, a difference between pulmonary capillary P_{O_2} (P_{c_O}) and arterial P_{O_2} (P_{a_O}) related to the magnitude of the venous admixture from anatomic shunts

PHYSIOLOGICAL SHUNTS

The lung has several million alveoli Because of normal regional differences in compliances and airway resistances, variations in ventilation inevitably result, producing localized differences in $P_{A_{CO}}$ and consequently in $P_{A_{O_2}}$ The ultimate example of physiological shunting is circulation through the capillaries of nonventilated alveoli, the venous admixture effect of such blood comparing to that of blood coursing through anatomical shunts

One of the interesting effects of regional differences in ventilation and $P_{A_{O_2}}$ is that $P_{a_{O_2}}$ is lowered even if hypoventilation of some alveoli is matched by hyperventilation of others This effect results from the nonlinearity of oxyhemoglobin dissociation Consider, for example, arbitrarily dividing the pulmonary blood flow into three equal streams coursing through capillaries in equilibrium with alveolar oxygen partial pressures of 60, 80, and 100 mm Hg One might assume that the mixed blood collected from these would have a P_{O_2} of 80 mm Hg, i e., (0 333 × 60) + (0 333 × 80) + (0 333 × 100) = 80 The correct P_{O_2}, however, would be found by calculating the P_{O_2} at the saturation of the mixed blood This calculation is performed as follows The dissociation curve indicates that saturations at P_{O_2} of 60, 80, and 100 mm Hg are 89%, 94%, and 97%, respectively The saturation of the mixture, therefore, would be (0 333 × 89) + (0 333 × 94) + (0 333 × 97) = 29 6 + 31 3 + 32 3 = 93 2% The P_{O_2} at a saturation of 93 2% is 75 mm Hg, rather than 80 mm Hg It is clear, therefore, that a lung characterized by large variations in P_{A_O} inevitably delivers a blood mixture which is hypoxic relative to mean P_{A_O}

The concept of anatomical and physiological venous admixture is analogous to the concept of anatomical and physiological dead space (Fig 6 9) The difference $P_{c_O} - P_{a_O}$ is a measure of venous admixture just as the difference $P_{A_{CO}} - P_{E_{CO}}$ is a measure of the admixture of dead space ventilation to alveolar ventilation (Riley and Cournand, 1949 and 1951, Riley et al , 1951) The fraction of the cardiac output which is venous admixture (Q_{VA}/Q_T) is proportional to the venous admixture effect on the saturation of capillary blood ($Sc_O - Sa_O$) divided by the total saturation difference between venous and capillary blood ($Sc_{O_2} - S\bar{v}_{O_2}$)

$$Q_{VA}/Q_T = (Sc_O - Sa_O)/(Sc_O - S\bar{v}_O)$$

In Figure 6 9, for example, Q_{VA}/Q_T = 97 − 95 5/97 − 72 = 1 5/25 = 0 06 This equation can be applied to any situation in which one wishes to measure relative flows of blood through two branches of a confluent system It finds application clinically in calculating flows through the anatomical defects of children with congenital heart disease

Alveoli can be classified by their ventilation-perfusion ratios, those with a high value contributing to the physiologic dead space and those with a low value contributing to the venous admixture-like effect of physiological shunts Inasmuch as normal alveolar ventilation is about 4 liters/min and cardiac output about 5 liters/min , a normal ventilation-perfusion ratio for the entire lung is approximately 0 8

Measuring dead space ventilation and measuring venous admixture is one means of detecting ventilation-perfusion abnormalities There are other means Nonuniform distribution of inspired air, for example, shows up on the nitrogen meter record of Figure 6 8 as a progressive increase in nitrogen concentration with time as the parts of the lung which are

most poorly ventilated empty Another popular method is to measure the concentration of nitrogen in alveolar air after the patient has breathed nitrogen-free oxygen for a specified period Normal individuals have less than 2 5% nitrogen in alveolar air after breathing oxygen for 7 min Abnormal lungs with localized areas of hypoventilation, however, do not "wash out" nitrogen with this rapidity and consequently have elevated alveolar concentrations at the end of this time

Low ventilation-perfusion ratios with increased venous admixture is the commonest cause of hypoxia in respiratory illness Bronchiectasis, pneumonia, cystic fibrosis, emphysema are some of the conditions in which this mechanism plays a fundamental role

Resistance to Diffusion of Oxygen from Alveolus to Capillary

The mechanism whereby oxygen passes from alveolus to pulmonary capillary was at one time a central issue preoccupying prominent departments of physiology at England's leading universities and prompting imaginative transcontinental expeditions to mountaintop laboratories (Henderson, 1938) J S Haldane at Oxford University contended that oxygen is secreted into the capillaries against a partial pressure gradient, whereas J Barcroft at Cambridge maintained that this transfer is entirely passive, following the laws of diffusion The issue has been resolved conclusively in favor of the latter, partly because methods for measuring gas pressures in blood improved It is now clear that venous blood is oxygenated because its P_{O_2} (about 40 mm Hg at rest) is lower than alveolar P_{O_2}, that the rate at which oxygen diffuses is a function of the partial pressure difference between alveolus and capillary, and that, under normal circumstances, virtually complete equilibrium is reached between alveolar and pulmonary capillary P_{O_2} (Fig 6 9) When resistance to diffusion is abnormally high, however, or when transit time through the pulmonary circuit is shortened, a measurable alveolar-capillary partial pressure difference may remain Under these circumstances, the total alveolar-arterial partial pressure difference is the sum of a diffusion gradient between alveolus and capillary plus the capillary to arterial difference attributable to anatomical and physiological venous admixture

Separating the diffusion from the venous admixture component of the total alveolar-arterial P_{O_2} difference is necessary for purposes of measuring the pulmonary diffusing capacity for oxygen Before passing to this topic, however, it should be clear that one of the causes of reduced P_{O_2} in arterial blood pathologically is incomplete equilibration of capillary blood with alveolar gas due to abnormal resistance to diffusion across the alveolar-capillary interface Interstitial fibrosis is the classic clinical condition producing hypoxia from this cause Increasing alveolar P_{O_2} by raising F_{I_O} is the logical way of relieving severe hypoxia from this cause

The Pulmonary Diffusing Capacity for Oxygen

The pulmonary diffusing capacity for oxygen (D_{O_2}) is the ratio of oxygen transfer in milliliters of oxygen per minute ($\dot{V}_{O_2}$) from alveolar gas to capillary blood divided by the pressure (mm Hg) required for this transfer

$$D_O = V_O / (P_{A_O} - \bar{P}_{C_O})$$

where P_{A_O} and $\bar{P}_{C_O}$ are partial pressures of oxygen in alveolar gas and pulmonary capillary, respectively (Forster, 1957) Inasmuch as the P_{C_O} continuously changes as blood flows through the capillaries, a mean value ($\bar{P}_{C_O}$) must be obtained as described in a subsequent paragraph

A normal D_{O_2} at rest is approximately 15 to 20 ml of oxygen/min /mm Hg P_{O_2} difference between alveolar and mean capillary oxygen tension The diffusing capacity reflects resistance to diffusion per unit area as well as total surface area for diffusion It is therefore reduced when the alveolar-capillary interface is thickened or where surface area for diffusion is attenuated It rises during exercise by as much as three or four times, presumably because the dimensions of the diffusing surface enlarge as additional capillaries open around each alveolus or as existing capillaries enlarge It increases from infancy to maturity and falls with age, probably reflecting changes in surface area for diffusion

Measuring D_{O_2} requires knowing V_{O_2}, or metabolic rate, P_{A_O} which can be calculated from the alveolar equation, and $\bar{P}_{C_O}$, which cannot be measured directly but which can be estimated from arterial P_{O_2} as follows· It was

indicated above that the total alveolar-arterial Po_2 difference is divisible into a diffusion and a venous admixture component The key to measuring $\bar{P}c_O$ is to create circumstances under which the venous admixture component vanishes or becomes negligible, for under this circumstance arterial Po_2 (Pa_O) approaches Pc_O, This can be done by producing hypoxia sufficient to displace Pa_O to the steep part of the dissociation curve, i e , the part for which substantial changes in saturation due to venous admixture result in relatively small changes in Pa_O To illustrate, it was shown above that the capillary-arterial Po_2 difference is 13 mm Hg if 6% of the cardiac output bypasses the lungs when PA_O and Pc_O are 100 mm Hg, and when the arterial venous saturation difference is 25% If this calculation is repeated at a saturation of 75% (Po_2 = 40 mm Hg), the saturation of venous blood will be 50% (Po_2 = 26 5 mm Hg), and the saturation of mixed arterial blood will be (0 06 × 50) + (0 94 × 75) = 3 00 + 70 50 = 73 5% The Po_2 at this saturation is 39 5 mm Hg, a difference of only 0 5 mm Hg from the pulmonary capillary Po_2 (40 mm Hg) By making the same calculation at a low Po_2, therefore, the venous admixture effect of 13 mm Hg was reduced to 0 5 mm Hg The reason for this striking difference is the characteristic of oxyhemoglobin saturation whereby a given change in saturation at high levels of saturation has a much greater effect on Po_2 than at low saturations

Measuring Do_2 requires not only eliminating the effect of venous admixture on the alveolar-arterial Po_2 difference but creating a measurable difference between PA_O, and Pc_O This can be accomplished by breathing low concentrations of oxygen and by exercise (Lillienthal et al , 1946) A low PA_O reduces the Po_2 gradient between alveolus and venous blood entering the capillary, the rate of diffusion is therefore slowed, the amount of oxygen taken up at any point along the capillary is less, and complete equilibration with alveolar gas is not achieved Exercise increases cardiac output and pulmonary blood flow, thereby reducing time for equilibration of Pc_O, with PA_O Both exercise and hypoxia, therefore, foster an end-capillary PA_O, − Pc_{O_2} sufficiently large to be measured reliably

In summary, by measuring the alveolar-arterial Po_2 difference at a high level of oxygenation to identify venous admixture, and at a low level of oxygenation during exercise, it is possible to create measurable differences between PA_O and Pa_O attributable to a difference between PA_O and Pc_O

BOHR INTEGRATION

The final step in calculating diffusing capacity is to derive a mean Pc_O ($\bar{P}c_O$) This can be done if one knows the Po_2 at the arterial and venous ends of the pulmonary capillary as well as at all intermediate points The former are measurable directly, the latter can be calculated from the oxyhemoglobin dissociation curve by Bohr integration (Fig 6 10) The fundamental premise is that distance or time (T) along the pulmonary capillary is proportional to the reciprocal of the tension difference between alveolar gas and capillary blood

$$[T \cong 1/(PA_O - Pc_O)]$$

This is true because the rate of diffusion, i e , the time (T) required for a given change in saturation (ΔSo_2) at a given point along a capillary, is proportional to the partial pressure difference between alveolus and blood at that point Thus,

$$\Delta So_2/T \cong (PA_O - Pc_O)$$

The data of Figure 6 10 were calculated as-

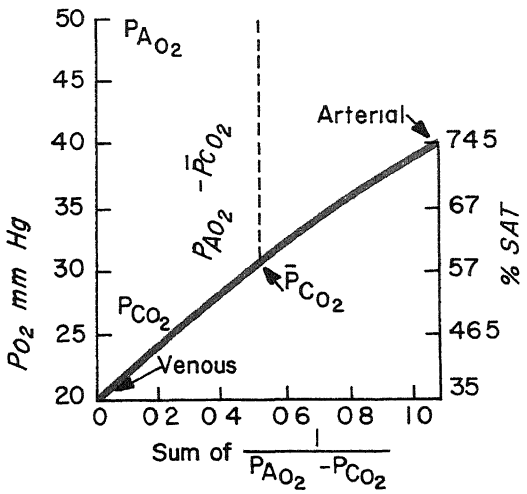

Fig 6 10 Change in P_O and oxyhemoglobin saturation during passage of blood through pulmonary capillary Data calculated by Bohr integration assuming conditions postulated in text Time or distance along capillary is a function of the sum of $1/PA_O - Pc_O$, as explained in text

suming the subject was breathing 14% oxygen, had an alveolar Po_2 of 50, an arterial saturation of 75% (Po_2 = 40 5) and an arterial-venous saturation difference of 40%, i e , mixed venous blood saturation of 35% and Po_2 of 20 mm Hg The end-gradient was 9 5 mm Hg and the mean gradient calculated by Bohr integration 29 mm Hg Assuming an oxygen consumption of 1740 ml /min , the diffusing capacity would be

$$1750 \text{ ml /min /29 mm Hg} = 60 \text{ ml /min /mm Hg},$$

a normal value during severe exercise

Although the circumstances of exertion and hypoxia required for this measurement are so Spartan as to limit its applicability, this method nevertheless remains the only direct approach to measuring the pulmonary diffusing capacity for oxygen Its ingenuity is obvious from the foregoing The premise that hypoxia itself does not affect what is measured may not be justified

Carbon Monoxide Diffusing Capacities

The use of carbon monoxide for measuring Do_2 is less trying on both subject and laboratory personnel None of the methods require hypoxia or exercise and some methods do not require analysis of blood samples

CO has a remarkable affinity for hemoglobin, its affinity being 210 times that of oxygen (Krogh, M , 1914) The Pco of plasma is therefore extremely low at a given concentration of HbCO Accordingly, plasma Pco can usually be assumed to be zero and the alveolar-arterial partial pressure difference becomes simply the alveolar Pco Analyzing blood and performing the equivalent of the tedious Bohr integration are therefore unnecessary

Dco can be converted to Do_2 by multiplying by 1 23 This figure indicates that oxygen is slightly more diffusible than CO This is because diffusibility is directly proportional to solubility and inversely proportional to the square root of the molecular weight Thus,

$$\frac{Do_2}{Dco} = \frac{Sol\ O_2}{Sol\ CO} \times \sqrt{\frac{m\ w\ CO}{m\ w\ O_2}} = \frac{0\ 0244}{0\ 0185} \times \sqrt{\frac{20}{32}} = 1\ 23$$

Diffusing capacity measured by whatever technique is subject to continuing scrutiny in efforts to define more precisely the significance of its measurement The complexity of the problem is apparent if one recalls that the lung is not one alveolus, one capillary, one dead space and one venous admixture as idealized in Figure 6 9, but millions of alveolar-capillary relationships covering a spectrum of ventilation perfusion-relationships Generally speaking, this spectrum is broader in disease than health (Bates and Christie, 1964), further complicating the interpretation of measurements designed to clarify the status of the lung

The concept of an alveolar-capillary "Membrane" is itself deceptive Oxygen and CO_2 diffuse through a number of layers in passing from air to hemoglobin or vice versa, including alveolar fluid, alveolar epithelium, tissue space between epithelium and capillary, capillary endothelium, plasma, red cell membrane and cytoplasm (De Reuck et al , 1962) There is evidence to suggest that the rate at which O_2 and CO combine with hemoglobin may limit Do_2 and Dco and that one therefore does not measure "membrane" properties so much as reaction rates One can conceive of O_2 transfer from alveolar air to red blood cell as diffusion across a series of resistances, for Do_2 has the dimensions of flow/pressure and $1/Do_2$, therefore, the dimensions of pressure/flow or resistance Roughton and Forster have subdivided total resistance into two resistances, one attributed to intracapillary processes (reaction rates with hemoglobin, diffusion in plasma and into red cell) and the other attributed to diffusion across the barriers separating air from plasma Thus,

$$1/D_L = (1/Dm) + (1/\phi Vc)$$

where D_L is diffusing capacity of the lung, Dm is diffusion across "membranes," Vc is the capillary blood volume and ϕ is the amount of oxygen taken up per unit time per milliliter blood of known hemoglobin concentration per milliliter Hg Po_2 Experimental data suggest that the intracapillary component ($1/\phi$ Vc) makes up a third or more of the total resistance One of the interesting applications of this formulation is its use for measuring pulmonary capillary blood volume (Vc). Normal values are on the order of 60 to 110 ml

Limitations and complexities not withstanding, however, it is clear that what diffusing capacity measures *1)* is reduced where histology of the lung suggests that the resistance to

diffusion is increased by thickening or change in the characteristics of the layers separating alveolar gas from pulmonary capillary blood, and 2) varies directly with changes in size of the pulmonary-capillary surface area for diffusion

Diffusion of CO_2

CO_2 is much more soluble in water than oxygen and its molecular weight is only slightly greater A comparison of its diffusibility with that of oxygen is as follows

$$\frac{D_{CO_2}}{D_{O_2}} = \frac{0\ 592}{0\ 0244} \times \sqrt{\frac{32}{44}} = 20\ 7$$

Because of this greater diffusibility, end-capillary alveolar P_{CO_2} gradients are generally thought not to occur

The dissociation curve for CO_2 is also very different from the oxyhemoglobin curve Whereas the latter is nonlinear, the CO_2 curve is relatively linear within physiological ranges of P_{CO_2} and CO_2 content It was explained above that it is because of the nonlinearity of oxyhemoglobin dissociation that local differences in $P_{A_{O_2}}$ result in an alveolar-arterial P_{O_2} difference Because CO_2 dissociation is more nearly linear, an alveolar-arterial P_{CO_2} difference from this cause is not likely to occur Thus, neither a diffusion gradient nor a venous admixture effect influence alveolar-arterial partial pressure relationships The validity of using arterial P_{CO_2} to measure alveolar P_{CO_2} rests on this statement

Hypoxia

This chapter includes discussion of four different causes of low arterial P_{O_2} for a subject breathing room air at sea level *1)* alveolar hypoventilation, 2) increased anatomic shunts, e g , right-to-left shunts in congenital heart disease, *3)* ventilation-perfusion abnormalities increasing venous admixture, *4)* increased resistance to diffusion The following characteristics are helpful in distinguishing among these physiologically when they are present in pure form Alveolar hypoventilation is invariably associated with elevated arterial and alveolar P_{CO_2}, the other causes are not Anatomic shunting is the only cause in which P_{A_O} remains relatively low when the patient breathes air with a high P_{O_2} The patient with hypoxia from a diffusion gradient commonly has a low alveolar P_{CO_2}, reflecting his attempt to raise alveolar P_{O_2} by increasing alveolar ventilation His arterial P_{O_2} drops precipitously with exercise because the increased requirements for oxygen diffusion can be met only by steepening the P_{O_2} gradient across the alveolar-capillary walls Moreover, his alveolar-arterial P_{O_2} difference remains high when he breathes an oxygen poor mixture This procedure, however, lowers the alveolar-arterial P_{O_2} difference when venous admixture is the primary cause of hypoxia

3 / THE MECHANICS OF BREATHING

The mechanics of breathing have captured the interest of workers in both the basic sciences and clinic, important contributions having been made by both groups individually or working together Fundamental concepts appeared in the German literature in the period 1915 to 1929, (Rohrer et al , 1925, Neergaard and Wirz, 1927) Technical advances in simultaneously recording volumes, flows, and small pressures with high fidelity have spurred rapid progress in this country and abroad, resulting in such feats as measuring the forces required for inflating the lung during the first breath of a newly born infant Most prominently associated with this activity in this country have been groups originally associated with the Departments of Physiology at the University of Rochester, at the School of Public Health of Harvard University, and at the Graduate School of the University of Pennsylvania Excellent reviews are included in four texts dealing with the respiratory system listed in the bibliography (Avery, 1964, Bates and Christie, 1964, Chernıak and Chernıak, 1962, Comroe and Mortimer, 1964)

Muscles of Respiration

Supplying oxygen to the alveoli and removing carbon dioxide from the alveoli is accomplished by the flow of air in and out of the lungs with each breath This is a mechanical process for which the muscles of respiration provide the force

DIAPHRAGM

Quiet breathing results from alternate contraction and relaxation of the diaphragm and intercostal muscles The former is attached circumferentially to fixed structures, vertebrae and sternum, and to relatively mobile structures, the lower ribs It is normally dome-shaped (Fig 6 11), its fibers run nearly vertically upward near its periphery and horizontally at its tendinous central portion Contraction during inspiration produces increased tension within the diaphragm itself and on its attachments Its central tendon is therefore pulled down, increasing the vertical dimensions of the thorax, while the lower ribs are moved somewhat upward, increasing the lateral and anteroposterior dimensions of the lower chest

The effectiveness of the diaphragm for changing the dimensions of the chest is related to the strength of its contraction and to its contour when relaxed Strength of contraction, as in any muscle, is a function of the number of motor units activated and of the synchronization and frequency of their discharge Interruption of both phrenic nerves immobilizes the diaphragm without changing its configuration Increasing the circumference of the lower chest pathologically, as in obstructive pulmonary disease, flattens the diaphragm, consequently immobilizing it to varying degrees irrespective of how forcefully it contracts

Descent of the diaphragm can be accomplished only by displacement of abdominal contents This is made possible by relaxation of the muscles of the abdomen during inspiration Although abdominal pressure does not normally interfere with the diaphragm's mobility, advanced pregnancy, extreme obesity, excessive flatulence, tight abdominal garments, and other circumstances can

The diaphragm probably contributes more to inspiration than do the intercostals This statement rests on estimates of vertical displacement (about 1 5 cm) and area (about 350 cm ^{2}) of the diaphragm during quiet breathing Since the volume of a single, quiet inspiration (tidal volume) is 500 to 700 ml , these estimates suggest that normal breathing is predominantly diaphragmatic The relative proportions between diaphragmatic and intercostal contribution probably vary among different individuals and with different age groups The ribs of infants, for example, are normally virtually horizontal Inspiration must therefore result almost exclusively from increase in the vertical dimensions of the chest by contraction of the diaphragm

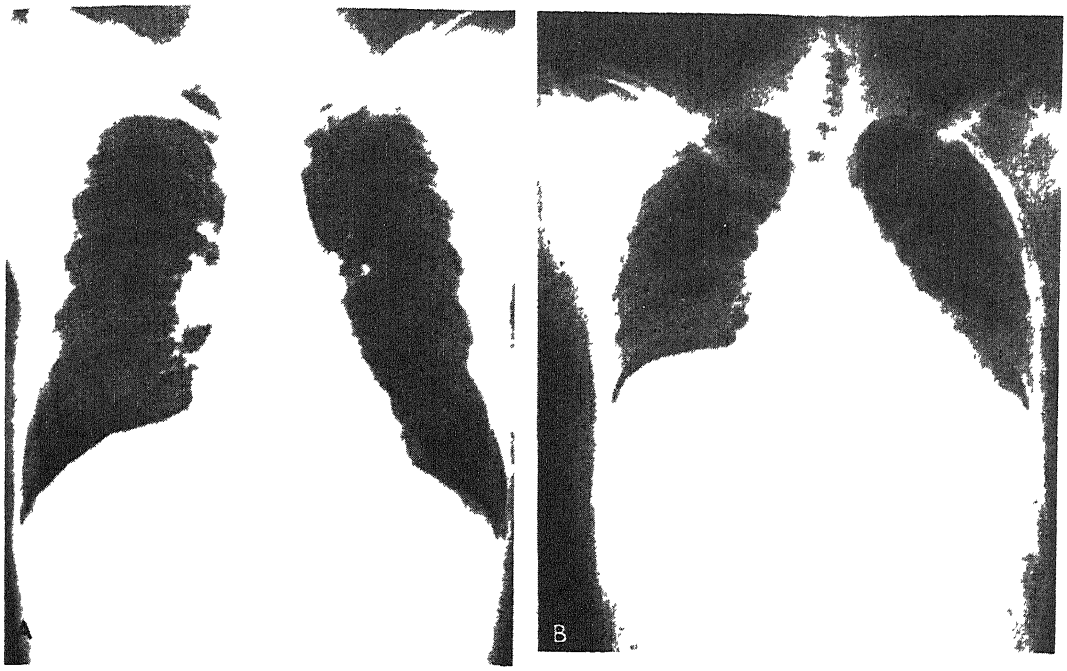

Fig 6 11 Roentgenograms of the chest taken in the antero-posterior projection Film on the left was taken after complete inspiration when lungs contain the total lung capacity Film on the right was taken after forced expiration when lungs contain the residual volume Note that the change in vertical dimensions of the chest is considerably greater than the change in transverse diameter

INTERCOSTAL MUSCLES

The action of the diaphragm is straightforward and clearly inspiratory The action of the muscles running between the ribs, however, is somewhat more complicated The external intercostals run forward and downward whereas the internal intercostals run backward and downward, i e , approximately at right angles to the external Both groups originate and insert on adjacent ribs and can be expected to bring these ribs closer together when contracting Whether a given rib moves upward, downward, or remains stationary, depends on the relative stability or fixation of adjacent ribs

Inspiration is associated with electromyographic evidence of intercostal activity (Bronk and Ferguson, 1935) The cephalad motion of the ribs indicates that the upper ribs are fixed relative to the lower When contraction of the abdominal muscles fixes the lower ribs during cough or forced expiration, the rib cage moves down, and electromyography again shows intercostal activity The intercostals contract during quiet inspiration, forced inspiration, and forced expiration, but not during quiet expiration (Campbell, 1958) Whether the internal and external groups have distinct functions in man is not clearly established

Adequate breathing continues in the absence of either the diaphragm or the intercostals In the absence of both, however, exogenous sources of power are usually needed for maintaining sufficient ventilation for life Inasmuch as the intercostals and diaphragm are innervated from separate segments of the spinal cord (C3 and 4 for the phrenic nerves as compared to thoracic segments for intercostal nerves), paralysis of one is not necessarily associated with paralysis of the other

MOTION OF THE RIBS

The ribs are more or less semicircular bones articulating with the vertebrae at one end and with the sternum or costal cartilages at the other Rib motion, therefore, includes rotation around an axis joining these two points of attachment ("bucket-handle motion") (Fig 6 12) In addition, the motion of the ribs includes elevation and depression of the sternal end Because this sternal end is lower than the vertebral end, elevating the shaft of the rib causes the sternum to protrude, increasing the antero-

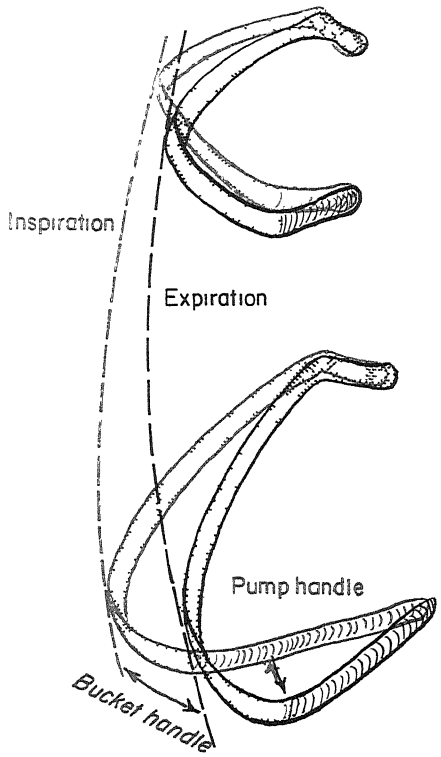

Fig 6 12 Motion of upper and lower ribs Solid outlines indicate position during inspiration (From Cherniak and Cherniak 1961)

posterior diameter of the chest Depression of the shaft of the rib correspondingly causes the opposite Inspiration, therefore, is associated with an increase in the vertical diameter of the chest due to contraction of the diaphragm, with an increase in transverse diameter due to the "bucket-handle" action of the ribs, and with an increase in anteroposterior diameter due to the effect of rib motion on the sternum

The motion of the ribs is not equivalent throughout the rib cage (Fig 6 12) The upper ribs are arcs of smaller circles and are more nearly horizontal than the lower ribs Moreover, the lower ribs on inspiration are affected by displacement of all superior ribs, their motion is, therefore, the sum of the narrowing of many interspaces rather than only the adjacent one Because of these differences, the changes in lateral diameter of the chest are greater in the lower than in the upper thorax (Fig 6 11)

As in the instance of the diaphragm, the contribution of costal motion to breathing depends on the force of intercostal contraction and on the position of the ribs prior to intercostal contraction. Accordingly, abnormal flaring or elevation of ribs and sternum interfere with the costal contribution to inspiration

ACCESSORY MUSCLES

Electromyographic evidence from man and action potential recordings from the phrenic and intercostal nerves of animals (Adrian and Bronk, 1929) indicate that *1)* quiet inspiration results from contraction of diaphragm and intercostals, and *2)* quiet expiration occurs in the absence of any muscular contraction whatsoever The accessory muscles are normally brought into play only for forced inspiration and expiration Many such muscles could be listed The distance runner struggling for air, for example, may use even the platysma for expanding his chest and the patient in paroxysms of cough probably contracts every muscle of trunk, thorax, and pectoral girdle during forced expiration The principle accessory muscles, however, are the anterior neck muscles (sternocleidomastoids and scalenes), which are used during forced inspiration to stabilize and raise the first ribs and upper sternum, and the abdominal muscles, which are essential for forced expiration The latter, together with the diaphragm, are used also for raising intra-abdominal pressure during defecation, urination, vomiting, parturition, cough, and the Valsalva maneuver The patient with paralysis of abdominal muscles is therefore at a considerable disadvantage

Lung Volumes

The lungs and chest return passively to their original volume after inspiration This end-expiratory volume is known as the functional residual capacity It is the volume which reflects the equilibrium position of the chest and lungs when undisturbed by muscle contraction It is also the volume into which each tidal volume is diluted during inspiration

By adding the inspiratory capacity to this volume during a maximal inspiratory effort, the lung volume is increased by about 2½ and contains the total lung capacity On the other hand, delivering the expiratory reserve volume by forced expiration reduces the end-expiratory volume by about one-half to the residual volume The vital capacity is the volume which can be expired after a maximal inspiration by forceful expiration, i e , it is the sum of the inspiratory capacity and the expiratory reserve These relationships are shown in Fig 6 13

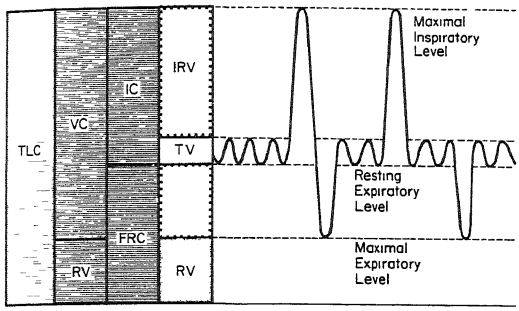

Fig 6 13 The subdivisions of the total lung capacity *TLC* = total lung capacity *VC* = vital capacity *RV* = residual volume *IC* = inspiratory capacity *FRC* = functional residual capacity *IRV* = inspiratory reserve volume *TV* = tidal volume *ERV* = expiratory reserve volume (From Comroe et al 1962)

The vital capacity and its subdivisions can be measured by collecting and measuring, in a spirometer, the volume of gas which flows into or out of the lungs during normal or forced inspiration and expiration However, the residual volume, functional residual capacity, and total lung capacity cannot be directly recorded These are commonly measured by "nitrogen wash-out" or "helium dilution " In "nitrogen wash-out" the subject is made to breathe nitrogen-free oxygen long enough (about seven minutes) to fully "wash-out" the nitrogen from his lungs His expired air is collected, its volume is measured, and it is analyzed for concentration of nitrogen The total amount of nitrogen collected is the product of the concentration and volume Since the original concentration of nitrogen in the lungs is known (about 80%) the lung volume can be determined Thus, if 50,000 ml of expired air were collected over the 7-min period and the concentration of nitrogen in the collected gas was 4%, the functional residual capacity would be 50,000 × 0 04 − 0 80 or 2500 Helium dilution is comparable in concept A measurement is made of the dilution of helium which results from adding the volume of the lungs to a closed circuit containing a known amount of helium

Whatever method is used, the functional residual capacity can be measured more reproducibly than the residual volume or total lung capacity because it is independent of muscular effort The residual volume is usually calculated by subtracting the expiratory reserve from the functional residual capacity, the total lung capacity by adding the inspiratory capacity

There are numerous normative data on lung volumes One commonly used empiric prediction formula for adults is (Baldwin et al , 1948)

Males, vital capacity = [27 63 − (0 112 × age)] × height in centimeters,
Females, vital capacity = [21 78 − (0 101 × age)] × height in centimeters

These reflect the fact that vital capacity is related to age, sex, and height A normal person's total lung capacity and residual volume can be estimated by knowing that the vital capacity comprises about 70% or 80% of the total lung capacity

The vital capacity and total lung capacity are reduced by weakness of the normal and accessory muscles of inspiration and expiration, by immobilization of the ribs and sternum, or by space-occupying defects of the chest The vital capacity is less in the supine position than in the upright position because the intrathoracic blood volume is increased in the supine position, displacing an equivalent volume of air

The functional residual capacity is the volume to which the lungs and chest arrive in the absence of muscle contraction It represents, therefore, an equilibrium position of the chest and lungs, intermittently disturbed by the forces of muscle contraction Factors affecting this equilibrium and its disturbance are discussed below

Pressures Required for Changes in Volume

THE LUNG

The chest wall, independent of the lung, and the lung itself are both hollow structures with elastic properties Each has a certain volume when pressures inside and outside are equal and each responds to a distending or retracting force by a change in volume proportional to that force The relationship between volume change and pressure required to inflate the lung alone is shown by the dotted line of Fig 6 14 It shows that the equilibrium volume of the lung, when no inflationary pressure is applied, is a small proportion of the total lung capacity (approaching 0 in the figure) and that increments in inflationary pressure produce specific increments of volume The slope of this line indicates the compliance of the lung, i e , the relationship between volume and pressure Compliance is equal to the volume change in liters divided by pressure change in centimeters of H_2O Compliance decreases with inflation,

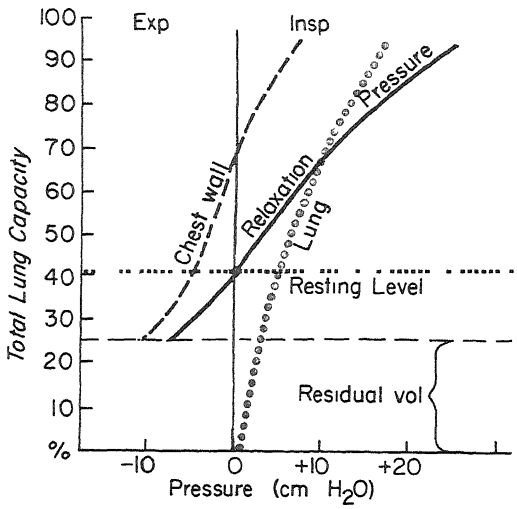

Fig 6 14 Pressure-volume relationships of chest and lung in relaxed subject (relaxation pressure) in lung alone and in chest wall alone See text for explanation (Adapted from Rahn et al 1946)

indicating that as the lung inflates, progressively greater force is required for a given volume change Under normal circumstances in man, it is not possible to measure the pulmonary compliance at volumes below the residual volume, for this would require opening the chest Compliance is therefore usually measured over the relatively linear segment of the curve which includes the volumes of the lung during normal breathing, i e , the functional residual capacity plus the tidal volume or more Normal values in man are approximately 0 2 liters/cm of H_2O (Frank et al , 1956)

The more a given lung is inflated the less is the compliance It is less for small lungs than for large lungs (0 0012 for rats as compared to 0 09 for dogs) and is reduced in man by circumstances which reduce the amount of lung, such as surgical removal of lung tissue It is also reduced by change in the composition of lung tissue (pulmonary fibrosis) and progressively, with time, if the distension of the lung with each breath is unvarying (Ferris and Pollard, 1960)

The fact that compliance is less for small lungs than for large lungs (Crosfill and Widdicombe, 1961) and less for a highly inflated lung than for less inflated lungs does not necessarily indicate fundamental differences in stiffness True difference in elastic properties between one lung and another are reflected only when correction is made for differences in size or volume. One approach is to divide compliance by the functional residual capacity (so-called "specific" compliance), normal values in adults are between 0 05 and 0 06 liters/ml of H_2O per liter Another approach is to measure the increase in transpulmonary pressure required to inflate the lungs to a volume midway between any resting level and full inspiration, normal values in man are 7 58 ± 2 53 cm of H_2O (Salazer and Knowles, 1964)

THE CHEST

The pressure-volume curve of the chest wall in the absence of the lung is displaced far to the left of the lung curve (Fig 6 14) This reflects the fact that the volume of the chest at a given distending pressure is considerably greater than the volume of the lung at that pressure Thus, although the volume of the lung when no pressure is applied is small, the volume of the chest is about 70% of the total lung capacity It is necessary to apply negative pressure to the chest (inside negative with respect to outside) in order to reduce its volume to the functional residual capacity, positive pressure, on the other hand, (inside positive with respect to outside) is required for inflating the lung to the functional residual capacity The compliance of the chest wall is about 0 2 liters/cm of H_2O

THE LUNG AND CHEST

Up to this point, the lung and chest have been treated as separate structures If the lung is now placed within the chest and its volume is to be the functional residual capacity, it will recoil and pull in on the chest with a force equal to the pressure required to distend it to the functional residual capacity (about 5 cm of H_2O) This retracting force of the lung on the chest wall is the basis of negative (below atmospheric) pressure between the visceral and parietal pleurae (interpleural[1] "space") As a result of it, the chest volume is less than it would be in the absence of the lung by a volume equal to the difference between the functional residual capacity and 70% of the total lung capacity

The relaxation pressure curve of an intact subject (Fig 6.14) depicts the relationship between pressure of air in the lungs and the

[1] "*Inter*pleural" is used here and subsequently to indicate between the visceral and parietal pleural surfaces "*Intra*pleural" is more commonly used, referring to the pleural cavity Inasmuch as there is normally no cavity or space as such, interpleural seems more appropriate

volume of the lung-chest system when the subject is completely relaxed The pressure is 0 at the functional residual capacity, for the elastic recoil of the lung is matched by an equal and opposite pull by the tensile properties of the relaxed chest wall Increasing the volume of the chest and lung above the functional residual capacity requires increasing the air pressure This pressure, or force, is equal to the force generated by contraction of the muscles of inspiration Decreasing the volume of the chest and lung below the functional residual capacity requires reducing the intrapulmonary pressure below atmospheric pressure, this pressure is a measure of the force generated by the muscles of forced expiration Fig 6 14 shows that the force developed by the muscles of inspiration up to a volume comprising about 70% of the total lung capacity is expended only on the lungs At higher volumes, however, force is needed for expanding the lungs as well as the chest During forced expiration, the energy of muscle contraction is expended exclusively on the chest wall The compliance of the chest and lung (slope of the relaxation pressure curve) is about 0 1 liter/cm of H_2O, i e , one-half the compliance of lung or chest individually

It is apparent that the relationship between lung and chest can be compared to that between two opposing coiled springs whose equilibrium is disturbed in one direction or the other by a transient force equivalent to contraction of the muscles of respiration The pressure which represents the recoil of the lung away from the chest wall (or the force required to keep the lung inflated at a given volume) can be measured in the intact chest by carefully placing a needle between the visceral and parietal pleurae, injecting a small bubble of air, and recording the pressure in the bubble with a manometer It can be measured more conveniently and safely by measuring the pressure in a structure within the chest but outside the lungs The esophagus is the most commonly used of these, pressure within it being recorded by having the subject swallow a small compliant balloon partially filled with air and recording the pressure within the balloon (Buytendijk, 1949, Mead, 1961)

LUNG CHEST, AND MUSCLE CONTRACTION

The maximum pressures which can be developed within the lungs by forcefully contracting the muscles of inspiration or expiration are

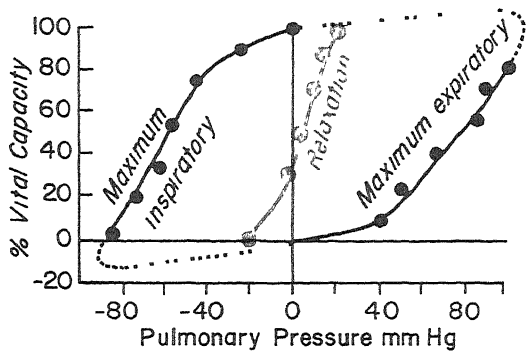

Fig 6 15 Pressure volume diagram of intact chest including the relaxation pressure curve (From Fenn 1951)

shown in Fig 6 15 The expiratory pressures are greater as lung volume increases, partly because the muscles of forceful expiration are stretched to a length at which they can develop greater tension, and partly because the recoil of the lung-chest system toward a smaller volume is greatest when the chest and lung are fully expanded The inspiratory pressures, represented by negative intrapulmonary pressure, are greater at low lung volumes because the muscles of inspiration are at a favorable portion of their length-tension relationship and because recoil of the chest toward a more inflated state is maximal The relative portion of the total pressure attributable to the muscle contraction and to recoil at each volume is represented by the difference between the relaxation pressure (recoil) and maximum pressure (recoil plus muscle contraction)

Ventilation

The volumes and pressures discussed in the previous section are independent of air flow or time Ventilation has the dimensions of both volume and time Normal ventilation in resting day-old infants (2 5 kg) is about 500 ml /min , with a respiratory rate of about 33 breaths/min , and a tidal volume of 15 ml (Smith, 1959) By adulthood (70 kg), normal ventilation has increased to about 6000 ml /min , at a respiratory rate of 12 breaths/min and a tidal volume of 500 ml Thus, the infant ventilates about 200 ml /min /kg as compared to less than one-half this amount in an adult

The flow of air into and out of the lung varies from instant to instant during normal breathing (Fig 6.16) If one inspires maximally to the total lung capacity and then expires as forcefully as possible, the plot of volume and

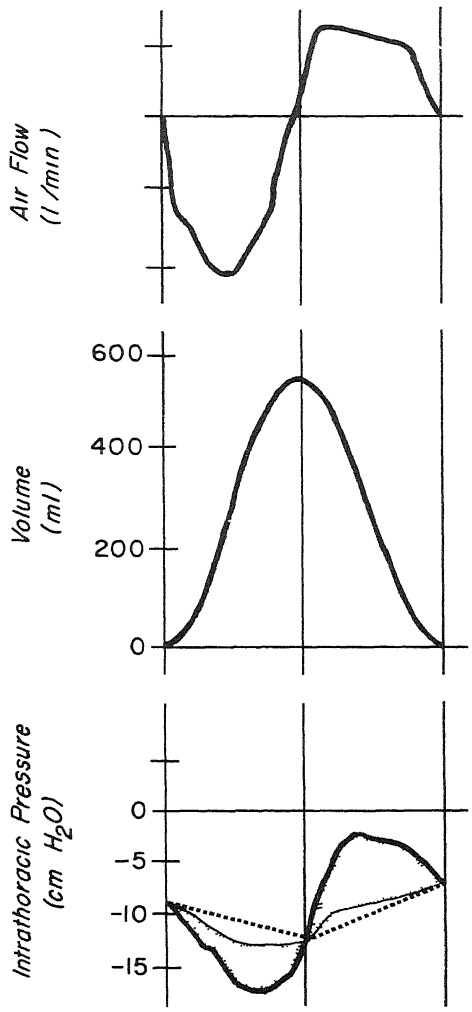

Fig 6 16 One breathing cycle showing air flow one tidal volume and intrathoracic pressures on simultaneous ordinates Inspiration is indicated by downward deflection on flow tracing and upward deflection on volume record See text for subdivision of intrathoracic pressure record (From Cherniak and Cherniak Saunders Philadelphia 1961)

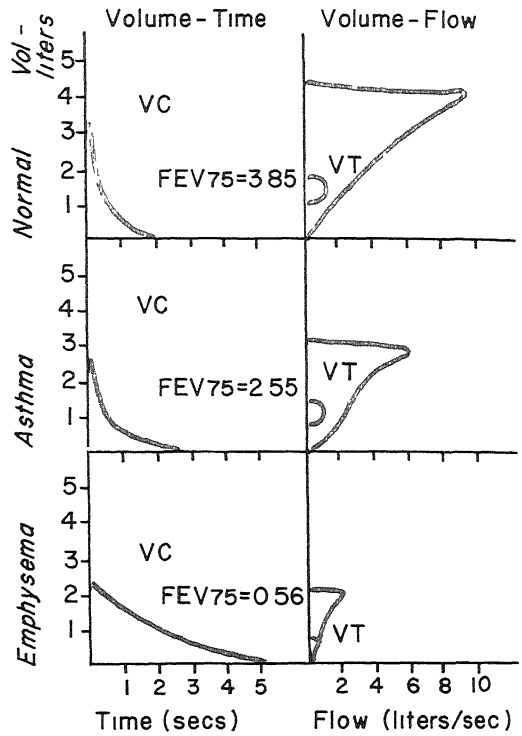

Fig 6 17 Volume of air forcefully exhaled after maximal inspiration Abscissa is time on left half of figure and flow on right half VC = vital capacity VT = tidal volume FEV 75 = forced expiratory volume in 75 seconds 1) Flow normally slows progressively as volume decreases 2) peak flows attainable in asthma and emphysema are low 3) flows during tidal ventilation are a small fraction of peak flows in normal individuals but a large fraction in emphysema 4) because the functional residual capacity is so elevated the patient with emphysema has a much reduced reserve of volume to which to inflate his lungs for attempting to increase flow (From Bates and Christie Saunders Philadelphia 1964)

flow rate as functions of time appears as in Figure 6 17 (normal) One can calculate from such tracings that the maximum expiratory flow rate exceeds 400 liters/min and the proportion of the vital capacity exhaled in 1 sec, 2 sec, and 3 sec exceeds 83%, 92%, and 97% respectively These values are all used in comparing normal and abnormal patterns of ventilation They are low where airway diameter is reduced, asthma and emphysema being the classic examples of obstructive respiratory abnormality (Fig 6 17) (Daymen, 1951)

PRESSURES REQUIRED FOR AIR FLOW

Ventilation, or air flow in and out of the lungs, occurs as a result of a pressure difference between the alveolar and oral ends of the airways During normal inspiration, the pressure of air in the alveoli falls transiently below atmospheric pressure It equals atmospheric pressure at the end of inspiration and rises above atmospheric pressure during expiration The velocity of air flow is proportional to the pressure difference The relationship between pressure difference and flow depends on the type of flow Two types or patterns are commonly recognized, laminar flow and turbulent flow The equation for laminar flow is expressed in Poiseuille's law, in which the pressure (P) differ-

ence between the two ends of a tube through which there is flow is directly proportional to the volume flowing per unit time (Q), to the viscosity of the fluid (v), to the length of the tube (L) and inversely related to the fourth power of the radius (r)

$$P_1 - P_2 = Q8LV/2\pi r^4$$

It is apparent from this equation that pressure is extremely sensitive to radius, a 2-fold decrease in radius of an airway, for example, requires a 16-fold increase in pressure if flow is to remain constant It is also apparent that pressure is directly and simply related to flow, e g , doubling pressure doubles flow ($P_1 - P_2 = KQ$) in which K is a constant incorporating the other terms

As flow increases in a tube of given dimension, a rate is reached at which the flow pattern ceases to be laminar and becomes turbulent Turbulence occurs when the product of density (d), linear velocity (V), and diameter (D) divided by viscosity (v) exceeds 2000

$$\text{Reynolds number} = dVD/v$$

The relationship between pressure and flow in the presence of turbulence is exponential, pressure being related not simply to the velocity of flow but to the square of velocity, e g , doubling flow requires a fourfold increase in pressure

$$P_1 - P_2 = KQ^2$$

Calculations of Reynolds numbers in different parts of the airways suggest that flow is predominantly laminar during quiet breathing but predominantly turbulent during even moderate hyperventilation Inasmuch as turbulence is favored not only by the factors included in calculating the Reynolds number but also by irregularities and branching of tubes, it is reasonable to assume that even during quiet breathing the pressures for moving air are required for both laminar and turbulent flows It is estimated that about 10% of flow resistance is due to turbulence during quiet breathing

RESISTANCE TO AIR FLOW

$$\text{Resistance} = \frac{\text{pressure}}{\text{flow}} = \frac{\text{cm } H_2O}{\text{liters/sec}}$$

Flow resistive pressures of the airways can be measured if flow and pressure difference between alveoli and environment are known Regional resistances at intermediate points between the alveoli and the room can also be determined if pressure is known at appropriate sites By measuring pressures in the pharynx with a small balloon, in the trachea by inserting a needle between the first and second tracheal rings, and in the alveoli by an indirect method described below, oral or nasal resistances, pharyngeal-laryngeal resistances, and intrapulmonary airway resistances can all be calculated (Ferris et al , 1964)

Alveolar pressures are measured with a body plethysmograph (Du Bois et al , 1956) A subject is enclosed in an airtight chamber and breathes into and out of this chamber The air within the chamber will be compressed and its pressure will rise whenever the external dimensions of the chest increase more rapidly than an equivalent volume of air is taken from the chamber into the lungs This occurs during inspiration when the fall in intrapulmonary pressure required for air flow is associated with rarefaction of gases within the lung until flow of air from the chamber equalizes pressures in lung and chamber at a new lung volume During expiration, the dimensions of the chest decrease more rapidly than the tidal volume is exhaled, the chamber pressure consequently falls as intrapulmonary pressure rises until pressure equilibration is again restored at the end of expiration The plethysmographic pressure, therefore, reflects intrapulmonary pressure, the precise relationship being defined by calibration An equivalent experiment can be conducted recording volume change in the plethysmograph at constant pressure rather than pressure at constant volume (Mead, 1960, Jaeger and Otis, 1964) Resistance can be calculated if instantaneous flow is recorded simultaneously with pressure

Normal values (centimeters of H_2O/liter/second) for total airway resistance during panting are 1 50 ± 0 49 cm of H_2O/liter/sec Normal values during quiet breathing are 1 26 ± 0 39 Resistances for women are about 20% higher than for men, presumably because the airways of women are narrower

About 20% of the oral-alveolar air flow resistance can be attributed to flow through the mouth, 27% to flow through the glottis and larynx, and about 53% to flow through the airways below the second tracheal cartilage During quiet breathing through the nose, on the other

hand, the nasal passages contribute about two-thirds of the total air flow resistance Resistance offered by the larynx and glottis during normal expiration is about twice its value in inspiration Resistances are least, therefore, during inspiration, using oral rather than nasal breathing and in men rather than women (Ferris et al , 1964)

RESISTANCE OF LUNG (VISCOUS RESISTANCE)

Alveolar pressures during ventilation are reflected in interpleural pressures as we have seen In addition, however, interpleural pressures register the force required for overcoming the viscous resistance of the lung (Marshall and Du Bois, 1946, McElroy et al , 1955) This latter has been estimated variously to comprise a negligible to substantial (28°C, 21°C, and 30°C to 40°C) proportion of the total pulmonary resistance, i e , air flow resistance plus tissue viscous resistance Although this figure, as many others concerning respiratory mechanics, are educated approximations, it is clear that interpleural pressure during ventilation represents *1*) compliant characteristics of the lung, *2*) air flow resistances through the respiratory tract, and *3*) tissue resistance of the lung

The components of the total pressure difference between atmosphere and esophagus which are attributable to elastic (compliant) characteristics and to flow-resistance are represented in Figure 6 16 (intrathoracic pressure) The elastic component is indicated by the thin solid line It is not a straight line (cf dotted line) because the relationship between lung volume and time is not linear The shaded portion is the additional pressure required for air flow and tissue components It is greater during expiration than during inspiration because air flow resistance is higher.

RESISTANCE OF CHEST (VISCOUS RESISTANCE)

Resistance of tissues of the chest have also been estimated. From 30 to 40% of the total respiratory resistance is attributed to this source both during quiet oral breathing (0 4 liter/sec) and during mild hyperventilation (flows of 1 liter/sec) (Fig 6 18)

INERTIA OF AIR, LUNG, AND CHEST

The final component of the total mechanical force for respiration, inertia, has been measured for lung and air (Mead, 1956) At atmospheric pressure, a force of only approximately 0 01 cm of water is required to produce a volume acceleration of 1 liter/sec /sec Clearly, this is a small component of the forces required for ventilation

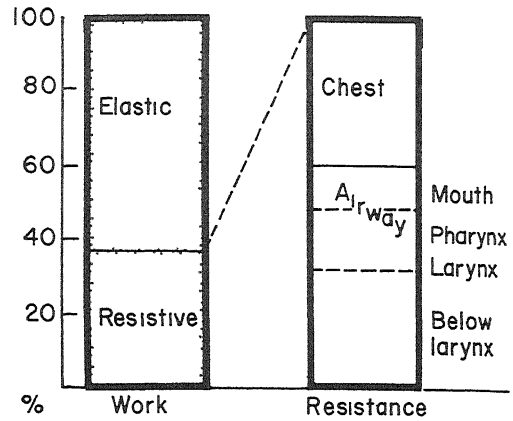

Fig 6 18 Subdivision of respiratory work and resistance Values for work bar for subject breathing 15 breaths per minute at a tidal volume of 500 ml Values for resistance bar for subject breathing through mouth Viscous resistance of lung was assumed to be 0 (See text)

The Work of Breathing

The chest and lungs are a pump operating against resistances to generate the pressures outlined above The concept of work is useful in expressing the energy required or expended for breathing (Otis, 1954)

$$\text{Work} = \text{force} \times \text{distance}$$

Force is equivalent to pressure (cm of water), and volume (ml) to distance, i e , ventilating 1 liter of air with a force of 1 cm of water pressure is equivalent to moving 1 ml of water (1 g) 1000 cm or doing 1 g -m of work

The total work of breathing has been estimated by placing a relaxed subject in a respirator and continuously measuring the pressure gradient between mouth and outside of the patient's body simultaneously with volume At a tidal volume of 500 ml and a frequency of 15 breaths per min , the work on the lungs, chest, abdomen, and air was approximately 0 32 kg -m /min The work done to stretch chest and lungs, i e , elastic work, was about 63% of the total work (Fig 6 18)

The work of breathing can be conceptualized by graphic representation The work done on the lungs during a single breath is shown in Figure 6 19 Oral-esophageal pressure differ-

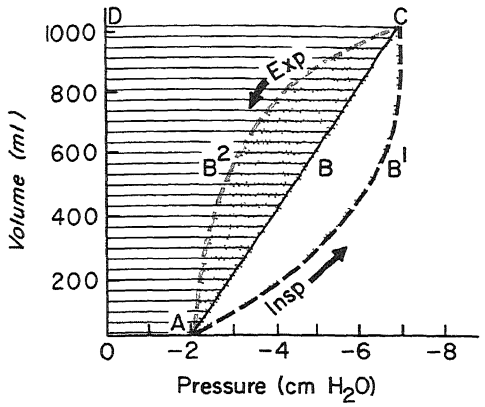

Fig 6 19 The relationship between lung volume and transpulmonary pressure during one inspiration and expiration of 1 000 ml See text for explanation (From Cherniak and Cherniak Saunders Philadelphia 1961)

ence is plotted on the horizontal axis and volume at any pressure on the vertical axis Point *A* is the plot of pleural pressure at the end of expiration when flow is 0, and volume is the functional residual capacity Point *C* plots pleural pressure at the end of inspiration when flow is 0 again, and volume is the functional residual capacity plus 1000 ml The line *AC* is, therefore, the compliance of the lung It is assumed to be straight because compliance is relatively linear over this range of lung volumes The elastic work (pressure × volume) done on the lungs is represented by the area of the trapezoid *ABCDO*

The pressures actually recorded during a breathing cycle are indicated by the loop AB^1CB^2 The area AB^1CB represents the nonelastic, i e , flow resistive, work done on the lungs and air during inspiration The area CB^2AB represents the nonelastic work done on lungs and air during passive expiration This is a portion of the elastic energy stored in the lungs at the end of inspiration The balance of the elastic energy, AB^2CDO, is not recovered during expiration and in this sense is "lost," possibly as heat

The shape of the loop AB^1CB^2 reflects nonelastic pressures It is, therefore, broad or more circular when flow rate is high (hyperventilation) or resistance increased (airway narrowing) Because the force required to stretch the lungs (elastic properties) is independent of the rate at which the lung is inflated, progressively increasing rates of ventilation augment flow-resistive work without affecting elastic work. Increased depth of breathing, on the other hand, increases elastic work, particularly since compliance decreases at higher lung volumes

Breathing is most economical when the balance of elastic and resistive work yields the lowest sum compatible with ventilation sufficient to meet the body's metabolic requirements It might be assumed that this would result in low tidal volumes and rapid breathing rates, for this type of breathing would sharply reduce elastic work However, as was brought out in the previous chapter, carbon dioxide excretion and oxygen supply are a function not of total ventilation but of alveolar ventilation

A tidal volume equal to the dead space (150 ml), for example, might accomplish a normal total ventilation (6 liters/min) at minimal elastic work but would be entirely wasted because no carbon dioxide would be excreted and alveolar oxygen pressure would not be maintained It is one of the important facts of biological economy that quiet respiration is accomplished at a tidal volume and frequency such that the sum of elastic and flow resistive work at an adequate alveolar ventilation is minimal This has been shown for man as well as for other animals (Otis, 1954)

The work of breathing can be expressed in terms of oxygen utilization This is about 0 5 ml of oxygen/liter of ventilation in normal individuals At a normal ventilation of 6 liters/min this is equivalent to 3 ml /min or about 1% of normal total requirements (300 ml /min) The oxygen cost increases with ventilation in a nonlinear manner, indicating progressively rising cost with the hyperventilation of exercise One estimate of oxygen utilization for breathing during severe exercise at a ventilation of 160 liters/min is 406 ml /min

Patients with obstructive disease expend a considerably larger proportion of their basal energy for breathing, for both resistance and ventilation are increased The augmented oxygen utilization and CO_2 production resulting from greater activity of respiratory muscles may place a significant additional burden on a marginal system

EFFICIENCY

The efficiency of the muscles of respiration can be calculated from the work they perform and the oxygen cost of doing this work

Efficiency = mechanical work/oxygen used

Values for mechanical work are about 0 03 kg-m /liter as compared to 0 6 kg -m /liter for the

work equivalent of oxygen utilization The efficiency, therefore, is about 5% This low mechanical efficiency indicates that most of the energy for respiration is in the form of heat

INTERPLEURAL PRESSURES

The pressure within the chest but outside the lungs measures both the elastic recoil of the lungs and the flow-resistance of air and lungs It is, therefore, most negative at high volumes, high inspiratory flow rates, and high inspiratory resistances It is subatmospheric throughout inspiration and expiration (Fig 6 16) except when the energy stored in the lungs at the end of inspiration is inadequate for the work of expiration This occurs during forced expiration, cough, sneeze, and expiration through narrowed airways In these instances, active work is done during expiration which must be added to the work of inspiration for calculating the total work of breathing It would appear graphically as an area extending to the left of the vertical axis in Figure 6 19

The fact that interpleural pressure is subatmospheric has important implications There will be flow into the thorax from any site at or above atmospheric pressure provided a flow-way is present Accordingly, air flows into the chest from the atmosphere and creates an interpleural space (pneumothorax) when the chest wall is perforated, venous blood flows toward the thorax and right auricle down the pressure gradient from the abdomen or other body part to the chest This gradient with respect to the abdomen is increased during inspiration not only because intrathoracic pressure falls, but because the descent of the diaphragms raises abdominal pressure by a few centimeters of water above atmospheric pressure Reducing or reversing this gradient by performing the Valsalva maneuver can compromise venous return sufficiently to cause hypotension and syncope

Another important indirect consequence of negative interpleural pressure concerns its effect on the patency of airways To the extent that these are exposed to interpleural pressures, they are subjected to a transmural force This force is a distending force at high lung volumes and rapid inspiration, a weaker distending force during passive expiration as interpleural pressure falls, and a compressing force during forceful or high resistance expiration when interpleural pressure rises above atmospheric pressure.

The pressure gradient across the airway wall depends not only on interpleural pressure but also on the pressure within the airway This is atmospheric when there is no air flow and the glottis is open During ventilation, it is more nearly atmospheric in the larger airways closer to the atmosphere and most nearly interpleural in the finer airways farther downstream on inspiration and farther upstream on expiration Accordingly, the airways subjected to the greatest transmural pressures are the larger ones Providing these with supporting cartilage is, therefore, good teleology Despite their cartilaginous support, however, these can be shown roentgenographically to undergo visible narrowing during forced expiration—a change which increases flow resistance

Airway patency is preserved not only by negative interpleural pressure and by cartilage, but by radial traction from the elastic tissue within which the airways are suspended This traction is a function of the relationship between length and tension of the lungs' elastic fabric, the number of elastic strands pulling on the airway per unit area of surface, and the degree to which the lung is stretched (lung volume) The significance of this support is shown in normal breathing by progressive slowing of air flow during forced expiration (Fig 6 17), indicating narrowing of the airways as lung volume decreases This narrowing is particularly pronounced in emphysema (Fig 6 17) where loss of elastic properties of lung tissue and the thinning out of parenchymal strands surrounding airways predisposes them to collapse especially during expiration This may be so pronounced that air flow ceases during expiration at lower volumes no matter the force with which the muscles of expiration contract A vicious cycle results as expiratory effort increases, interpleural pressure rises, airways undergo additional compression, and airflow is further slowed Breathing at pathologically high lung volumes, one of the hallmarks of obstructive abnormality, is a logical recourse

HYSTERESIS AND SURFACE ACTIVITY

The change in volume of the lung with pressure has been described during inspiration (Fig 6 14) During expiration, when the lung is allowed to deflate, the curve of its volume-pressure behavior does not retrace itself, but is displaced to the left forming a loop (Fig 6 20) The area of this loop represents an amount of

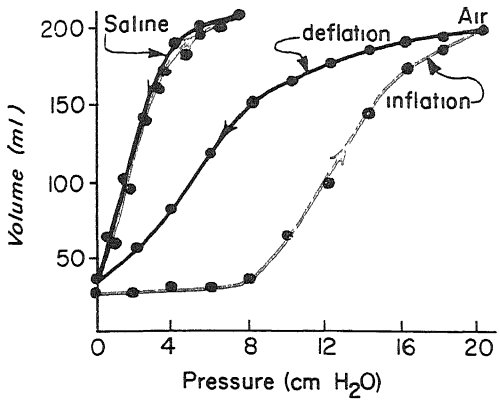

Fig 6 20 Air versus saline filling excised cat lungs at room temperature Saline curves obtained from excised gas free cat lungs suspended in saline bath at room temperature and filled from a saline reservoir Air curves taken from the gas-free state obtained with the lungs hanging in air and filled from an air reservoir maintained at a constant pressure Volumes all taken relative to the initial volume of the lungs as removed from the animal During inflation with air the volume equilibrated slowly and the lungs filled irregularly During deflation equilibrium was reached rapidly and the lungs emptied uniformly (From Radford 1957)

energy which is unaccounted for (hysteresis), i e , at any volume the product of volume and pressure is less on expiration than during inspiration The explanation for this "loss" is unclear It is related, however, to a force, surface tension, present at the interface of air and the fluid lining the alveolar walls This is clearly shown in Figure 6 20 in which the normal hysteresis of air-filled lungs is seen to be virtually eliminated by substituting saline for air Some of the concepts relating to this important observation are the following

The lung is comprised of several million more or less polygonal or spherical alveoli interconnected by tubes It is tempting, therefore, to assume that some properties of the lung compare to those of a physical model made of a T-tube with an inflated bubble or balloon at each end of the top of the T If the bubbles or balloons are inflated so that the pressure (P) is uniform throughout and if the stem of the T is then clamped off, one balloon or bubble may empty into the other rather than remain inflated The reason for this instability of the system is explained by the relationship between pressure (P), intramural tension (T), and radius of curvature (r) of curved surfaces This is stated in the LaPlace equation $P = 2T/r$ If one assumes that at inflation the tension within the walls of the bubbles and the radii of curvature are precisely equal, the bubbles will both remain inflated If, however, the radius of one bubble decreases slightly, the pressure in this one will rise if intramural tension remains constant and air will flow into the other bubble whose radius will increase, lowering its pressure (Fig 6 21) This phenomenon is not normally seen in the lung, i e , once the lung is inflated, it remains so throughout rather than collapsing in one area (atelectasis) and over-inflating in another

The stability of the lung is partly due to the fact that intramural tension (T) is small for the surfaces of the alveoli This property is attributed to a substance in the fluid lining the air spaces which reduces surface tension (Pattle, 1963) The bubble of fluid which opens up into the airway is, therefore, low in its intramural tension and therefore low in its tendency to contract or deflate

A substance which reduces the surface tension is a normal constituent of lung tissue extracts (Clements, 1957) Such extracts have a surface tension approximately $\frac{1}{10}$ the surface tension of water and $\frac{1}{40}$ the surface tension of other body fluids Phospholipids or lipoproteins have been implicated, lecithin being specifically identified among this group of compounds

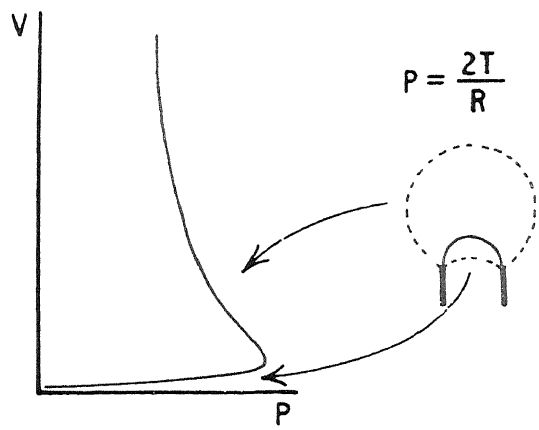

Fig 6 21 Volume pressure curve for a bubble on a tube As pressure rises volume changes little until a critical point is reached at which volume increases without further pressure rise This point is reached when radius of curvature (R) passes through a minimum value equal to the radius of the tube Thereafter at a constant tension (T) in the wall of the bubble pressure falls as radius or volume of the bubble increases Alveoli of the deflated lung pop open when the lung is gradually inflated as though following this law (From Mead 1962)

Extracts from lungs of children suffering from inability to maintain the inflation of their lungs (respiratory distress syndrome) are deficient in this surface active agent (Avery and Mead, 1959)

Not only do the surface active materials decrease surface tension, but they decrease it more when surface area is small than when it is large Surface tension is consequently less in small alveoli than in large ones Assuming alveoli change in size during inspiration and expiration, surface tension is less at the end of expiration than at the end of inspiration This decrease in surface tension with deflation and size balances the increase in pressure one would anticipate from the LaPlace equation if surface tension remained constant and radius decreased Stability is promoted, therefore, both because surface tension is generally reduced and because it adjusts itself to surface area

It appears, therefore, that the mechanical properties of alveoli reflect those of at least two concentric layers one is a film characterized by surface activity which normally stabilizes the air spaces of inflated lung and has its own pressure volume characteristics on inflation and deflation, the other is the alveolar epithelium together with the collagen, elastin, and other tissue possessing its independent mechanical attributes

THE FIRST BREATH

Breathing motions of a sort go on *in utero*, for material injected into the amniotic fluid can be recovered from the lungs after birth Therefore, the lungs contain fluid before the first breath The following are some of the mechanical considerations pertaining to their dramatic change to organs of respiration

To the extent that the spaces of the lung are distended with fluid, the pressure required for expansion conceivably is less than if they were collapsed, for some of the smaller airways will have a larger radius and, by the LaPlace equation, will enlarge with less pressure In point of experimental fact, lungs containing some fluid expand at a lower pressure than airless lungs containing no added fluid

The chest is compressed by pressures up to 95 cm of H_2O during vaginal delivery Some fluid is expressed from the lungs by this force in babies born with cephalic presentations The balance of fluid must pass into the circulation either directly across the alveolar epithelium into the pulmonary capillaries or indirectly through the lung lymphatics into the systemic circulation

The change from the airless to air-filled state is precipitous, it occurs in less than 1 sec after onset of breathing (Fawcitt et al , 1960) The functional residual capacity at 10 min of age is about 17 ml /kg , is about 30 ml /kg after 30 min , and is at this same value 4 days later Interpleural pressures recorded through an esophageal balloon during the first inspiration vary from -10 to -70 cm of H_2O The first expiration is associated with positive interpleural pressures as high as 20 cm of H_2O (Karlberg et al , 1962) Presumably these pressures are the result primarily of diaphragmatic and abdominal muscle contraction

4 / CONTROL OF BREATHING

CONTROL OF INSPIRATION AND EXPIRATION

In this chapter first the neural mechanisms which are responsible for rhythmic inspiration and expiration are described This is followed by analysis of those mechanisms which influence the rate and depth of breathing in such a way as to keep the carbon dioxide tension and oxygen tension of the arterial blood within the ranges compatible with normal functioning of the body At present most of the essential facts about the neuromuscular machinery for breathing and the sensors and stimuli which are concerned with regulating alveolar ventilation are known

As described in chapter 3, inspiration during eupnea is accomplished by contraction of certain muscles, such as the diaphragm and interosseus external intercostals, which may be called *primary* muscles of inspiration, while expiration is the result of the elastic recoil of the lungs and thoracic cage, and the action of gravity when the inspiratory muscles relax With increased demands for ventilation, additional muscles, collectively called *accessory* muscles of inspiration, are activated to produce a more rapid and deeper inspiration, certain muscles also contract during expiration to accelerate the return of the chest to the resting end-expiratory position In eupneic breathing, therefore, for inspiration and expiration to occur it is necessary simply for the motor neurons supplying the primary muscles of inspiration to show intermittent bursts of activity

The initial observation which is important in considering regulation of breathing is that apnea occurs when the CO_2 tension of the blood is below certain levels if at the same time the O_2 tension is above certain levels This situation can be produced simply by hyperventilating with atmospheric air, or an even longer period of apnea can be produced by hyperventilating with oxygen After hyperventilation is terminated apnea will supervene until CO_2 tension becomes elevated to a certain level or until O_2 tension becomes lowered below certain levels Thus, it is seen that the initiation of breathing after hyperventilation depends upon stimuli which derive either from a rise in CO_2 tension or from a fall in O_2 tension or from an interaction of these changes

The relative importance of CO_2 and O_2 in influencing breathing in an individual at sea level (ambient pressure of 760 mm Hg) is illustrated when the percentages of these gases in inspired air are altered If the O_2 percentage is increased above the amount normally found, even up to 100%, negligible influences on rate and depth of breathing are observed Also, if the amount of O_2 in inspired air is moderately lowered, namely, down to about 18%, typically, little or no change in breathing is observed Some persons will show stimulation of breathing as the O_2 is lowered to around 16% and levels of 10 to 12% regularly cause hyperpnea From these facts it is apparent that reduction in O_2 tension is not an important factor in regulation of breathing until the tension is reduced below some critical level which is somewhat lower than that found in normal resting subjects breathing air at a pressure of one atmosphere Any slight increase in the CO_2 tension of arterial blood, on the other hand, causes an increase in breathing, and a decrease in CO_2 tension is associated with apnea even when the O_2 tension is moderately below that which is found normally at sea level Such facts provide a basis for the interpretation that the inspiratory process at sea level in normal subjects is related to the action of CO_2 on certain neurons in the respiratory center in the medulla oblongata, causing them to discharge, and the termination of inspiration, resulting in expiration, occurs as a result of "feedback" of inhibitory influences to these neurons This mechanism serves to keep the CO_2 tension of arterial blood at a constant level of about 38 to 40 mm Hg in the presence of wide fluctuations in O_2 tension of arterial blood as long as the latter are at levels from about 80 to 90 mm. Hg and up

It is customary and convenient to speak of the collections of nerve cells in the brainstem which are concerned with the integration of the activity of the muscles of respiration as the *respiratory center* But the use of the term should not be taken to imply that the controlling nervous elements are a compact circumscribed mass, or confined to a closely restricted area Section through the brain at any level rostral to the upper border of the pons usually does not alter significantly the respiratory rhythm But sections at various levels behind this cause pronounced disturbances in respiration If a cut is made through the medulla caudal to the tip of the calamus scriptorius, all breathing ceases

Legallois (1824) located the respiratory center in the lower part of the medulla oblongata, and Flourens (1851, 1858) found a small spot about the size of a pin's head just beneath the forepart of the *calamus scriptorius* in the floor of the fourth ventricle, on either side of the midline He showed that after bilateral destruction of this area, which he named *noeud vital* (vital knot), the breathing ceased It appears, however, that the respiratory failure in these animals could have been secondary to circulatory failure related to loss of vasomotor tone

Markwald (1887) described powerful and prolonged tonic inspiratory movements or "cramps" which supervened after bilateral section of the vagus nerves and division of the brainstem immediately behind the posterior colliculi He concluded that a center inhibitory to inspiration was located in the latter situation, but that the vagi also had an inhibitory action, consequently the inspiratory "cramps" appeared only after vagal influence had been abolished as well Markwald's observations were confirmed shortly afterward by other experiments The subject was studied further by Lumsden (1923), who found that the prolonged inspiratory movements occurred only if the section passed through the pons a few millimeters behind its anterior border and occurred whether or not the vagi were divided The inspiratory cramps or *apneuses*, as Lumsden preferred to call them, last for several seconds He postulated their dependence upon an *apneustic* or *inspiratory center* at the level of the striae acusticae, which was dominated normally by an inhibitory or *pneumotaxic center* situated in the upper part of the pons The duty of the latter center was, through its inhibitory influence, to help to transmute the apneustic movements into the rhythmical movements characteristic of normal respiration After section of the brainstem behind the striae acusticae, the respirations consisted of a series of gasps occurring at relatively long intervals Lumsden concluded that these represented the activity of a primitive *gasping center* situated in the lower part of the medulla from which the two higher centers had evolved It was considered to be of little importance in higher animals

Lumsden's results were confirmed in the main by Stella (1938) and by Pitts, Magoun, and Ranson (1939) Stella, however, found in contradiction to Lumsden, that section through the pons (i e , separation of the pneumotaxic center) did not result in apneusis unless the vagal influence was abolished also (see Fig 6 22) The results of Pitts and his associates are in essential agreement with those of Stella They found that animals decerebrated through the upper part of the pons maintained a normal type of respiration which responded in the usual way to chemical and peripheral nerve stimulation so long as the vagi were intact, but immediately developed apneustic respiration and a complete cessation of rhythmical movements when both vagi were severed Stimulation of the central end of one of the cut vagi temporarily restores the respiratory rhythm The apneustic center is, therefore, under a double inhibitory influence, either one of which is capable of converting the apneustic type of respiration to the rhythm of normal or nearly

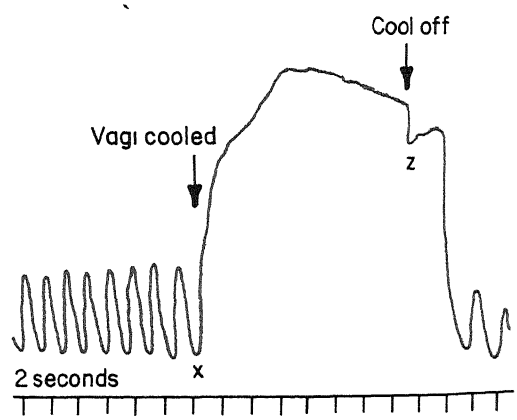

Fig 6 22 Showing apneusis Section of the brainstem along a plane passing dorsally immediately behind the posterior colliculi and ventrally 2 5 mm below the upper border of the pons Between *x* and *z* the vagi were blocked by cold Time 2 sec (After Stella 1938a)

normal respiration The vagal impulses influencing the apneustic center are initiated by the stretch of the lung toward the latter part of the inspiratory phase of normal breathing Studies by Cohen (1958) indicate that the pneumotaxic center shows rhythmic activity synchronous with breathing when its connections with the respiratory center are intact but fails to show rhythmicity when these pathways are cut

The apneuses, like normal respirations, are affected powerfully by the CO_2 tension of the blood, being increased in depth by having the animal breathe an air mixture containing a high concentration of CO_2, and reduced in depth, or prevented from occurring, by carbon dioxide lack According to Stella, the pneumotaxic center is bilateral but its connections with the apneustic center are mainly homolateral, i e , uncrossed

Pitts, Magoun, and Ranson (1938) describe the respiratory center in the cat, which they locate in the reticular formation of the medulla, as consisting of an inspiratory and an expiratory division, both centers are bilaterally represented The *inspiratory center* occupies the rostral half or two-thirds of the reticular formation overlying the olivary nuclei on both sides, i e , beneath the caudal third of the floor of the fourth ventricle (Fig 6 23) When stimulated a maximal coordinated inspiration results, involving both diaphragm and thorax If stimulated during apneusis, the magnitude of the inspiratory movement is increased, if stimulated during an interval between apneuses, an apneustic movement is produced The expiratory center lies in the reticular formation dorsal to the inspiratory center Electrical stimulation within this area causes expiration, if stimulated during inspiration or during apneusis, these movements are inhibited Regular respirations—inspiration alternating with expiration—are induced by rhythmical stimulation of the inspiratory center, expiration then occurs passively Rhythmical stimulation of the expiratory center also produces regular respiration, spontaneous inspirations then alternating with the expiratory movements Intimate synaptic connections exist between the diffusely distributed neurons within each center and between the two oppositely acting centers on the same side, as well as between similarly acting centers on opposite sides of the medulla Thus, unilateral stimulation of a small area of the inspiratory center causes maximal contraction of all the inspiratory muscles Excitation of one center causes simultaneous activation of its fellow of the contralateral side, accompanied by reciprocal inhibition of both oppositely acting centers Thus, the alternating rhythm of inspiration is established and sustained, and the respiratory movements synchronized on the two sides of the body The functional importance of the bilateral connections is demonstrated in a striking manner by making a deep longitudinal cut through the midline of the caudal part of the medulla, then the respiratory rhythms on the two sides of the body become asynchronous (see Fig 6 24)

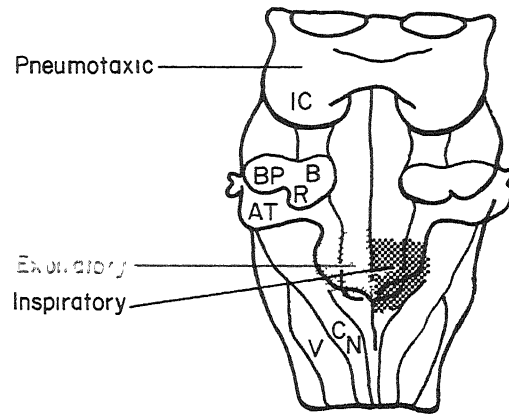

Fig 6 23 Dorsal view of lower brainstem of cat showing location of pneumotaxic inspiratory and expiratory centers Extent of expiratory center shown in light stippling inspiratory center in heavy stippling Though the centers are bilateral each is outlined on one side only for the sake of simplicity IC inferior colliculus AT acoustic tubercle B brachium conjunctivum B P branchium pontis R restiform body CN cuneate nucleus (Redrawn from Pitts Magoun and Ranson 1939a)

The similarity in the effects of stimulation of the expiratory center and of the central end of the vagus, namely, inhibition of inspiration and of apneusis, has led Pitts and his colleagues to the conclusion that the vagal respiratory effects are mediated through the expiratory center The influence of the pneumotaxic center probably is exerted in the same way

The respiratory center is connected with the motor neurons of the phrenic and intercostal nerves in the cervical (C 3, 4, and 5) and upper thoracic segments of the cord (T 2-6) by descending tracts which run in the anterior columns and in the ventral parts of the lateral columns of the spinal cord

nisms concerned with controlling inspiration and expiration the reader may refer to Wyss (1964) and Monnier (1968)

SPONTANEOUS ACTIVITY OF THE MEDULLARY RESPIRATORY CENTERS

This has been a subject of interest to physiologists for many years Some investigators, such as Coombs and Pike (1917), and Schafer (1918) have denied that the center is capable of spontaneous activity, maintaining that afferent impulses, especially those set up in the lung by the stimulus of stretch and conveyed by the vagus, and those initiated from proprioceptors in the respiratory muscles and traveling by the posterior nerve roots, were essential However, the results secured within recent years by means of improved methods of investigation indicate that, in certain species at least, the brainstem continues to discharge impulses to the respiratory muscles after all or nearly all afferent paths have been severed For example, rhythmic bursts of impulses can be recorded from the central stump of the phrenic nerve of a decerebrate animal after section of the vagi, glossopharyngeal and other cranial nerves entering the pons and medulla, and division of the spinal cord below the level of the seventh cervical segment Such an extensive operation would certainly interrupt all important afferent paths including those from the carotid sinus and the aortic arch It is not to be supposed, of course, that the respirations would be normal after such a radical procedure, for even if not essential for maintaining the activity of the center, afferent nerve influences are of the utmost importance in the regulation of that activity and the production of the normal respiratory rhythm Evidence for automaticity of the respiratory center of a cold-blooded species has been secured by Adrian and Buytenijk (1931) They succeeded in recording rhythmical action potentials from the excised brainstem of the goldfish, the potential changes had the same range of frequency as the respiratory movements (Fig 6 25)

The spontaneous respiratory activity is apparently dependent primarily upon the inspiratory center, the expiratory center playing an inhibitory role to interrupt intermittently the inspiratory discharge According to Cohen (1958) impulses are not discharged spontaneously from the pneumotaxic center Pitts and his colleagues suggest that the pneumotaxic center is excited from the inspiratory center, that a proportion of the impulses discharged from the latter region ascend to the pontine center whence impulses descend to the expiratory center, a discharge of *inhibitory* impulses is transmitted from the latter to the inspiratory center As the discharge of impulses from the expiratory center ceases, the inspiratory center resumes its activity, and the cycle is repeated A rise in the rate of discharge of the inhibitory impulses will increase the rate of breathing, while a reduction in the frequency of the dis-

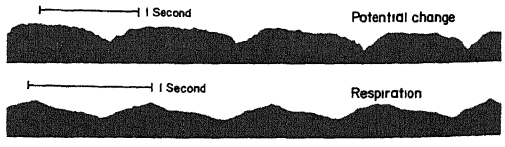

Fig 6 25 Comparison of electrical potential wave rhythm and rhythm of respiratory movements (After Adrian and Buytendijk 1931)

charge will be followed by slowing of the respirations

It appears, then, that in the intact animal the automatic alternating rhythm of the medullary centers is maintained largely by inhibitory impulses from the pneumotaxic center and from vagal afferents impinging upon the expiratory centers, which in turn inhibit, intermittently, the activity of the inspiratory centers The vagal influence is evoked by inflation of the lungs (i e , by inspiration), expiration, a passive act, follows (chap 3) Under ordinary physiological conditions the vagal regulating influence appears to play the dominant role

Of the two main methods which have been used for localizing inspiratory and expiratory centers, namely stimulation vs "sounding" for action potentials, the latter would seem to be somewhat more suitable Stimulation serves to expose only a dominant or major influence Neurons having opposite effects could be present and could be stimulated simultaneously, but the effects only of the dominant one of the two groups would be expected to appear Hence, inspiration elicited from a given site would not rule out the possibility that expiratory neurons also are present in this region, nor could an expiratory response elicited from a specific site prove that no inspiratory neurons were being stimulated simultaneously According to Brookhart (1940) lower strengths of stimuli applied to the regions in which the inspiratory center and expiratory center are supposed to be located will elicit various types of effects, and somewhat stronger stimuli are required to produce the effects reported by Pitts and co-workers On the other hand the recording of a burst of impulses only during one phase of the respiratory cycle would constitute evidence that only the inspiratory or expiratory neurons, depending on the time relations, were activated at that site under the conditions of the experiment When the "sounding" method is used, according to Gesell, Bricker, and Magee (1936), for the most part, impulses are recorded from a given site during both inspiration and expiration This would indicate that expiratory and inspiratory neurons are intermingled and would tend to make one doubt that there are anatomically discrete expiratory and inspiratory centers

A difficulty with the "sounding" method for determining the location of inspiratory and expiratory neurons of the respiratory center is that impulses may be picked up directly from motor neurons Achard and Bucher (1954) investigated the region of the respiratory center with needle electrodes and determined by subsequent histological examination the precise

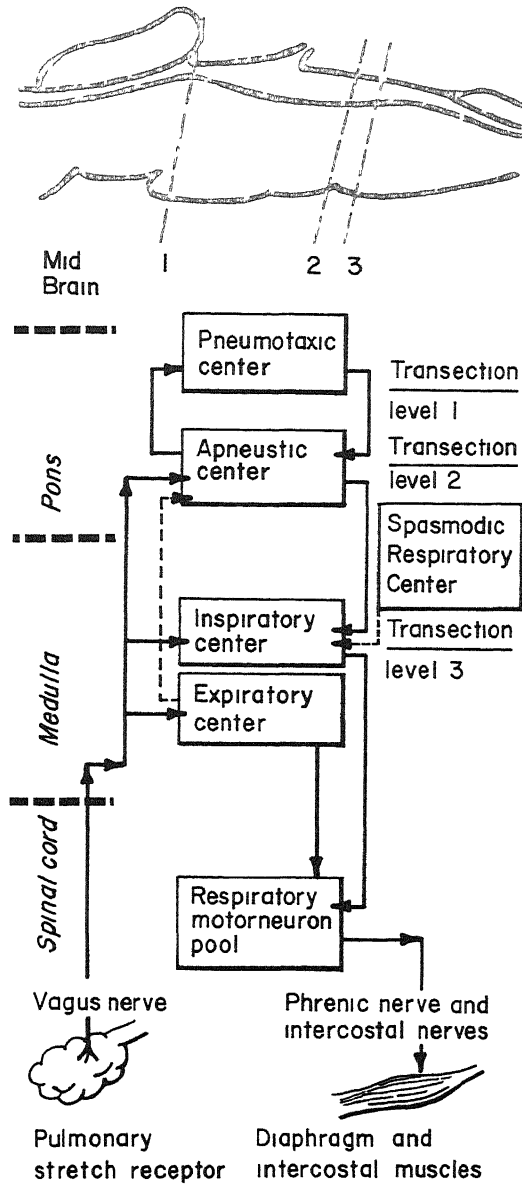

Fig 6 26 Schematic representation of organization of central respiratory mechanisms in the brainstem of the cat Key to transection levels is indicated above In vagotomized cats transection rostral to level 1 allows eupnea to be present transection between levels 1 and 2 causes apneustic breathing to appear transection between 2 and 3 results in eupneic breathing or gasping or occasionally Biot s breathing and transection caudal to level 3 is followed by absence of respiration (Reproduced by permission from Wang Ngai and Frumin 1957)

cells from which recordings were obtained Any purely inspiratory activity obtained by them was from *motor neurons* involved in inspiration, while action currents recorded from numerous other electrodes located in the area of the respiratory center did not permit a distinction between respiratory rhythms and the continuous asynchronous "background" activity in the reticular substance It must be concluded, therefore, that the question of the precise location of inspiratory and expiratory neurons within the medulla has not yet been answered

The relative importance of the pneumotaxic center in maintaining rhythmic breathing after vagotomy seems to differ according to the species of animal studied and the conditions of the experiments According to Hoff and Breckenridge (1954) in dogs, and under certain conditions in cats, midpontine section combined with bilateral vagotomy does not cause cessation of breathing, this has been confirmed by Wang and co-workers (1957) In fact vagotomy has been reported to have no effect on breathing in some instances in animals having the brainstem sectioned in the midpontine region Hoff and Breckenridge have returned to the view that the cause of the rhythmic discharge of respiration lies within the medulla itself "Just how the rhythm of respiration develops within the medulla is still problematical, and it may well be possible that within the confines of the medulla itself anatomical pathways are to be found wherein reciprocating self-limiting circuits, akin to those postulated between medulla and pons in earlier hypotheses, determine the rhythm of breathing "

The situation at present can be summarized by stating that the presence of a respiration-regulating group of neurons in the upper pontine region, the so-called pneumotaxic center, has been clearly demonstrated and has an important role in regulation of rhythmic breathing in the intact animal However, it seems to be clearly demonstrated, also, that rhythmic breathing still can occur when both this mechanism and the vagal reflexes are eliminated Finally, the precuse manner in which the pontine elements influence respiration has not been determined In Figures 6 26 and 6 27 are shown two recent attempts to explain the organization of the respiratory center

Profound inhibition of breathing can be produced by stimulation of the anterior cingulate cortex on the medial surface, and the orbitoinsulotemporal polar cortex on the ventral surface

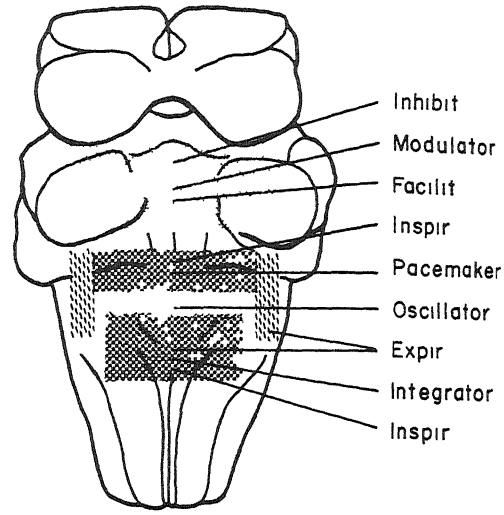

Fig 6 27 Schematic representation of functional concept of central regulation of respiration Relative locations in the brainstem of a cat of the regions which subserve the various functions are indicated (Reproduced by permission from Brodie and Borison 1957)

of the cerebral hemisphere In man, arrest of breathing has been produced in patients under light Pentothal anesthesia from the anterior cingulate and posterior orbital surface, and in the conscious patient from the same areas and from the anterior insula and the ventromedial aspect of the temporal pole Acceleration of respiration has been observed in carnivores on stimulating the motor cortex, the anterior ectosylvian and the sylvian gyri, and the middle and anterior portion of the cingulate cortex Precisely what role these cortical areas play in the control of breathing is not clear at present (See *Handbook of Physiology*, sect 1, vol 2 p 1347-1351)

NATURE AND LOCATION OF CO_2-SENSITIVE CELLS IN THE MEDULLA

That cells in the respiratory center show increased rates of discharge in response to an increase in CO_2 tension or hydrogen ion concentration in them, or in their immediate vicinity, is generally accepted The precise mechanisms of central sensitivity to changes in cH and Pco_2 however are not known One may recall that before the discovery of carotid bodies (which anatomically are not very far from the respiratory center) it was believed that oxygen lack had a stimulant effect directly in the respiratory center, and it is known now that such effects are on a reflex basis

Leusen (1954) showed that an increase in the hydrogen ion concentration in cerebrospinal fluid perfusing the cerebral ventricles stimulated ventilation, and he believed that this effect was exerted directly upon the respiratory center However, Loeschcke (see Grodins, 1964) showed that local application of acid to the floor of the fourth ventricle failed to stimulate breathing, hence he postulated the existence of a cerebrospinal fluid (CSF) bathed chemosensitive area outside the respiratory center Subsequently, Mitchell et al (1963) reported that specific areas on the ventrolateral surface of the medulla (bounded medially by the pyramidal tracts, laterally by the roots of the 8, 9, 10, and 11 cranial nerves, rostrally by the pons, and extending caudally about 6 mm) show chemosensitivity similar to that exhibited by the receptors of the carotid bodies Application to this area of pledgets containing CSF which was equilibrated with high P_{CO_2}, or having a high cH, or containing nicotine or acetylcholine, produced hyperpnea, whereas local cooling or application of procaine caused inhibition of respiration The authors postulate that all medullary CO_2 sensitivity is mediated via these "receptors" on the ventrolateral surface of the medulla The idea of specific chemoreceptors situated on the ventrolateral surface of the brainstem and influenced directly by changes in the cerebrospinal fluid has been further supported by Loeschcke (1965), Florez and Borison (1967), and Schlafke and Loeschcke (1968) Leusen (1969) states that agreement among researchers on the localization of central chemosensitive structures has not been reached, and Pappenheimer et al (1965) and Fencl et al (1966) have presented arguments against the view that there are such receptors located on the surface of the brainstem Leusen (1969) suggests a compromise interpretation, namely that both superficial and more deeply located zones are normally active but that the deeper zones are more sensitive to anesthesia and oxygen lack so that in anesthetized or shocked animals the relative importance of the superficial medullary chemoreceptors in maintaining breathing would be increased If this is correct the role of the superficially located chemoreceptors would be somewhat similar to that of the peripheral chemoreceptors of the carotid and aortic bodies (p 6-55) Evidence which supports this view is presented by Cozine and Ngai (1967), who failed to obtain effects on respiration by applying procaine to the ventrolateral medullary chemoreceptors except when the deeper structures were depressed by anesthesia or anoxemia

Reflex and Motor Mechanisms

HERING-BREUER REFLEXES

The Hering-Breuer reflexes are effects on the respiratory cycle which are elicited by inflation and deflation of the lungs The receptors concerned are in the lungs, and the afferent pathways are in the vagus nerves The function of these reflexes apparently is to regulate the respiratory cycle rather than to alter significantly the pulmonary ventilation for any prolonged period The observations made by Hering and Breuer (1868) were that inflation of the lungs causes arrest of inspiration expiration then ensuing, and deflation of the lungs has an inspiration-exciting effect They found that these effects were abolished when the vagus nerves were sectioned Another way to demonstrate the effects of lung distention is to block the airway at the beginning of either inspiration or expiration When inflow of air is prevented, a stronger inspiratory effort results than in the preceding cycle, and when egress of air is blocked at the end of inspiration, a longer interval than the preceding one occurs before the onset of the next inspiratory effort In eupnea apparently the inflation effect during inspiration alone is a factor As inspiration proceeds, distention of the lungs occurs, and impulses are carried by vagal afferents to the respiratory center where they cause inhibition of the inspiratory neurons, thus terminating inspiration .Once the lungs begin to deflate, impulses are no longer set up in the vagal afferents and, consequently, the inspiratory neurons again are free to discharge

The mechanical problem in studying the Hering-Breuer reflexes can be circumvented in the case of the rabbit since this animal has a slip of muscle on the posterior surface of the diaphragm which can be dissected free and recorded from, separately from the remainder of the diaphragm This diaphragmatic slip of muscle can be used as an indicator of the degree of activation of inspiratory muscles If the lungs are distended, the rate and amplitude of contraction of the slip decrease, and if the lungs are deflated, an increase in rate and amplitude of contraction of the slip is observed (Fig 6 28)

The stimulating effect of lung deflation on

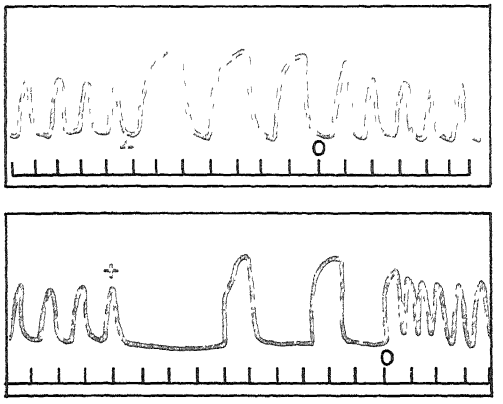

Fig 6 28 Record of contractions of isolated slip of a diaphragm of a rabbit to illustrate Hering-Breuer reflexes Upstroke is produced by contraction of the slip i e inspiration Above at + the trachea occluded at the end of expiration and at 0 the obstruction was removed Below at + the trachea was occluded at the end of inspiration and at 0 the obstruction was removed (After Head)

inspiration is related under ordinary conditions to failure in the production of the normal amount of inspiration-inhibiting influence at the end of inspiration However, severe deflation, as from pneumothorax, results in activation of other receptors, and reflex stimulation of inspiration follows Finally, if lung inflation is severe, not only is inspiration inhibited but active expiration is elicited reflexly This may not require a third type of receptor, but may be simply the result of greater degree of activation of the same kind of receptors which are concerned in the reflex inhibition of inspiration The role of vagal reflexes in regulating inspiration and expiration has been described in detail by Wyss (1954) Paintal (1963) reviewed what is known about the location and response patterns of pulmonary receptors

A physiological role of the Hering-Breuer reflexes is to regulate the extent of lung inflation so that the tidal volume tends to fall within a certain range Also, these reflexes serve to insure filling and emptying of the lungs despite a considerable increase in resistance in the airway As would be expected, the typical result following bilateral vagotomy is an increase in the depth of breathing The inspiratory act under these conditions is seen to be unnecessarily long since the chest tends to remain in the inspiratory position for a short period after ingress of air has stopped This is an inefficient process since muscular work is being done while no air is being moved. Also, a decrease in respiratory rate develops in most animals after vagotomy This probably is a compensatory change, secondary to the increased depth, which results in an amount of pulmonary ventilation similar to that which was present before vagotomy An increased depth of breathing without a decrease in rate would soon wash out CO_2 so that the stimulus to the respiratory center would be removed, hence the rate soon would decrease to cause restoration of normal CO_2 levels It should be mentioned, however, that the effects of vagotomy on rate and depth of breathing vary greatly depending upon the anesthetic agent which is used, and furthermore, changes are progressive for a prolonged period following vagotomy

The effects on respiration of direct stimulation of the central end of the vagus nerve sectioned at the cervical level are somewhat unpredictable, since the nerve contains several types of afferent fibers which carry impulses to the respiratory center These include *1)* aortic arch afferents, *2)* aortic body afferents, *3)* inspiration-inhibiting fibers activated normally during lung inflation, *4)* inspiration-exciting fibers activated physiologically by excessive lung deflation, and *5)* fibers concerned with visceral pain, and possibly still other types of fibers However, strong stimulation of the central end of the vagus nerve usually causes apnea, and this may persist for a few seconds after cessation of stimulation This result could be elicited if the effects of stimulation of *1* and *3* above were sufficient to override the effects of stimulation of *2* and *4*

The Hering-Breuer reflexes are basically proprioceptive in nature In this case contraction of skeletal muscle not only increases the tension in muscles and shortens them, but elastic objects, the lungs, also are put under greater tension The lungs also are supplied with receptors from which information is carried back to the same neurons that activated the muscles The muscles of respiration, like skeletal muscle in general, are supplied with proprioceptive innervation through which their contraction is regulated in the same way as described for the limb musculature

REFLEX EFFECTS FROM BARORECEPTORS

A sudden rise in pressure in the sino-aortic zones elicits reflexly a decrease in rate and depth of breathing If the pressure rise is considerable, apnea may be produced Typically, adaptation is rather rapid so that breathing is

restored even though the new pressure level is maintained Part of the recovery of respiration is related to adaptation in the receptors themselves, but also it occurs as a consequence of the rise in P_{CO_2} during apnea The opposite change, a sudden fall in pressure in the sino-aortic zones, elicits hyperpnea Thus, any sudden change in blood pressure per se tends to elicit respiratory responses During rapid bleeding or following injection of vasodilator drugs, such as nitroglycerin or bethanechol (a choline derivative), respiration is stimulated (Fig 6 29), and the effect is prevented in considerable part by sino-aortic denervation (Schopp, Gilfoil, and Youmans, 1957) The respiration-stimulating effect of nitroglycerin which still remains after denervation can be partly or completely prevented if a device is used to prevent the fall in arterial blood pressure

The effects on respiration elicited from the baroreceptors probably are of importance in influencing the venous return (Youmans, 1958) Vasodilation promotes pooling of blood, especially in the abdominal viscera, and increased respiratory activity promotes the movement of blood from the abdominal portion of the inferior vena cava on into the thoracic portion The concept of the respiratory pump, as a factor in aiding venous return, introduced by Donders in 1859, seems accurate according to the studies reviewed by Brecher (1956) Conversely, the respiratory inhibition during a rise in blood pressure, especially in a person in the orthostatic position, would favor pooling of blood in the splanchnic region so that venous return would be decreased, thus cardiac output would be lowered, and the rise in blood pressure would be counteracted In short, one may interpret the respiratory responses from baroreceptors, along with effects on heart rate and arteriolar tonus elicited at the same time, as being concerned with the stabilization of arterial blood pressure However, characteristics of these reflexes are such that they are useful only in counteracting sudden changes of brief duration, they are overridden easily by other influences

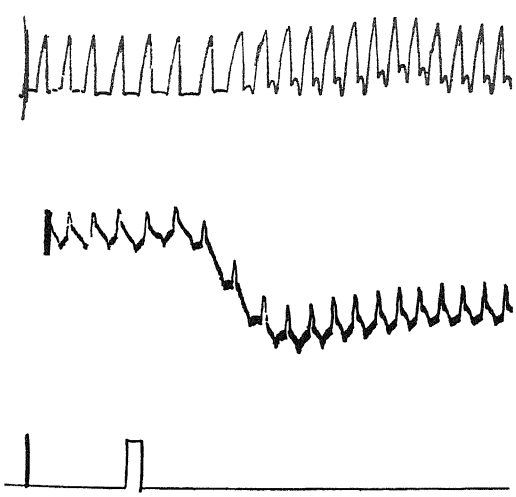

Fig 6 29 Effects on blood pressure (below) and respiration (above) following injection of 0 1 mg/kg of nitroglycerin into dog anesthetized with α-chloralose The respiratory stimulation can be prevented if the fall in arterial blood pressure is counteracted by means of rapid infusion of blood from a pressure-regulating device (From studies by Schopp Gilfoil and Youmans 1957b)

CONTROL OF ACTIVITY OF THE ABDOMINAL MUSCLES

In the resting, supine subject, abdominal muscles may be completely inactive throughout the breathing cycle (Campbell, 1958) In moderate hyperpnea they become active during expiration, and in more severe hyperpnea they show a rapidly augmenting activity during the early part of expiration, with a decrease well before the next inspiration begins Abdominal muscles usually are active during expiration in the subject in the standing position, and they contract in response to continuous positive pressure breathing in a subject in the supine position The degree of their response to positive pressure is proportionate to the level of pressure applied Gesell and Moyer (1941) reported that the contraction of abdominal muscles in response to positive pressure breathing in dogs did not occur after bilateral vagotomy at the cervical level Their discussion was based on the tacit assumption that vagotomy had this effect because of elimination of impulses from the lungs Apparently, no one had questioned the source of this reflex effect on abdominal muscles until recently Studies by the Wisconsin group (Youmans et al , 1963) revealed that positive intrapulmonary pressure elicits contraction of abdominal muscles in dogs with closed chest, but does not do so if the chest is open, even though lung distention in the latter case is greater, hence, Hering-Breuer reflexes apparently are not concerned Bishop (1964) likewise has concluded that the abdominal muscle response to positive pressure breathing "is not a simple corollary of the Hering-Breuer reflex but is a separate reflex served by its own vagal pathway "

Results of extensive studies (Youmans et al , 1963) indicate that activity of abdominal muscles may be increased selectively on a reflex basis when volume of blood in certain "low pressure" portions of the cardiovascular system is reduced Although it is clear that anything which stimulates breathing tends to cause appearance of, or an increase in, activity of abdominal muscles, on the other hand, a number of procedures, which lead to changes in amplitude of contractions of abdominal muscles, do so without causing corresponding changes in tidal volume In experiments on dogs it was found that several procedures (including bleeding, tilting the animal to the head-up position, aortic occlusion, and positive pressure breathing) cause marked changes in amplitude of steady-state contractions of abdominal muscles, while having little or no effect on tidal volume In Figure 6 30, a schematic representation is shown of main factors and mechanisms concerned with influencing the activity of abdominal muscles In addition to the well-known influences from chemoreceptors and baroreceptors, acting by way of the respiratory center, it is postulated that atrial mechanoreceptors (extensively studied by Paintal (1963) and others) are concerned with reflex inhibition of tonus of abdominal muscles Any decrease in volume of the atria is envisaged as causing an increase in tonus of abdominal muscles through withdrawal of this inhibitory effect The consequent rise in intra-abdominal pressure serves to reduce the capacity of the venous system and hence promotes better cardiac filling The influences from alterations in cardiac filling apparently can be exerted independently of the effects on amplitude of breathing (as shown for example by the fact that occlusion of the postcaval vein causes an immediate increase in activity of abdominal muscles, while occlusion of the ascending aorta causes immediate inhibition of such activity, yet minimal and similar effects on inspiration occur) Therefore, it is necessary to assume, as shown in Figure 6 30, that impulses from atrial mechanoreceptors can be channeled to the motor neurons which innervate the abdominal muscles without influencing the respiratory center The only new concept presented in the schema is that atrial mechanoreceptors (activated by increased atrial volume) are concerned with reflex inhibition of tonus of abdominal muscles Campbell (1958) suggested the possibility that changes in activity of abdominal muscles during the respiratory act may be determined in part by reflexes which do not operate through the respiratory center He further stated that some of the control of abdominal muscles may be for the purpose of modulating changes in abdominal pressure, because of the effects on circulation, and that receptors in the circulatory system, in either the abdominal or thoracic cavities, might be involved Bjurstedt (1953), more specifically postulated that tonus of abdominal muscles may be influenced reflexly from receptors in the circulatory system that are sensitive to changes in filling As to the question of an abdominal muscle tonus center (*ACC* in the schema), it is noteworthy that Gesell, Magee, and Bricker (1940) observed steady-state "expiratory" discharge in neurons in the medulla and suggested that these units may be concerned with posture rather than with exhalation More recently Haber et al (1957) recorded two types of "expiratory" patterns from neurons in the medulla, which they differentiate as early vs late The late "expiratory" discharges are similar to Gesell's steady-state type Since they occur at maximum frequency in the anesthetized dog well after the end-expiratory position has been reached (at a time when there is no movement of air and when abdominal muscular activity and intra-abdominal pressure are maximal) it would seem to be at least as appropriate to call them abdominal compression discharges as to call them expiratory discharges Haber et al (1957) also found that the neurons are carbon dioxide sensitive and may become inactive as a result of hyperventilation This is also a characteristic of the neuronal system which is concerned with maintaining steady-state activity in abdominal muscles (Youmans et al , 1963)

Among the best evidence for reflex influences on abdominal muscle tonus elicited from a cardiac chamber is that reported by Turner (1961), who demonstrated that distention of the left atrium produces inhibition of tonus of abdominal muscles in dogs being artificially respired and having the systemic and pulmonary circulation maintained constant by means of a pump This would seem to implicate the left atrium as at least one site from which tonus of abdominal muscles can be influenced, but it does not rule out the possibility of influences from still other sites in the heart or pulmonary circuit

REFLEXES INITIATED IN OTHER PARTS OF THE BODY

The experiments of Churchill and Cope (1929) showed that a reflex increase in the re-

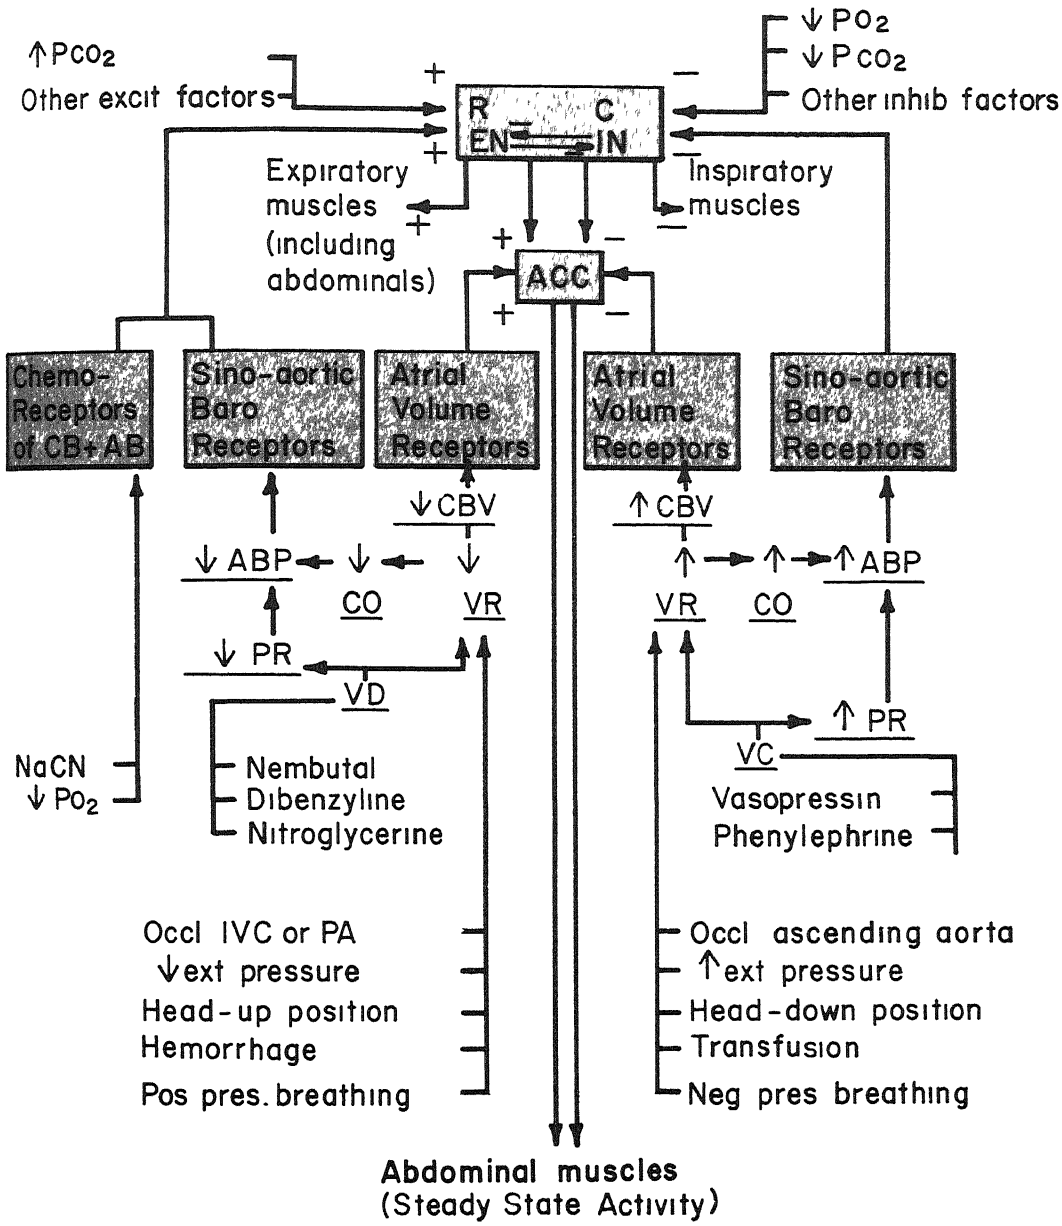

Fig 6 30 Schematic representation of main factors and mechanisms concerned with altering the level of activity of abdominal muscles in response to cardiorespiratory changes The left side of the diagram illustrates excitatory influences which affect the activity of abdominal muscles either through the respiratory center or more directly The right side shows opposite changes which promote a decrease in the activity of abdominal muscles *RC* the respiratory center *EN* expiratory center *IN* inspiratory center *ACC* abdominal compression center *CB* carotid body *AB* aortic body *CBV* central blood volume *ABP* arterial blood pressure *CO* cardiac output *VR* venous return, *PR* peripheral resistance *VC* vasoconstriction *VD* vasodilation *IVC* postcaval vein *PA* pulmonary artery + excitatory influence − inhibitory influence

spiratory rate results from distention of the pulmonary vascular bed When the vessels of the lung, which was isolated from the body except for its nerves, were injected with fluid to cause overfilling of the vascular bed, rapid shallow breathing immediately ensued Section of the vagal fibers abolished the response

Stimulation of almost any afferent nerve may bring about a reflex change in respiration Stimulation of pain fibers is especially potent

in this regard, and the respiratory effects of the excitation of the cutaneous nerves by extremes of heat or cold are well known The thermal effect upon respiration is apparent in the panting of the dog The increased pulmonary ventilation in fever is also partly due to the stimulation of receptors (*thermoreceptors*) responsive to a rise in temperature The thermoreceptors are situated peripherally, especially in the skin, and centrally in the hypothalamus, the latter, being stimulated through the rise in temperature of the blood, set up impulses which are transmitted to the respiratory centers, the pneumotaxic center in particular The great increase in pulmonary ventilation occurring in muscular exercise is dependent in part upon reflexes originating in the active muscles and moving joints Proprioceptive impulses from the diaphragm and other respiratory muscles during one respiratory movement exert an important influence upon the succeeding movement Stimulation of sensory nerves in the respiratory tract, as by ether anesthesia, or of the abdominal viscera, either during surgical operations or as the result of disease may cause profound changes in breathing Also, as pointed out by Harrison and his associates (1932) stimulation of afferent nerve endings in the great veins and right auricle by the rise in venous pressure is a possible factor in the hyperpnea of exercise or in the dyspnea of cardiac failure The glossopharyngeal nerve contains afferent fibers which inhibit respiration during the second stage of the act of swallowing Abrupt inhibition of respiration is also caused by the inhalation of an irritant gas through stimulation of nasal branches of the fifth nerve In other instances irritation of these endings may cause sneezing—a modified respiratory act Coughing is most commonly reflex in character, and may be initiated by the stimulation of afferent nerve endings in the trachea and larynx

Also, there are receptors in the heart, which notably are activated by veratridine injected into the coronary arteries, and elicit inhibition of respiration—along with a decrease in heart rate and inhibition of arteriolar tonus The physiological role of these receptors is not known, but stretching of the cardiac chambers by overfilling elicits a similar response and it is possible that these receptors are concerned in this reflex.

Regulation of Pulmonary Ventilation

RESPIRATORY ADJUSTMENTS TO CO_2

Pulmonary ventilation in a normal subject at rest is kept relatively constant at a given level in response to the carbon dioxide tension, hydrogen ion concentration, and oxygen tension in specific sites Thus, ventilation is such as to tend to keep the values for $P_{A_{O_2}}$, $P_{A_{CO_2}}$ and pH within a narrow range As a consequence of an increase in metabolic rate oxygen tension tends to be decreased and carbon dioxide tension and hydrogen ion concentration tend to be increased This does not happen to any considerable degree because changes in these chemical stimuli elicit an increase of pulmonary ventilation to counter a rise Or one can visualize that if the basal metabolic rate (BMR) suddenly should increase by a given increment the respiratory minute volume (RMV) would also be increased by feedback from sensors responding to the chemical stimuli so that the levels of $P_{A_{O_2}}$, $P_{A_{CO_2}}$, and pH would be kept virtually the same as before the rise In the case of responses to exercise, however, additional mechanisms are utilized to regulate RMV

Although it is generally accepted that the major chemical stimuli which are concerned with influencing pulmonary ventilation are known, there are a number of questions which require further study These include questions concerning sites and mechanisms of action, relative sensitivity in the different sites, and possible interactions between the stimuli

The CO_2 content of inspired air is negligible, as far as human physiology is concerned, and can be increased somewhat without causing an increase in RMV Its concentration at sea level can be increased by about 1% (7 6 mm Hg) before a measurable increase in pulmonary ventilation occurs If 4% CO_2 is breathed, the RMV is approximately doubled on the average, but the effect may be scarcely noticed by the subject Any further increase in CO_2 from 4% up to 10% produces a correspondingly greater RMV, and at the latter level it may be 8 to 10 times the resting level Also the subject may have symptoms of dizziness, faintness, and headache Increasing the CO_2 percentage beyond 10 does not result in significantly greater increases in RMV, and at levels above 20% the

RMV may begin to show a decrease Also, these levels cause convulsive seizures From the practical standpoint it would appear that if CO_2 is to be administered to stimulate breathing, there would be little use for any mixture containing less than 5% or more than 10% CO_2

It is generally agreed that the primary site of action of CO_2 in producing effects on breathing is in the respiratory center or in the immediate vicinity of the center Cells in a respiratory center which has been isolated from extrinsic neural influences still show alterations in rates of discharge in response to corresponding changes in CO_2 tension of the blood reaching them, and injection of bicarbonate directly into the respiratory center causes an increased activity of these neurons

Considerable attention has been given to the question of the precise mechanism by means of which CO_2 exerts its stimulant action It has been debated whether CO_2 itself has such an effect, or whether the effect is exerted indirectly as a consequence of the concomitant increase in hydrogen ion concentration There is evidence, analyzed by Gray (1950), that both a rise in P_{CO_2}, and in cH, in the respiratory center, contribute to and supplement each other in causing an increase in pulmonary ventilation.

Another mechanism, reflex in nature, is available for the stimulation of breathing as a consequence of a rise in the P_{CO_2} of arterial blood The chemoreceptors, already described as concerned with producing circulatory adjustments in response to changes in P_{O_2} and P_{CO_2}, when subjected to a sufficient rise in P_{CO_2} will elicit an increase in RMV The extensive literature dealing with chemoreceptors has been summarized by Heymans and Neil (1958) and others in the proceedings of the J S Haldane Centenary Symposium (Cunningham and Lloyd, 1963) The fact of reflex stimulation of breathing in response to rises in P_{CO_2} of the blood flowing to the aortic and carotid bodies has been demonstrated by a number of methods and is generally accepted A question which has been vigorously disputed, however, is whether the respiratory center in the intact subject is more sensitive than the chemoreceptors In other words, does the chemoreceptive reflex mechanism constitute the first line of defense against a rising P_{CO_2} in arterial blood or does the respiratory center have the greater sensitivity Heymans has supported the view that the chemoreceptors are concerned with reflex drive of breathing even under resting conditions at sea level, while Schmidt and Comroe have favored the interpretation that these receptors are activated in significant degree only after considerable increases in arterial P_{CO_2} The details of the argument are reviewed by Heymans and Neil (1958), who conclude that the question remains open as to how much the chemoreceptors participate in the response to moderate hypercapnia in the intact animal However, the majority viewpoint seems to be that the normally sensitive central mechanism responds to rising CO_2 and through increased ventilation prevents a rise in P_{CO_2} of arterial blood sufficient to elicit a response from peripheral chemoreceptors If, on the other hand, the respiratory center is rendered relatively insensitive to CO_2, for example, by anesthetic agents and narcotic drugs, respiration is depressed, and P_{CO_2} rises to a level sufficient to set up peripheral chemoreceptive drive of breathing According to the latter interpretation the CO_2-induced chemoreflex constitutes a secondary line of defense to help insure pulmonary ventilation when the sensitivity of the respiratory center is reduced

Although it would appear that influences from peripheral chemoreceptors are not always needed, and perhaps would not be a significant factor in eliciting an increase in RMV in response to a slowly rising CO_2 tension in a normal subject, these receptors are concerned in eliciting the initial response to a sudden rise in $P_{A_{CO_2}}$ It is reported that in an animal with peripheral chemoreceptors denervated and normoxic, so that no significant oxygen lack drive is a factor, the response to inhaled CO_2 is demonstrably different from that of the animal prior to denervation The denervated animal responds after a longer latent period and then more sluggishly (Leitner et al , 1965) This result is not surprising and does not necessitate the conclusion that impulses from peripheral chemoreceptors elicited by the normal CO_2 tension are concerned in driving breathing in the animal at rest Perhaps more applicable to the question is the claim that after chronic denervation of peripheral chemoreceptors the resting $\dot{V}_E$ of the unanesthetized animal is about 80% of what it was before denervation and the $P_{A_{CO}}$ is about 10 mm Hg higher (Mitchell et al , 1964, Bouverot et al., 1965) This appears to

indicate that about 20% of the drive during normal breathing at rest is derived from peripheral chemoreceptors

Ezaguirre and Lewin (1961) approached the question of sensitivity of the peripheral chemoreceptors directly by determining the number of impulses in afferent nerve fibers from the carotid body of the cat breathing different oxygen mixtures at various P_{CO} levels produced by different levels of ventilation If we may assume normal sensitivity of the chemoreceptors in their study it may be concluded from their results that impulses are discharged from peripheral chemoreceptors in response to a normal P_{ACO} (since a rise from 30 to 40 mm Hg produced a considerable increase in frequency) Also a reduction in oxygen content in inspired air from 50 to 20% resulted in a slight increase in the number of impulses set up in the nerve fibers from the carotid body The latter effect was slight enough, however, to indicate that the influence of oxygen lack on chemoreceptors at normal P_{A_O} is negligible

The lowering of P_{CO_2} in arterial blood can be achieved by voluntary hyperventilation or by excessive artificial ventilation of anesthetized subjects Following hyperventilation, apnea is observed, and breathing is resumed when either P_{CO_2} rises to approximately the level found in the subject under resting conditions or when the P_{O_2} of arterial blood drops to a level sufficient to set up reflex drive of breathing on an O_2 lack basis, whichever occurs first, After one has hyperventilated moderately with atmospheric air, oxygen lack develops quickly as the store of oxygen in the lungs is absorbed and utilized, breathing is resumed in response to the oxygen lack stimulus before the P_{CO_2} has been restored to the normal resting level Then the oxygen lack is relieved by a few breaths, and apnea appears again Gradually, the P_{CO_2} level becomes restored and takes over as the sole drive This is the basis for the appearance of a few cycles of periodic breathing after hyperventilation As would be expected if one hyperventilates with 100% O_2, rather than air, just as much CO_2 is blown off as before, with a given degree of respiratory activity, but the P_{O_2} in alveolar air is quite high at the end of the period of hyperventilation Consequently a longer time will be required for the O_2-lack stimulus to appear than for the P_{CO_2} level to be restored Therefore, following hyperventilation with 100% O_2 the elevation of P_{CO_2} may be the initial factor in the restoration of breathing

RESPIRATORY ADJUSTMENTS TO O_2

The P_{O_2} in inspired air can be reduced by lowering the atmospheric pressure in a decompression chamber in which the subject has been placed, or he may breathe prepared gas mixtures having various ratios of O_2 to N_2 Since O_2 tension is lowered in proportion to the decrease in barometric pressure with altitude, one may indicate the altitude at which the experimentally induced P_{O_2} would be encountered Thus a certain altitude, as far as P_{O_2} is concerned, is simulated by the experimental conditions For example, if one breathes a mixture of 10 5% O_2 and 89 5% N_2 at 760 mm Hg pressure, the P_{O_2} is about one-half that in atmospheric air at the same pressure This approximates the P_{O_2} found in atmospheric air at an altitude of 18,000 ft where the barometric pressure is about 380 mm Hg The details concerning respiratory responses to P_{O_2} lower than that of room air at sea level have been described by Dripps and Comroe (1947) and by Rahn and Otis (1949) The major observations may be summarized as follows Some subjects show a slight stimulation of breathing when the O_2 is lowered to 16 to 18% while others do not respond until a level in the range from 16% down to 12%, or even lower in occasional subjects, is reached At levels of 10% or below, breathing is stimulated but irregularities may develop As the O_2 tension in inspired air is lowered and respiratory minute volume increases, the CO_2 tension in alveolar air and arterial blood falls Thus at the same time that the oxygen-lack stimulus is operating to cause an increased RMV, the CO_2 and cH drives of breathing are being withdrawn It is apparent, therefore, that the stimulating effects of oxygen-lack per se on breathing could be recorded if the fall in CO_2 tension were prevented, as by adding the appropriate amount of CO_2 to the inspired air In the discussion of hyperventilation it was noted that a relatively slight reduction in CO_2 tension (3 to 4 mm Hg) results in apnea when there is no accompanying O_2 lack At altitude, therefore, where the CO_2 tension is lowered more than this (secondary to increased RMV), it must be assumed that respiratory drive is entirely on an oxygen-lack basis or that a readjustment in sensitivity to

CO_2 tension has occurred Acutely, the former seems to be true, while after prolonged exposure to low oxygen tension the latter change apparently occurs

Papers on respiration written before the discovery of the chemoreceptors of the carotid bodies refer to a stimulant action of oxygen lack on the respiratory center It is now believed that a lowered O_2 tension in the medulla does not result in stimulation of breathing, and decreases in O_2 tension of arterial blood, within ranges that the animal can tolerate for significant periods, do not cause stimulation of breathing if the carotid and aortic bodies have been denervated Thus, the only sensitive mechanism which responds to oxygen lack and elicits an increase in RMV is the chemoreceptor reflex Here, too, as in the case of the CO_2 effect, the precise level at which a lowered arterial O_2 tension elicits stimulation of breathing is disputed Comroe and Schmidt (1938) first reported that the O_2 tension in blood perfusing the carotid bodies was lowered to about 50 mm Hg before the receptors were activated, but others have reported the threshold to be above 100 mm Hg Po_2 Experiments showing the effects on RMV of blocking the chemoreceptors do not serve to establish the level of activity under normal resting conditions if anesthetic agents are used, since, as already explained, these substances usually cause depression of the respiratory center so that some part of the drive of breathing is transferred to the chemoreceptors If oxygen lack stimulates breathing only through activation of chemoreceptors, then depression of breathing should be produced as a result of breathing mixtures containing more oxygen than that found in atmospheric air Loeschcke (1953) reported an 8% reduction of RMV for about a minute when 32% O_2 in N_2 was substituted for room air in unanesthetized man, and this was followed by a rise until equilibrium was reached after about 4 min On returning to room air, RMV increased a little for a few minutes and then returned to the control level Dripps and Comroe (1947), however reported only 3 1% reduction in RMV caused by inhalation of 100% O_2, whereas Baker and Hitchcock (1947) found an increase in ventilation in response to 100% O_2 The results cited indicate that if there is any drive of breathing related to O_2-tension effects in normal subjects at sea level it is so small that it can be detected only by very careful measurements Furthermore, it is possible that even the slight increases in ventilation which have been reported are not related to the removal of chemoreceptor drive, but rather to a rise in Pco_2 tension in the respiratory center secondary to the vasoconstriction produced by high O_2 tension in the arterioles of the brain (See Kety, S S and Schmidt, C F, 1948)

According to studies reported by Witzleb at the Haldane Centenary Symposium (Cunningham and Lloyd, 1963) in cats under chloralose-urethane anesthesia, which were artificially ventilated, excitation of chemoreceptors usually was apparent at an arterial Po_2 tension of about 100 mm Unless the anesthetic agents, or other conditions of the experiment sensitize the chemoreceptors to O_2 in some way, this result would indicate that influences from chemoreceptors, though slight, are concerned in regulation of respiration, even when the O_2 tension of arterial blood is within the range which occurs in a subject breathing air at sea level

CHEMORECEPTORS OF THE CAROTID AND AORTIC BODIES

The typical responses to significantly lowered oxygen tension in inspired air include *1)* stimulation of breathing, *2)* cardiac acceleration, and *3)* a rise in arterial blood pressure It is now clear that both the stimulation of breathing and vasoconstriction, which in turn causes an increase in blood pressure, can be attributed to reflex effects elicited from chemoreceptors of the carotid and aortic bodies, whereas the cardiac acceleration cannot be so explained Several researchers have demonstrated by experiments employing perfusion of the carotid bodies, that a lowering of oxygen tension in them does not cause cardiac acceleration (See M deBurgh Daly and J N Scott in Cunningham and Lloyd, 1963) Actually, cardiac inhibition occurs but much of this effect must be attributed to baroreceptor reflexes Since one of the changes elicited reflexly from the carotid bodies is vasoconstriction, the arterial blood pressure rises as a result of the increased peripheral resistance, hence if the baroreceptors of the carotid sinuses and aortic arch and their innervation are intact, reflex bradycardia is elicited However, even when the rise

in arterial blood pressure is buffered, lowering of the oxygen tension in the blood perfusing the carotid bodies does not elicit cardiac acceleration, provided the animal is also being artificially respired Daly has concluded that the cardiac acceleration which occurs in response to hypoxia is secondary to the respiratory stimulation He presents evidence that the increase in respiratory movements reflexly elicits the acceleration

From the studies of Daly, Bernthal and others, it is clear that reflex effects on heart rate from the carotid bodies cannot be determined, unless the arterial blood pressure is kept constant and artificial respiration is utilized When these conditions are met, a reduction in oxygen tension of blood perfusing the carotid body usually causes a moderate decrease in heart rate

Sodium cyanide injected intravenously causes cardiovascular and respiratory changes similar to those occurring in response to hypoxia (respiratory stimulation, increase in arterial blood pressure, cardiac acceleration) Since cyanide prevents the utilization of oxygen by tissues, it is possible that the mechanisms concerned in the response to it are the same as those involved in responses to inadequate oxygen supply Also the responses to cyanide (when it is introduced into the blood perfusing the carotid body) are similar to those produced by decreasing the oxygen tension of the perfusing blood Several other compounds have been shown to have a stimulant action on chemoreceptors of the carotid bodies, and several theories have been advanced to explain how either oxygen lack or inability to use oxygen in the presence of an oxygen excess can be transduced into impulses in the afferent fibers which innervate chemoreceptors

Recent work done in Anichov's laboratory, and other studies reviewed by him, indicate that widespread effects result from stimulation of carotid body chemoreceptors He states that the machinery of the "stress" reaction, extensively described by Selye, is set in motion, and that adrenocorticotropic hormone (ACTH), epinephrine, and norepinephrine are liberated

Ordinarily the chemoreceptors of the aortic bodies (which are much less accessible and hence have not been studied so extensively) have been considered to be of the same type as those of the carotid bodies However, Comroe and Mortimer (1964) have reported that, in dogs, hyperpnea can be elicited from the carotid bodies and aortic bodies, but from the latter arterial hypertension and tachycardia are elicited The latter effect, as explained, is not elicited from carotid bodies

EFFECTS OF HYDROGEN ION CONCENTRATION AND THE INTERACTIONS BETWEEN RESPIRATORY DRIVES

Since changes in P_{CO_2} are accompanied by changes in pH, a question may be raised whether changes in hydrogen ion concentration as such have an influence upon breathing Gray (1950) has emphasized the point that in metabolic acidosis pulmonary ventilation is greatly increased while arterial P_{CO_2} is below normal Obviously then if it is true to begin with that only three drives (P_{O_2}, P_{CO_2}, cH) operate to control breathing, increased acidity per se is capable of stimulating breathing since neither of the other two factors has changed in a direction which would cause such stimulation Gray further states that an increase in RMV is not regularly associated with an increase (and in fact may occur in the presence of a decrease) in drive related to any one of the three factors considered to be concerned with the control of pulmonary ventilation, however, at least one of three changes must be present *1)* rise in arterial P_{CO_2}, *2)* decrease in arterial P_{O_2}, or *3)* increase in arterial cH It is envisaged that any one of these may assume the major role in driving respiration under certain circumstances In the case of administering CO_2 the arterial cH increases almost linearly with the increase in arterial P_{CO_2} so that, according to Gray's multiple factor theory, the stimulation of breathing is greater than would be produced by either the rise in P_{CO_2} alone or the rise in arterial cH alone

The evidence seems to be sufficient to establish that the level of pulmonary ventilation in subjects at rest is determined by either the arterial CO_2 tension, the arterial O_2 tension, the arterial cH or by interaction of these three drives The relationship between each of these drives and the other two has been discussed at length in physiological literature Gray advanced the hypothesis that effects of the three factors are simply *additive*, and, in line with this view he presents an equation for calculation of the ventilation ratio (ratio of alveolar ventilation under new conditions to alveolar ventilation under control conditions) from the changes in P_{CO_2}, P_{O_2} and cH of arterial blood

According to Gray's theory if P_{CO_2} is lowered further below the level which leads to apnea because of lack of a CO_2 stimulus to the respiratory center, the P_{CO_2} effect is further subtracted Stated in another way, if breathing is put on an oxygen-lack drive, the lower the P_{CO_2}, the lower will be the amount of respiratory stimulation because of the lesser P_{CO_2} effect to be added to the oxygen-lack drive In experiments by Nielsen and Smith (1952) the alveolar P_{O_2} tension was maintained at constant low levels, eliciting O_2-lack drive, while the effects of adding CO_2 were tested It was found that CO_2 had no effect, or only a slight effect, on the ventilation under these conditions until a threshold value of arterial P_{CO_2} of about the same magnitude as that which causes initiation of breathing under normal conditions was reached Hence, it appears that the CO_2 level does not at all influence the level of ventilation when breathing is being maintained by the hypoxic stimulus Christensen (1954) comments that it is difficult to see how Gray's multiple factor theory can explain an unchanged ventilation when the alveolar and arterial P_{CO_2} are changed between 21 and 33 mm Hg at a constant alveolar P_{O_2} It seems possible that just as P_O is not a factor in respiratory regulation when it is above a certain level, P_{CO_2} may not be a factor at all when it is below a certain level The interaction of chemical stimuli in driving respiration is discussed in detail in the recent review by Leusen (1969) He concludes that the influences of $P_{A_{CO_2}}$ and cH are additive, whereas the combined effects of $P_{A_{CO}}$ and $P_{A_{O_2}}$ cannot be equated to an algebraic sum of the effects of the two stimuli As shown by Eyzaguirre and Lewin (1961) and Eyzaguirre and Koyano (1965) the number of impulses elicited by a given change in $P_{A_{CO}}$ or in cH in the peripheral chemoreceptors is maximal in the presence of a low local P_{O_2} but minimal when the P_{O_2} is very high, thus it appears that the effect of high P_O is virtually to block the stimulant effect of increased P_{CO_2}

Immediate respiratory responses to exposure to a given reduction in P_{O_2} in inspired air are of lesser degree than those which are seen after chronic exposure Acclimatization occurs so that during prolonged exposure pulmonary ventilation is increased, as indicated by a further lowering of the alveolar P_{CO_2} beyond that observed initially Rahn and Otis (1949) suggest that a rise in alkalinity of the blood due to decreased oxyhemoglobin saturation inhibits the respiratory stimulation that would be expected to result from the decrease in P_{O_2} per se Regardless of the mechanism of acclimatization which occurs during chronic exposure to lowered P_{O_2} in inspired air, when it has occurred, there is increased pulmonary ventilation, lowered alveolar P_{CO_2}, increased alveolar P_{O_2} beyond that observed initially, and a lowered alkali reserve During the process of acclimatization, alkali is removed by urinary execretion The pH of the blood is within the normal range It appears that other more complex changes in respiratory control are involved in the gradual adjustments to hypoxia For example, the alveolar P_{CO_2} which is lowered initially may return to or even exceed the level in normal subjects at sea level, hence sensitivity of the regulatory mechanism to CO_2 must have become readjusted In short, in acute hypoxia the CO_2 drive may be largely or completely eliminated, but it must be assumed that the CO_2 drive is in some degree restored during acclimatization

Other Patterns of Ventilation

MECHANISMS OF HYPERPNEA DURING EXERCISE

During exercise pulmonary ventilation increases, and the rise is proportionate to the amount of increase in muscular activity Since an increased rate of production of CO_2 and of acid metabolites and an increased rate of utilization of oxygen occur as a consequence of increased muscular activity, a priori it is logical to think that the respiratory stimulation is induced by the same three factors which are considered to operate in the resting subject However, a number of studies show that muscular exercise is not regularly associated with either a decrease in arterial P_{O_2}, or a rise in arterial P_{CO_2} or cH In individual experiments none of these factors shows a change during exercise in the direction needed to elicit increased respiratory activity (Grodins, 1950)

The P_{CO_2} of *mixed venous* blood is increased and the P_{O_2} decreased during exercise, but no respiration-influencing receptor located on the *venous* side of the systemic circuit has been demonstrated (The presence of bodies similar to the aortic bodies around the pulmonary artery and receiving a blood supply from it have been described, and if such receptors exist they might be expected to elicit stimulation of breathing during exercise) There is evidence that respiration is stimulated reflexly by im-

pulses arising in the working muscles or the joints which are acted upon by these muscles Still another possibility is that during voluntary activity impulses are directed in descending nerve tracts into the respiratory center to exert a stimulant effect, but there appears to be no evidence that this is the mechanism (see Kao in Cunningham and Lloyd, 1963) In any case it appears that accessory respiratory drives are brought into play during exercise so that increased ventilation may occur even before a change in P_{CO_2}, P_{O_2} or cH have had time to occur at the sites upon which these stimuli act The factors which are concerned in the stimulation of breathing, which most respiratory physiologists believe must be present in exercise over and above that related to the three chemical stimuli which operate under resting conditions, are referred to by Grodins (1950) as the *exercise stimulus* It is probable that afferent influences from various sources are concerned and also that chemical excitants not yet identified play a role

PERIODIC BREATHING

Under certain conditions irregular or "periodic" breathing may develop There are two major types Biot's breathing and Cheyne-Stokes breathing In Biot's breathing there are periods of variable length during which breathing is present, and these alternate with apneic periods of different lengths The transitions from the periods of activity to apnea and back are abrupt In contrast to this in Cheyne-Stokes breathing, although periods of respiratory activity alternate with apneic periods, the amplitude of breathing increases gradually to a maximum and then decreases gradually until the next period of inactivity Biot's breathing has been observed in meningitis and other pathological conditions affecting the medulla Cheyne-Stokes respiration has been observed in a number of different circumstances, some of which are pathological and some physiological (Fig 6 31)

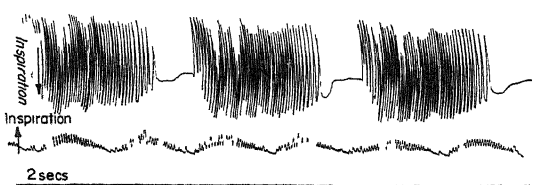

Fig. 6 31 Two examples of periodic breathing (After Lewis)

Cheyne-Stokes breathing occurs in some normal subjects at moderately high altitudes, (for example, 12,000 to 15,000 ft) and it may be seen in normal sleeping infants Experimentally, it may be produced in normal subjects following a prolonged period of voluntary hyperventilation, and it can be produced by having the subject breathe deeply through a tube of a certain length In the latter case, the dead space is increased by a specific amount, and if there is too little or too much increase in dead space, Cheyne-Stokes breathing will not develop Several drugs, notably morphine, may cause the appearance of Cheyne-Stokes breathing The condition is commonly seen in persons suffering from chronic congestive heart failure, and in such cases the periodicity tends to be aggravated by sedation or during sleep

The basis for Cheyne-Stokes breathing after hyperventilation seems to be that oxygen-lack drive appears and then is relieved several times before the P_{CO_2} finally is built back up to levels sufficient to drive normal respiration (see above) The oxygen-lack drive presumably is elicited reflexly from peripheral chemoreceptors However, there is evidence that two or more types of initial defect may cause Cheyne-Stokes breathing For example, during periodic breathing there are also cyclic changes in the blood pressure level, and in some instances the rise in mean arterial blood pressure occurs during the phase of respiratory activity while in other cases the rise in blood pressure is during the apneic phase These two types most likely are related to quite different basic mechanisms The former has been demonstrated to occur in dogs having the sino-aortic baroreceptors and the carotid and aortic bodies denervated or isolated (Youmans and Schopp, 1957) hence, chemoreceptive drive could not have been a factor It is still probable, however, that the other type of periodicity is dependent upon a seesawing between reflex and central drives

Guyton et al (1956) have described experiments in which Cheyne-Stokes breathing was produced if the time required for blood to flow from the heart to the brain was prolonged by increasing the length of the channels Since circulation time is increased in chronic heart failure, this may be the change that leads to periodic breathing in patients suffering from this condition

Eyster (1906) produced periodic breathing in dogs by elevating the intracranial pressure His records show that breathing occurred when

blood pressure rose above the level of the intracranial pressure, and apnea was present when the pressure was below this level In clinical cases with increased intracranial pressure, Eyster observed the same pattern of cyclic changes in respiration and blood pressure as that produced experimentally in dogs

DYSPNEA

Dyspnea literally means difficult breathing When the respirations cannot be carried out with ease and practically unconsciously, the individual is said to be dyspneic The term therefore implies a subjective element Dyspnea thus differs from hyperpnea The latter term means simply increased pulmonary ventilation, and this may occur quite unconsciously or if the subject is aware of the augmentation of the breathing, there is not necessarily any sensation of difficulty or distress When the hyperpnea becomes extreme and yet leaves the need for which it has been instituted unsatisfied, discomfort or distress is experienced, and the term dyspnea is applicable Meakins offers the following concise definition "Dyspnea is the consciousness of the necessity for increased respiratory effort "

Since the respiratory and circulatory functions are directed toward the acquisition of oxygen and the elimination of carbon dioxide, dyspnea may result if either of these functions be disturbed to such an extent that the normal gaseous exchanges cannot be accomplished On the other hand, the oxygen requirement and the carbon dioxide production may be so great that the *normal* respiratory and circulatory mechanisms find difficulty in meeting the demands of the moment Or again the supply of oxygen itself may be inadequate as a result of a low oxygen tension in the atmosphere (e g , high altitudes) In considering the causes of dyspnea we must, therefore, in many instances look beyond the lungs themselves

The fundamental or immediate causes of dyspnea can in most instances be reduced to the following categories *1*) Stimulation of the respiratory center either *a*) reflexly from the peripheral chemoreceptors (anoxia or increase in H-ion concentration due to fixed acids), *b*) directly, by CO_2 excess, *c*) a combination of *a* and *b* as in asphyxial states, or *d*) by impulses from cerebral centers or by afferent impulses, especially of a painful character, from abdominal or peripheral regions *2*) Hypersensitivity of the Hering-Breuer reflex, thus bringing about earlier inhibition of the inspiratory phase and causing, as a consequence, a more rapid shallow type of breathing

The abnormal conditions chiefly associated with dyspnea are

1) Prevention of adequate oxygenation of the blood in the lungs (arterial hypoxia, chap 5)

2) Interference with the transport of the respiratory gases Anoxia of the hypokinetic or anemic type *a*) slowing of the circulation as in cardiac failure, *b*) severe anemia, breathlessness chiefly on exertion

3) Restriction of the action of the diaphragm or intercostals

4) *Acidosis*, reduced alkali reserve or retention of CO_2

5) Increased metabolism

6) *Nervous conditions*, e g , emotional disturbance, neurasthenia, hysteria, encephalitis, or the direct stimulation of the respiratory center by cerebral tumor, hemorrhage or edema

Dyspnea Due to Pulmonary Diseases. Dyspnea is a feature of various respiratory diseases as follows

1) In some instances, e g , laryngeal or bronchial obstruction and asthma, the dyspnea is due to a combination of anoxia and CO_2 retention

2) In other instances owing to the reduced distensibility of the lungs resulting from edema, congestion, inflammation, fibrosis, etc the Hering-Breuer reflex is thought to be abnormally sensitive

3) Limitation of the movements of the diaphragm and chest wall In emphysema, for example, owing to the loss of lung elasticity the resting position of the chest is one of nearly full inspiration The diaphragm is fixed and the thorax elevated Any further enlargement of the chest entails unusual effort on the part of the intercostal muscles (see also chap 3) and the enlistment of the accessory muscles of respiration Expiration involves active contraction of the expiratory muscles

Cardiac Dyspnea. Dyspnea upon exertion is a symptom in patients having certain chronic pulmonary and heart lesions, e g , mitral stenosis Stimulation of the carotid and aortic bodies by oxygen want or of the respiratory center by carbon dioxide excess probably is not in most cases responsible for the dyspnea, since the oxygen saturation of the arterial blood may not be reduced to any important degree, and the

carbon dioxide tension is within or even below the normal range, and cardiac output may be normal Pulmonary engorgement leading to diminished distensibility of the lung is considered to be the prime cause of cardiac dyspnea Although the reduction in the vital capacity may be roughly proportional to the dyspnea, the two do not bear the relationship of cause and effect Due, however, to the diminished distensibility—the stiffness of the lung—a greater inspiratory effort is expended in breathing the extra volume of air which the muscular exertion demands The recoil of the lung is also moderately reduced so that expiration instead of being a passive act may require the aid of the contraction of expiratory muscles The intrapleural pressure, therefore, instead of remaining "negative" throughout the respiratory cycle may become positive toward the end of expiration (Christie and Meakins, 1934) The reduced distensibility possibly also has the effect, as already mentioned, of increasing the sensitivity of the Hering-Breuer reflex with the production of shallow breathing

When pulmonary edema supervenes in patients with congestive heart failure, interference with the uptake of oxygen and the production of arterial hypoxia (stimulation of carotid body) may possibly be a factor Hindrance to the absorption of oxygen, caused by the presence of exudate in the alveoli and the edematous swelling of the alveolar walls, is accompanied by little or no interference with the elimination of carbon dioxide, this is probably due in part to the much greater solubility of carbon dioxide than of oxygen and, in consequence, to the freer diffusion of the former gas through the edema fluid In congestive heart failure arterial hypoxia with a normal or even a subnormal carbon dioxide content of the arterial blood may exist, even in the absence of pulmonary edema

Experimental support can be cited for the view that reduced distensibility of the lungs as a result of congestion is an important factor in cardiac dyspnea It has been mentioned elsewhere (Chap 6) that distension of the pulmonary bed causes rapid shallow breathing

Though there is much to be said for the reflex origin of cardiac dyspnea, not all are agreed as to its paramount importance. Another possibility is that the hyperpnea and dyspnea of the cardiac patient *during rest* are due to reduced blood flow through the respiratory center, resulting in a high CO_2 tension, and possibly to the accumulation of acid products of its own metabolism

Orthopnea In congestive heart failure with dyspnea at rest the breathlessness is usually more pronounced in the recumbent than in the sitting position When propped up with pillows, the patient may be comfortable but becomes dyspneic when he lies down Many theories have been advanced in attempts to explain the less difficult breathing in the upright position Among these are

a) removal of the weight of the abdominal viscera which interferes with the descent of the diaphragm in the recumbent position, *b*) reduction in the intracranial venous pressure and the improved draining of blood from the medulla and in consequence, augmentation of the flow through the respiratory center, *c*) draining of blood from the pulmonary circuit This is probably the most important factor The vital capacity is less in the recumbent than in the sitting posture This is true even for the normal person, but in cardiac cases the effect is accentuated by the pulmonary vascular engorgement and decreased distensibility of the lung induced by recumbency

Cardiac Asthma (Paroxysmal Nocturnal Dyspnea) In some patients with severe chronic congestive heart failure acute dyspnea which may terminate in pulmonary edema comes on during the night The patient has a feeling of suffocation He assumes the upright position and may go to the window for air These attacks are related to excessive engorgement of the lungs with blood so that pulmonary capillary pressure rises to the point of producing transudation into the alveoli As indicated above, the volume of blood in the lungs increases when one changes from the upright to the recumbent position Patients with chronic heart failure already have an elevated venous pressure which increases further when they recline The key question is with regard to the fact that paroxysmal nocturnal dyspnea comes on after a delay usually of several hours since the effects of changing from the upright to the recumbent position insofar as they are related to gravity might be expected to occur within seconds or minutes. The clue to this problem probably is provided in the observation that edema fluid in patients with congestive heart failure is transferred from the interstitial spaces into the blood, and a rise in blood volume occurs slowly during the night. This leads to a further elevation of venous and pulmonary cap-

illary pressure The paroxysm could be set off in two ways The pressure in the pulmonary capillaries could rise to the point of producing transudation and hence impairment of exchange of O_2 and CO_2 On the other hand, the venous pressure might reach the critical level at which overdistention of the heart would result in a decrease in the output of the heart Once this occurs a vicious cycle is produced decreased output leads to further elevation of venous pressure, and elevation of venous pressure leads to further overdistention of the heart and decreased output In either case the change to the orthostatic position would be beneficial in that the blood would tend to remain in the dependent part of the body and thus decrease the volume and pressure of blood in the heart and lungs Also, it should be noted that acute cardiac decompensation, produced by exceeding the critical pressure on the curve which relates cardiac output to venous pressure, leads to a rise in pulmonary capillary pressure and hence to acute pulmonary edema

Anemia. The anemic subject at rest typically is not dyspneic The hemoglobin, though reduced in amount, becomes saturated with oxygen in the lungs The oxygen tension and consequently the quantity of the gas in simple solution in the arterial blood are normal The arterial blood of a patient whose hemoglobin is 30% of the normal value will, however, contain only a little over 6 volumes % of oxygen In the healthy resting body the blood in its passage through the capillaries gives up about 5 volumes % If the velocity of blood flow through the tissues in anemia were the same as during health, a unit volume of blood would tend to give up an equivalent amount of oxygen If this occurred there would be a reserve of only 1 volume %, i e , the venous blood would be almost completely reduced, and the tissues including the carotid and aortic bodies, would suffer at all times from anoxia The circulation rate (cardiac output) is, however, increased in severe anemia so that each unit of blood gives up a smaller proportion than that of its oxygen load The chemoreceptors apparently are not stimulated, and the patient is not dyspneic while resting, even though his hemoglobin is greatly reduced Not only is the output of the heart increased, but a redistribution of the blood flow occurs The vessels of the skin are constricted, and a greater proportion of the total blood volume is driven through other regions The extent to which the circulatory readjustments can compensate for the blood defect is limited, therefore during exertion the extra demand for oxygen cannot be met Oxygen want follows, the respiratory mechanism is stimulated, hyperpnea and dyspnea result

It is to be remembered that in anemia the carriage of carbon dioxide may also be interfered with since hemoglobin plays an important role in the transport of this gas (see sect 4, chap 1)

Increased Metabolism. Exercise may bring about a great increase of metabolism Reflexes initiated in the active muscles and possibly the irradiation of impulses from the motor cortex are thought to play an important part in the hyperpnea of exercise (p 6–57) As the severity of the exercise is increased, hyperpnea merges into dyspnea The athlete and the untrained person differ widely in respect to the degree of muscular exertion which will produce this physiological type of dyspnea The difference depends upon the following factors

Vital Capacity In the average normal man the pulmonary ventilation increases from four to five-fold before the dyspneic point is reached The athlete on the other hand, since his vital capacity is greater, shows a correspondingly greater increase in his pulmonary ventilation before dyspnea supervenes The existence of any pulmonary condition which reduces the vital capacity will depress the level of the dyspneic point

Circulation Rate The trained man's circulation rate increases to a greater degree than the untrained, and so more oxygen is delivered to his tissues

Neuromuscular Integration Coordination of the several muscles in a given muscular act is more precise in the trained than in the untrained man There is thus less waste of effort In the performance of a given amount of work, therefore, the untrained man consumes a greater volume of oxygen, i e , he is a less efficient machine

A pathological increase in metabolism, e g , hyperthyroidism, fever, etc , does not, in the absence of some respiratory or circulatory abnormality, cause dyspnea during rest The increase in metabolism would need to be around 300% before dyspnea might be expected to occur and such a metabolic level is never reached in these or any other pathological condition Nevertheless, in hyperthyroidism, dyspnea will follow upon a degree of exertion which would cause no distress in a healthy per-

son, for the greater metabolic rate, due to the disease, added to that of the exercise will increase the metabolism sufficiently to raise the pulmonary ventilation above the dyspneic point The dyspnea of hyperthyroidism, when pulmonary and cardiovascular complications are absent, therefore, is like that of anemia, in that it is evident only upon exertion

Acidosis. The importance of pulmonary ventilation in resisting a rise in the hydrogen ion concentration of the body fluids has been dealt with elsewhere (Sect 4, chap 11) Nonvolatile acids, e g , lactic in muscular exercise, β-hydroxybutyric and acetoacetic acids in diabetes, and retained acids in nephritis, react with bicarbonate The alkali reserve becomes reduced, but the ratio,

$$\frac{H_2CO_2}{NaHCO_3} = \frac{1}{20}$$

is maintained through the stimulating effect of CO_2 upon the respiratory center It is thus that the CO_2 of the alveolar air (and so of the arterial blood) is kept at a level proportional to the reduction in the denominator of the equation When this can no longer be effected, i e , when the hydrogen ion concentration of the blood rises, the acidosis being then uncompensated, the center is stimulated both directly and through reflexes initiated from peripheral chemoreceptors

The production of fixed acids in diseased conditions rarely causes such a high degree of hyperpnea that dyspnea results, unless the circulatory and respiratory mechanisms are very inefficient or the metabolic rate is increased According to Means the "alkali reserve" must drop to around 12 volumes % before dyspnea supervenes as a result of the acidosis itself In milder grades of acidosis, however, dyspnea occurs upon exertion The hyperpnea due to the increased metabolism of the exercise is then added to that due to the acidosis, with the result that the dyspneic point is soon reached

In severe diabetic acidosis *air hunger*, or Kussmaul breathing, may be seen in the comatose patient

Carbon dioxide retention may, as in emphysema, be accompanied by a compensatory rise in bicarbonate and a normal blood reaction (compensated CO_2 excess), dyspnea is not a notable feature in this condition In other instances of CO_2 retention, compensation is incomplete (uncompensated CO_2 excess or gaseous acidosis) and dyspnea results In others, again, the CO_2 retention is due to the depression of the respiratory center itself, as in morphine narcosis, in such instances, although compensation is incomplete, dyspnea of course does not occur

5 / HYPOXIA, ASPHYXIA, DYSBARISM, OXYGEN THERAPY, AND RESUSCITATION

Types of Hypoxia

The terms *hypoxia* and *anoxia* are synonymous, although the former etymologically is more suitable Both terms are in common use and will be used interchangeably in the following discussion The most useful definition of hypoxia is that it refers to any condition in which there is an inadequate *supply* of oxygen to the tissues According to this definition it is synonymous with *oxygen lack* or *oxygen want* Upon the basis of three quite different categories of causes Barcroft classified anoxia into *anoxic*, *anemic*, and *stagnant* types The categories described by him still need to be differentiated, but changes in the names of two of them seem to be preferable A fourth type, caused by cyanide (p 6-78) and known as histotoxic anoxia, was added by Peters and Van Slyke, however, there is no oxygen lack in this case, but rather inability of the cells to utilize the oxygen brought to them, with the result that oxygen tension of the tissues is actually elevated Hence, it would seem to be preferable not to classify cyanide poisoning as a form of hypoxia For reasons which will become apparent in the subsequent discussion *arterial hypoxia* is preferable to anoxic anoxia in Barcroft's classification, and *hypokinetic hypoxia* is a better term for stagnant anoxia The three major types of oxygen lack, together with the principal causes of each are listed below Also, it should be realized that two or more of these types or causes can be present simultaneously, and each type may be either acute or chronic

OXYGEN LACK
MAJOR TYPES AND CAUSES

Arterial Hypoxia. Arterial hypoxia *is characterized by a lower than normal* Po_2 *in arterial blood* (Oxygen capacity of blood and rate of blood flow are normal or elevated)

A Low Po_2 in inspired air
  1 Altitude
  2 Breathing in closed space[1]
  3 Breathing artificial gas mixture containing lower Po_2 than that found in atmospheric air

B Decreased pulmonary ventilation
  1 Airway obstruction[1]
  2 Weakness or paralysis of respiratory muscles[1]
  3 Depression of respiratory center by drugs[1]
  4 Pneumothorax

C Inadequate oxygenation in (abnormal) lungs
  1 Poor mixing[1]
  2 Impaired diffusion (alveolar-capillary block)
  3 Bronchiolar constriction (asthma)[1]
  4 Filling of alveoli with fluid Pulmonary edema, pneumonia, pulmonary hemorrhage, drowning[1]

D Venous-arterial shunts Various types of cardiac or vascular abnormalities in which unoxygenated blood is mixed with oxygenated blood

Anemic Hypoxia. Anemic hypoxia *is characterized by a lowered oxygen capacity of the blood* (The Po_2 of arterial blood and rate of blood flow are normal or elevated)

A Less than normal hemoglobin content *Anemias* of all types
B Hemoglobin combined with something other than oxygen, e g , *carbon monoxide*
C Hemoglobin altered so that it cannot combine with O_2 *Methemoglobin* found after poisoning with chlorates, nitrites, ferricyanides, acetanilid, etc

Hypokinetic Hypoxia. Hypokinetic hypoxia *is characterized by a decreased rate of blood flow*

A Generalized Congestive heart failure, hemorrhage, shock, etc
B Localized Vasospasm, thrombosis, embolus

[1] Arterial Pco_2 is increased

Some confusion has arisen in the use of the term *anoxemia* In some of the medical dictionaries and textbooks it is defined as synonymous with arterial hypoxia while some authors (Comroe and Dripps, 1950) use it as referring to a diminution of oxygen in the blood whether it be related to decreased Po_2 or decreased hemoglobin

Comroe (1965) and Lambertsen (1968) believe that the designation of another type of tissue anoxia as overutilization anoxia is needed This is to refer to a decrease in Po_2 in tissues related to increased utilization of oxygen by the tissue, as in severe muscular exercise Also Lambertsen (1968) suggests the name "hypotonic anoxemia" for arterial anoxia and "isotonic anoxemia" for anemic anoxia

Asphyxia. *Asphyxia* refers to conditions in which hypoxia is combined with *hypercapnia*—an increased CO_2 tension in the arterial blood and hence in the tissues also It will be noted that a number of the causes of arterial hypoxia also lead to hypercapnia, while in some cases, notably at altitude, hypercapnia is not a factor The opposite change, a lowered CO_2 in the body, is referred to as *hypocapnia* or *acapnia* The reactions in asphyxia are related to effects of decreased arterial and tissue Po_2 and increased arterial and tissue Pco_2 Asphyxia of some degree is present in a number of those conditions listed in the classification of causes of oxygen lack, since elimination of CO_2, as well as uptake of oxygen, is impaired Respiratory stimulation and dyspnea are prominent, and the stimulation is derived from both the lowered Po_2 and increased Pco_2 Cyanosis, being related to the presence of an increased amount of reduced hemoglobin in the blood in the cutaneous capillaries (p 6–78), also is characteristic of asphyxial states as well as those in which arterial anoxia is present without hypercapnia Blood pressure tends to be elevated due to the stimulant action of CO_2 on the vasoconstrictor center, except in the terminal stages Chronic adjustments to asphyxia include the increase in erythrocyte count, hematocrit, hemoglobin, and oxygen capacity of the blood, which are induced by the lowered Po_2 tension, and renal excretion of acid to compensate for the rise in cH produced by retention of CO_2

TENSIONS AND VOLUMES PER CENT OF OXYGEN IN THE BLOOD IN HYPOXIA

In the *arterial* type of hypoxia both the Po_2 and the volumes per cent of O_2 are lowered The blood has a normal or elevated O_2 capacity (20 volumes % or more), but it is not exposed to Po_2 which is high enough to produce the usual degree of saturation (95 + %) However, even though the blood is carrying less than a full load of O_2, when it reaches the capillaries in tissues which are functioning at a lower than normal oxygen tension it may unload as much oxygen/100 ml of blood as occurs normally That is, normally about 20 volumes % would be present in the arterial blood and 15 volumes % in mixed venous blood, while in arterial hypoxia arterial blood capable of holding 20 volumes % might actually contain 15 and give off 5 so that the mixed venous blood would contain only 10 volumes %. In the latter case 50% desaturation of hemoglobin would be produced at the tissue level as compared with 25% in the normal

In *hypokinetic* hypoxia both the Po_2 and volumes per cent of O_2 in the arterial blood are normal, however, as the blood flow through the tissues is slower than in the normal state and the cells continue to use oxygen at an essentially normal rate, the Po_2 in the tissues becomes lowered, and this causes the unloading of more O_2 per unit volume of blood flowing through the tissues In very active tissues which are subjected to a severely deficient blood flow, virtually all of the oxygen in the blood delivered to the tissue may be extracted This indicates that the Po_2 in such tissues approaches zero Such a situation can not exist for more than a very short time before damage to the tissue results

Hypokinetic hypoxia may be generalized as in conditions in which the cardiac output is significantly reduced below the level which would be present in a normal subject under similar circumstances On the other hand a localized reduction in blood flow may occur in specific tissues or organs and lead to reduction in or losses of functions of the involved organ Myocardial infarction, however, is an example of localized hypoxia resulting in loss of a function which leads to generalized hypoxia and worsening of the hypoxia in the myocardium

In *anemic* hypoxia the arterial Po_2 is normal so that saturation of hemoglobin approaches 100%, but the volumes per cent of O_2 carried is reduced in proportion to the reduction in the amount of hemoglobin Hence, if blood carrying, for example, 10 volumes % of O_2 at full saturation of the hemoglobin gives up 5 volumes %/100 ml of blood flowing through the

tissues, it is apparent that the O_2 in the tissues is so low as to cause 50% desaturation Again this is to be contrasted with the normal state in which, on the average, only about 25% desaturation occurs as blood flows through the tissues

Arterial Hypoxia at Altitude

Arterial hypoxia, uncomplicated by hypercapnia, is observed in individuals breathing air at high altitudes or in decompression chambers Knowledge of both the acute and chronic adjustments to altitude is of great interest since man ascends rapidly in airplanes or resides for years at levels of 15,000 to 18,000 ft

The per cent composition of atmospheric air is the same at altitude as at sea level But the barometric pressure decreases with altitude It is noteworthy that at an altitude of 18,000 ft the barometric pressure is about 380 mm Hg or one-half of that at sea level The oxygen tension, therefore, is diminished to one-half of that at sea level, since the Po_2 at any altitude is calculated by multiplying the barometric pressure by 0 2094 Thus, a second vertical scale showing oxygen tension could be derived simply by multiplying each of the figures in the barometric pressure scale by 0 2094

At altitude as one breathes air containing a lower Po_2 than that of air at sea level the alveolar Po_2 becomes lowered The decrease in alveolar Po_2 at altitude if severe enough is counteracted in part by an increase in pulmonary ventilation, although this response is not as prominent immediately as it is after some delay

Conditions at altitude can be simulated in an air tight chamber from which the air has been partially evacuated At a given barometric pressure a certain altitude is simulated as far as gas tensions are concerned Chambers have been constructed in such a way that they may be very rapidly, i e , explosively, decompressed and the reactions of the subject followed from moment to moment. During acute exposure to simulated altitude, produced by rapid decompression of a chamber containing the subject, alveolar ventilation is increased so that alveolar Pco_2 is lowered, and the amount of decrease is proportional to the reduction in ambient pressure (increase in altitude) For example, shortly after decompression to a simulated altitude of 18,000 ft the alveolar Pco_2 is in the range of 27 $\pm$ 2 mm Hg, and the alveolar Po_2 is in the range of 42 $\pm$ 3 mm Hg The alveolar Po_2 is less than half that found at sea level At this point it should be noted that the water vapor tension in alveolar air, being determined by body temperature which is constant, remains at 47 mm Hg at all altitudes, and when expressed in terms of percentage, it increases in direct proportion to the decrease in total pressure in the alveoli For example, at sea level the percentage of water vapor is $47/760 \times 100$ whereas at 18,000 ft it is $47/380 \times 100$ At an altitude where the barometric pressure is only 74 mm Hg, water boils at body temperature and the alveoli are filled with water vapor

Immediately after sudden exposure to altitude, respiratory adjustments occur, however, conditions continue to change from one 5-min period to the next for a period of 30 to 60 min (Riley, Otis, and Houston, 1954) Some of the bases for these changes already have been discussed

The immediate circulatory adjustments to acute arterial hypoxia are an increase in heart rate and blood pressure, the cyanosis that appears is a result of an increase in the amount of reduced hemoglobin in arterial blood The amount of desaturation can be estimated from the alveolar Po_2 and the oxygen-hemoglobin dissociation curve

In the normal subject breathing air (about 21% O_2) about 95% saturation of the hemoglobin of arterial blood with oxygen is attained In a person breathing air at any given altitude somewhat less than 95% saturation would occur but might be achieved if the O_2 percentage in inspired air were increased sufficiently It is found that at 18,000 ft it would be necessary to breathe about 45% O_2 in order to attain 95% saturation, and at about 34,000 ft , 100% O_2 is needed It follows that at altitudes higher than 34,000 ft some degree of arterial hypoxia will occur even when the subject breathes pure O_2, and at very high altitudes intolerable degrees of oxygen lack would be experienced even when breathing 100% O_2 The limit at which aviators can fly in nonpressurized cabins breathing 100% O_2 is in the range of 40,000 to 45,000 ft Above this level cabins containing gases under pressures higher than that of the ambient air are required

Several mountain climbing expeditions have been made in the past by different groups of physiologists for the purpose of studying the effects of low oxygen tensions upon the respiratory functions and of determining the factors underlying the phenomenon of acclimatization An expedition was made to Monte

Rosa (15,000 ft) in 1894 by Mosso and by others subsequently, to the peak of Teneriffe (12,000 ft) in 1910 by Zuntz, Barcroft, and associates, and in 1911 to Pike's Peak (14,100 ft) by the Anglo-American expeditions of which Haldane, Douglas, Henderson, and Schneider were members In 1921 to 1922 Barcroft headed a party to Cerro de Pasco (14,200 ft) in the Peruvian Andes A Himalayan expedition was led by Hartman in 1931, and in 1935 Dill led a party to the Chilean Andes Pugh (1957) reported observations made on Mt Everest during the successful British expedition of 1952

GENERAL SIGNS AND SYMPTOMS

Airplane ascents, if made rapidly without the use of oxygen, may result in sudden loss of consciousness due to the reduction in oxygen supply to the brain When the ascent is made more slowly, or the altitude is not so great as to cause immediate loss of consciousness, the aviator may at first experience sensations of excitement, exhilaration and well being As higher altitudes are reached effects of a more serious nature develop, often insidiously Mental and sensory dullness, muscular weakness, headache, vomiting, cyanosis, dyspnea, and perhaps a tendency toward periodic breathing may be induced A common and dangerous effect is the development of fixed ideas which may result in the performance of foolhardy and ill-judged actions

When a person climbs to a mountain height, the time taken in the journey allows a certain degree of physiological readjustment to take place, and the symptoms are usually less intense But, as in the case of the aviator, mental features, e g , a feeling of elation, exhilaration, talkativeness, and sometimes emotional outbursts, laughing or crying, quarrelsomeness, or the development of fixed ideas are prominent Mental tasks, e g , calculations, memory tests, and telling the time from the mirror image of a clock face are performed less efficiently Similar effects upon the mind are produced upon persons exposed to low oxygen pressures within a steel cabinet The mental effects as pointed out by Barcroft are not unlike those caused by drunkenness To quote his words,

"Alcohol affects different persons in different ways, so on my journeyings in high altitudes I have seen most of the symptoms of alcoholism reproduced I have seen men vomit, I have seen them quarrel, I have seen them become reckless, I have seen them become morose I have seen one of the most disciplined of men fling his arms about on the ledge of a crevasse to the great embarassment of the guide I have seen the most loyal companion become ill-tempered and abusive to the point at which I feared international complications would arise "—Lessons from High Altitudes

Complete prostration may follow the earlier symptoms If the individual remains at the high altitude the symptoms pass off after a time, as he becomes acclimatized to the low oxygen tension

At a simulated altitude of about 20,000 ft (i e , in a decompression chamber) most subjects experience failing vision, incoordinations, and inability to write or to execute simple mental tasks within 15 min or so after the extra oxygen supply has been cut off, at 26,000 ft none are able to retain "effective consciousness" for this length of time without oxygen

CHANGES ASSOCIATED WITH ACCLIMATIZATION

At an altitude of 14,200 ft as at Cerro de Pasco where Barcroft and his party carried out their investigations, the barometric pressure is around 440 mm Hg The partial pressure of oxygen is therefore about 92 mm Hg The oxygen tension of the alveolar air is not as far below that of the atmosphere as at sea level, and varied among the greater number of the party from 55 to 60 mm Hg The closer approximation of the atmospheric and alveolar oxygen tensions at high altitudes is due to the increased breathing which is brought about through the action of the lowered oxygen tension in the blood The oxygen tension is slightly lower in the arterial blood than in the alveolar air which indicates that the passage of the gas is due purely to diffusion and not to an active secretion by the pulmonary epithelium If this occurred, as had been suggested (Haldane), one would expect the arterial oxygen tension to be higher than that of the alveolar air Alveolar carbon dioxide tension also, as a result of the increased pulmonary ventilation, is lower than that at sea level, it varied in different individuals of Barcroft's party from 23 to 29 mm Hg At 14,200 ft the arterial blood is from 85 to 88% saturated with oxygen

A marked increase in the number of red cells (see sect 4, chap 3) and a corresponding increase in hemoglobin content of the blood occur at high altitudes The blood volume is also augmented The natives of mountainous regions

have a red cell count of from 6 to 8 million/mm^3 The greater quantity of hemoglobin of course raises the oxygen capacity of the blood and so tends to compensate for its lowered oxygen saturation That is, the *total* oxygen content of the arterial blood tends in spite of the low saturation to rise Nevertheless, it may not be evident at first sight how a rise in the oxygen capacity is of advantage, for blood of normal hemoglobin content even when only 80% saturated possesses a quantity of oxygen which is quite adequate for the needs of the tissues It has already been pointed out, however, that the important factor in supplying the tissues is the oxygen pressure gradient between the plasma in the capillaries and the tissue cells So then, if there are a greater number of red cells, each will be required to give up less of its oxygen store in passing through the capillaries to furnish a given quantity of oxygen (see anoxia due to anemia, p 6-80) Consequently, the saturation and the oxygen tension of the venous blood will be maintained at a higher level than otherwise would be possible This means that the mean intracapillary oxygen pressure will also be higher, and as a result the tissues are more effectively supplied with oxygen

The reduction in the alveolar carbon dioxide results in a corresponding decrease in the carbon dioxide tension of the arterial blood The ratio $H_2CO_3/NaHCO_3$, which tends to be altered by the loss of carbon dioxide, is adjusted by a decrease in the excretion of acid and ammonia in the urine, a consequent lowering of the "alkali reserve" and depression of the CO_2 dissociation curve (p 6-15) The actual pH of the plasma changes little if at all Up to about 12,000 ft if any change occurs it is toward the alkaline side, above this level the blood reaction shows little further change or tends to return to normal Lactic acid, which was thought at one time to be produced in excess as a result of the anoxia, is actually formed in smaller amounts at high altitudes than at sea level Even during severe exercise at 15,000 ft and higher altitudes, the lactic acid concentration in the blood is lower than during exercise of comparable severity at sea level

Barcroft and his party observed a shift to the left in the oxygen dissociation curve of hemoglobin, i e , the affinity of hemoglobin for oxygen was increased The shift in the dissociation curve is ascribed by Barcroft to an increased alkalinity of the *interior of the red cell* This increased alkalinity is in turn a direct result of the rise in the number of red cells The buffering power of the blood is increased through the greater facility offered for the action of the "chloride shift" mechanism (pp 6-11 and 6-18) In other words when a given amount of carbon dioxide is liberated by the tissues, it is distributed among a greater number of red cells than under normal circumstances, therefore, the alkalinity of each cell is reduced to a proportionately less extent There have been conflicting reports concerning this question of the shift in the oxygen dissociation curve Some observers have been unable to confirm Barcroft's finding, while others claim that a shift to the right occurs It appears that up to about 14,000 ft the affinity of hemoglobin for oxygen increases, but at higher levels the dissociation curve tends to assume the form found at sea level, and at altitudes of 19,000 ft there is a definite shift to the right

One might suppose that an increased circulation rate would be an important adjustment to the rarefied atmosphere, whereby an adequate oxygen supply to the tissues would be maintained, but except for a temporary increase during the first few days, no change in cardiac output occurs at altitudes of less than 14,000 or 15,000 ft Above 15,000 ft the greater degree of anoxia results in an increase in the minute output of the heart Before acclimatization, the pulse rate during rest increases by from 15 to 20 beats/min at altitudes between 15,000 and 18,000 ft At greater altitudes, especially in persons in poor physical condition, the increase in rate may be greater than in the normal The blood pressure shows little or no change up to 15,000 ft , a small rise may occur at higher altitudes

Those who have lived all their lives at very high altitudes (around 14,000 ft) have a larger vital capacity than dwellers at sea level Moderate altitudes, up to about 7500 ft , appear to have little or no effect upon the chest development

Although anoxia is the most serious effect of high altitudes with which the mountain climber or aviator has to contend, rapid ascents, as by airplane, cause other important physiological disturbances which should be mentioned, namely *1*) expansion of gases in the gastrointestinal tract, *2*) aeroembolism (see below), and *3*) pressure disturbances in the ears

Expansion of Gases in the Gastrointestinal Tract Like the gases of the atmosphere those in the stomach and intestine increase in volume in proportion to the reduction in pressure Gas having a volume of 1 liter at sea level expands to 2 liters at the pressure (375 mm Hg) existing at 18,000 ft , to 4 liters at 34,000 ft , to 6 liters at 42,000 ft (pressure 128 mm Hg) Distention of stomach and intestine will

result unless the abdomen is supported by a belt or other means, or the gases are freely evacuated In rapid ascents distress or even severe pain results if there is any hindrance, as by an obstruction in the colon, to the ready passage of flatus

Dysbarism

The term *dysbarism*, or decompression sickness (see Behnke, 1965), refers to the signs and symptoms which result when the total pressure of ambient gases suddenly is reduced It refers to the effects of reduction in pressure as such Dysbarism is seen in deep sea divers or caisson workers when they pass too quickly from the high pressure in which they have been working to the ordinary pressure of the atmosphere, hence the name *caisson* disease has been used The "bends" is a popular name for the condition In dysbarism the *percentage* reduction in pressure is a more important factor than the absolute amount of decrease A sudden reduction in pressure to approximately 45% of the pressure with which the subject was equilibrated ordinarily is necessary in order to cause dysbarism A diver who has been exposed to a pressure of, for example, 8 atm usually can be subjected to a quick reduction in pressure to 4 atm without developing symptoms, then after he has been at this pressure long enough to approach equilibrium with the surrounding pressure he can be quickly lowered to 2 atm where he remains for a time and next the pressure can be lowered to 1 atm

The cause of symptoms during rapid decompression is the formation of bubbles of gas in fatty tissues and blood The gas is mainly nitrogen The total amount of nitrogen dissolved in the body when one is exposed to a gas mixture having the same percentage composition as atmospheric air is several times that of O_2 and double that of CO_2. Also, nitrogen diffuses less readily and, unlike O_2, it is not used in metabolic processes When body fluids are saturated with N_2 at a given pressure and the ambient pressure suddenly is lowered, N_2 is evolved in gaseous form just as CO_2 is evolved from carbonated water when the cap is removed from the bottle containing it Bubbles in the blood tend to lodge in the smaller vessels and obstruct the flow of blood Symptoms vary depending upon the sites where the bubbles lodge Fatty tissue usually is the site of bubble formation since N_2 is five times more soluble in oil than in water The involved tissues include subcutaneous tissue, bone marrow, adrenal cortex, myelin sheaths, etc Bubbles in the myelin sheaths of sensory nerves cause pain (bends), paresthesias, itching, etc , and those in myelin sheaths of motor nerves may cause temporary paralysis It has been recognized for many years that obese persons are more susceptible to "the bends" than lean persons

In rapid ascents in airplanes, dysbarism is not a problem up to 20,000 ft since the reduction in pressure is less that 55%, and, in fact, symptoms ordinarily do not appear below 30,000 ft Above this level, however, dysbarism is common The tendency to develop decompression illness is greater the more rapid the ascent The most effective way to prevent or diminish the effects of rapid decompression is to have the aviator breathe 100% oxygen or an oxygen-helium mixture for a time before the flight and thus wash much of the nitrogen out of the body When this is done the aviator should be able to ascend quite rapidly to 40,000 ft (continuing to breathe 100% O_2) without discomfort

The effects of aeroembolism in flyers during rapid ascent take the form most commonly of severe pain in one or more of the large joints and itching of the skin or cutaneous sensations of heat or cold Other more serious symptoms such as paralysis, intense burning pain in the chest, or pulmonary edema may, though rarely, occur. The symptoms are rarely as severe in the decompression which occurs in ascent of altitude, as they are in compressed air illness, since the amount of gas which can be released is not as great

The *explosive decompression* technique which is used to study adjustments to lowered P_{O_2} in the inspired air also is useful in the study of dysbarism A rate of ascent can be simulated in this way which is much faster than any which has been attained even in rockets Many thousands of flying personnel have been subjected to explosive decompression The subject is instructed to breathe with mouth open As the gas in the lungs expands during decompression it rushes out through the open airway Gas in the sinuses also expands suddenly and exhausts through the natural channels, but if these openings are not patent severe pain is produced

Experimental animals have been found to have an astonishingly high tolerance to explosive decompression at simulated high altitudes (from sea level to 50,000 ft —750 to 87 mm Hg) The rate of decompression in the experi-

ments of Whitehorn and his associates ranged from about 1100 mm Hg/sec to as high as 33,000 mm Hg or more/sec That is to say, decompression from 750 mm Hg to 87 mm Hg was brought about in the latter instance in 0 02 sec Then the animal was quickly recompressed and the effects of anoxia thus prevented The chief effects observed in these experiments were distension of the hollow viscera and lungs, fixation of the expanded thorax in the inspiratory position and of the diaphragm in the expiratory position, due to upward pressure of the distended stomach and intestines, sharp but temporary fall in blood pressure with cardiac slowing, hemorrhages into lungs and hollow organs, or rupture of the latter The fall in blood pressure seems to be due to decreased cardiac filling caused by the increased intrathoracic pressure, due in turn to the rise of the diaphragm The cardiac slowing does not occur after bilateral section of the vagus nerves In no instance out of some 700 decompressions on several different species of laboratory animal did a fatality occur from a single decompression The injuries which are most likely to occur from explosive decompression are damage to ears and lungs, though rupture of the stomach or intestine may result

Respiration in a Sealed Cabin

In flight beyond the earth's atmosphere the passengers must be in a sealed compartment The total pressure of gases in the compartment could be reduced quickly to one half that at sea level without causing any difficulty in normal subjects providing the Po_2 were kept up to a level sufficient to prevent arterial hypoxia This could be done if the percentage of O_2 were about 35 to 40 at a cabin pressure of 380 mm of Hg However, it may be argued that it might be preferable to maintain ambient gases at the level normally encountered at sea level The atmospheres within manned aerospace capsules launched by the United States, prior to the fire which resulted in the death of three astronauts, consisted of 100% O_2 at one-third of an atmosphere This results in an oxygen tension of 250 mm Hg in inspired air or well above the 150 mm Hg which normally is inspired at sea level A disadvantage of this may be the greater fire hazard, and the oxygen tension above normal could lead to decreased erythropoiesis The presence of some amount of an inert gas such as nitrogen or helium would help prevent atelectasis and could have other advantages not yet apparent After all, the human body has evolved over thousands of years to survive in a mixture consisting largely of nitrogen At present it is being planned that the occupants of a space station who will spend weeks in an artificial atmosphere will breathe a gas mixture at one atmosphere that has a percentage composition with respect to oxygen and nitrogen not much different from that of the atmosphere The question of the optimal composition of the ambient atmosphere to be maintained in a manned space station was discussed fully in a conference conducted by the Space Science Board (see Carlson, 1967)

Average values for the daily metabolic turnover of a "standard" man are presented in Table 6 6 (compiled by H G Clamann, United States Air Force School of Aviation Medicine, Randolph Field, Texas) Calculations of what supplies must be taken in a sealed cabin for trips of any duration can be made on the basis of such data

Pneumonia

In *lobar pneumonia* the oxygen saturation of the arterial blood varies in different cases from normal to less than 70% The signs and symptoms of anoxia usually appear when the saturation is around 85% Cerebral symptoms, e g , sleeplessness and delirium, cyanosis and dyspnea increase with the oxygen desaturation In lobar pneumonia the carbon dioxide content of the arterial blood is reduced on the average by about 15% (Meakins and Davies) The "alkali reserve," however, is normal or only slightly reduced The blood pH may in some cases be increased From these findings it appears that there exists a partially compensated alkalosis, induced by the hyperventilation (blowing off of carbon dioxide) elicited by reduced oxygen tension of the arterial blood The increased ventilation of the alveoli also increases the percentage of oxygen in the alveolar air, but this cannot, as we shall see presently, increase appreciably the oxygen in the arterial blood.

In *bronchopneumonia* a higher degree of oxygen desaturation of the arterial blood is usually present than in the lobar type The cyanosis may be extreme There is often *retention* of carbon dioxide and a rise in plasma bicarbonate results, to compensate, in part at least, the gaseous acidosis The carbon dioxide

Table 6 6

content of the arterial blood may be 80 vol % or more

The Causes of Hypoxia in Pneumonia Two main factors concerned in the production of the hypoxia are the passage of blood through unaerated (consolidated) portions of the lung and shallow breathing Typically the blood of pneumonia patients has a normal oxygen capacity and the oxygen dissociation curve at a given carbon dioxide tension is not appreciably different from that of normal persons

In *lobar pneumonia* during the stages of engorgement and red hepatization the alveoli of the affected portion of the lung are poorly aerated Mucus blocks the bronchioles, and the *air spaces* are filled or their walls coated with exudate But a large proportion of the vessels of these unaerated regions are still pervious Consequently, blood traversing such areas must remain poorly oxygenated This blood with a low oxygen saturation and a high carbon dioxide content mixes with blood which has passed through aerated regions The general arterial blood therefore has its oxygen saturation reduced in proportion to the amount of unsaturated blood with which it is mixed (see also "Shunt," p 6-76) When the pneumonic area passes into the stage of gray hepatization the vessels of the affected lobe become obliterated to a large extent and the pulmonary blood then passes through aerated regions (Fig. 6 32). That is, the arterial blood is no longer vitiated by blood from nonaerated areas Therefore in a typical case of lobar pneumonia when the disease is confined to a single large area and the breathing is not shallow, there is little anoxemia at this stage. If however, bronchopneumonic areas coexist, the respiratory functions will be affected as described below (See "Oxygen Therapy," p 6-81)

In *bronchopneumonia*, patches of lung tissue are cut off from their air supply The fine bron

Fig 6 32 X-ray photograph of lung (injected with barium) from a case of lobar pneumonia (after Gross) *Upper right* Consolidated area—red hepatization The main vessels are constricted and the finer vascular structure is less dense than in the normal lung *Lower right* Consolidated area—gray hepatization The main vessels are patent but the finer vessels have been occluded *Lower left* Healthy portion of lung except for compensatory congestion, the vessels are dilated

chioles become plugged with mucus, groups of alveoli become filled with exudate, and the alveolar walls are edematous and thickened Yet, obliteration of the vessels to any great extent does not occur Blood continues to flow through unaerated areas This blood which has a low Po_2 on mixing with that from aerated alveoli lowers the saturation of the general arterial blood

Shallow Breathing In pneumonia breathing is frequently very rapid and shallow Instead of the tidal air being around 500 ml as in health it may be reduced to 250 ml or less It will be recalled that about 150 ml are required to fill the anatomical dead space, therefore only 100 ml will enter the air sacs of the healthy parts of the lung The expansion of the lungs is not equal in all its parts The alveoli toward the hub of the radiating rays expand less than those near the periphery Those parts, such as the apex, which are indirectly expanded have even in health a tendency to be ventilated less than those which are directly expanded In shallow breathing, these differences are greatly exaggerated Although the tidal volume is only half the normal, the total quantity of air breathed per minute (minute volume) is, as a result of the increased respiratory rate, much greater than normal Since a proportion of the alveoli are very poorly ventilated or not at all, owing to the unequal expansion of the lung, those in other areas tend to be overventilated The O_2 tension in the latter is therefore raised But so far as the oxygenation of the blood is concerned, the overventilation of some alveoli cannot make up for the underventilation of others We know that the hemoglobin is nearly saturated already at the ordinary alveolar oxygen tension of 100 mm Hg As already mentioned the dissociation curve of hemoglobin in pneumonia does not differ appreciably from that in health, and the most, therefore, that could be expected from a rise in the alveolar O_2 tension would be an increase of 2% or less in oxygen saturation of the blood traversing overventilated regions and a slight increase in the amount of O_2 held in simple solution In other words, the blood flowing through the poorly ventilated parts of the lung will have a low saturation since the O_2 tension is low, while that flowing through the overventilated parts will be little above the normal The net result will be a low oxygen saturation of the mixed arterial blood

Matters are different in the case of CO_2 elimination The shape of the CO_2 dissociation curve which shows a progressive slope throughout the entire range of CO_2 tensions is quite unlike that for oxyhemoglobin (Fig 6 33) The greater total ventilation results in a lowering of CO_2 tension in the overventilated parts of the lung and, consequently, in a "blowing off" of CO_2 from the blood circulating through these regions CO_2 is retained in the blood circulating through poorly ventilated regions In the patient with lobar pneumonia the amount of CO_2 blown off may exceed that retained, the net result will be a lowering of the CO_2 content of the arterial blood In bronchopneumonia a larger proportion of the pulmonary blood circulates through nonaerated areas As a consequence, CO_2 retention is greater, and a normal or a higher than normal CO_2 content of the blood is more usual

The Cause of Shallow Breathing in Pneumonia Pleuritic pain, by restricting the respiratory excursions, may result in this type of breathing In other instances it may be of a reflex nature resulting from the inflammatory process which, through a reduction in the distensibility of the pulmonary tissue perhaps exalts the sensitivity of the afferent vagal endings

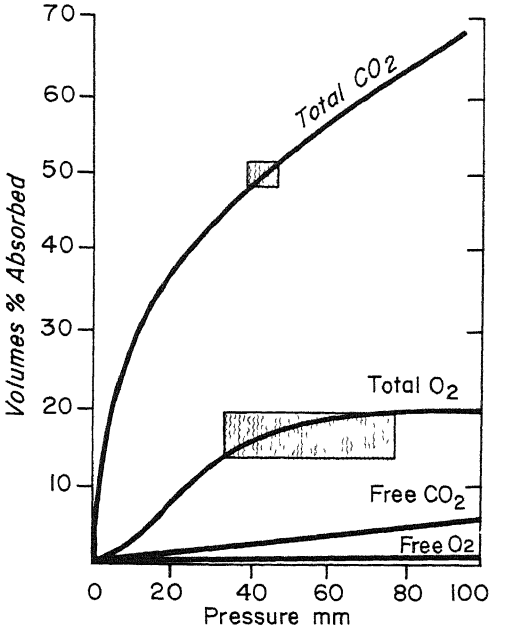

Fig 6 33 Carbon dioxide and oxygen dissociation curves The small rectangles indicate the extent of the variation of the O_2 and CO_2 of the subject s blood when at rest (From L J Henderson 1928)

in the alveolar walls Thus the inspiratory movement possibly is terminated before a full excursion has been completed (see Hering-Breuer reflex, p 6-47) In support of a reflex origin may be mentioned the experiments of Dunn and of Binger, Brow, and Branch who produced this type of breathing in animals by the intravenous injection of potato starch granules These, acting as small emboli, plugged the pulmonary capillaries The rapid shallow breathing was immediately abolished by section of the vagi or prevented if the nerves had been cut before the injection Also, in pneumonia it has been found that oxygen inhalations, even though they may restore the oxygen saturation of the arterial blood to normal, do not necessarily abolish the shallow breathing This constitutes further evidence for the existence of a nervous element in the production of this type of breathing Shallow breathing may also result from other diseases involving the alveoli, e g , inflammation by irritant gases (phosgene and chlorine), pulmonary edema, miliary tuberculosis, and pulmonary emboli, which would be expected to stimulate afferent nerve endings

Bronchial Asthma

This is a paroxysmal disease in which acute oxygen want is caused by a spasm of the smooth muscles of the finer bronchioles Edema of the bronchiolar mucosa is probably also present The alveoli are poorly ventilated, and some may be completely cut off from their air supply The high percentage of carbon dioxide and low percentage of oxygen in the alveolar air result in a low oxygen saturation of the arterial blood and the retention of carbon dioxide The acidosis related to CO_2 retention is met by the excretion of a highly acid urine and a rise in the "alkali reserve " An intense plum-colored cyanosis may develop The continued stimulating effect of oxygen want and carbon dioxide excess upon the respiratory mechanisms causes severe dyspnea

Difficulty is experienced both in inspiration and expiration, but since there is a natural tendency for the bronchioles to narrow during expiration and dilate during inspiration, the greatest respiratory effort is exerted during expiration The respiratory muscles contract with great force, and the accessory muscles of respiration are brought into play The expiratory muscles compress the chest, the abdominal muscles contract in the attempt to squeeze the air from the lungs The intrapulmonary pressure is greatly elevated, and the air escapes through the constricted tubes with a distinct wheezing sound Due to the difficulty and prolongation of the expiratory phase, normal deflation of the lungs cannot occur before the next inspiration ensues The lungs, therefore, remain somewhat expanded even at the end of expiration That is, during the asthmatic paroxysm a very large volume of residual air is present in the lungs (Fig 6 34) The tidal volume and the vital capacity are greatly reduced The changes in volume of the overdistended lung are small and not commensurate with the excursions of the thoracic walls As a consequence, the high value of the intrathoracic negative pressure induced during inspiration causes the structures at the root of the neck to be drawn toward the thoracic cavity to take up the space which the lungs are unable to fill During expiration the veins of the neck and face become engorged The restricted movements of the lung also greatly reduce the effect of mechanical mixing upon the lung air, the process of diffusion being depended upon to a larger extent for the freshening of the alveolar air

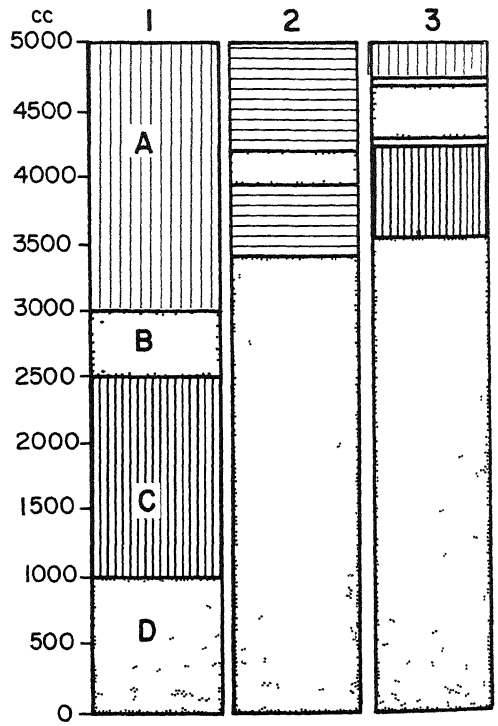

Fig 6 34 Diagram showing subdivisions of the lung air in asthma (2) and emphysema (3) compared with the normal (1) *A* Inspiratory reserve volume *B* tidal volume *C* expiratory reserve volume and *D* residual volume

CAUSATION

Asthma often shows a strong hereditary tendency The bronchiolar spasm may be of a *reflex nature* and due to the stimulation of hypersensitive afferent vagal endings in the larynx, or of trigeminal fibers by some nasal abnormality, the bronchoconstrictor impulses travel via efferent vagal fibers On the other hand, the bronchiolar spasm may be an *allergic phenomenon*, i e , the result of sensitization to some foreign protein This is the most common cause of the condition It is then frequently associated with other allergic conditions, e g , hay fever, urticaria, or eczema either in the patient himself or in members of his family The foreign protein may be inhaled Pollens of various grasses and flowers, the dandruff of animals, e g , horse, cat or dog, or feathers are among the most common excitants, or the exciting cause may be some kind of food or the protein of bacteria within the respiratory tract itself The sensitivity of certain individuals to foreign proteins presents many features resembling those of anaphylactic shock in animals Sudden death may result from the injection of horse serum (e g , diphtheria antitoxin or antitetanic serum) into an asthmatic subject A guinea pig when injected with a protein to which it has previously been sensitized dies rapidly from anaphylactic shock The bronchiolar muscle is strongly contracted The air is trapped so that the lungs are maximally distended and do not collapse when the thorax is opened Even when the pulmonary tissue is deeply incised the air does not escape from the distended lung This manifestation of anaphylaxis is associated with (and perhaps due to) the liberation of histamine It is well known that anaphylaxis and histamine administration produce almost identical effects in the guinea pig (Fig 6 35)

The *treatment* of asthma resolves itself into the relief of the paroxysm and the removal of the underlying cause Epinephrine or ephedrine acts by inhibiting the bronchiolar muscle during the attack Atropine blocks the action of the bronchoconstrictor (vagal) fibers In the allergic form of the disease every effort is made to identify the offending protein Antihistaminic drugs have been employed with varying degrees of success

Chronic Emphysema

The lungs in emphysema (Greek *em* + *physema*, a blowing) are in a state of extreme distention as a result of the enlargement of the air sacs The latter, however, show fewer alveoli in their walls owing to the atrophy of the interalveolar septa Contiguous air sacs within a lobule coalesce or even adjacent lobules may fuse to form large air spaces For this reason the total respiratory surface is reduced The alveolar and capillary walls become thickened and the interstitial pulmonary tissue increased Many capillaries become occluded The pulmonary elastic tissue is reduced in amount so that the lungs, when removed from the thorax, do not collapse normally but remain in an overexpanded state The peripheral lobules, which in health expand to the greatest extent, are those mainly affected in emphysema, the enlarged lobules appearing as blebs upon the surface of the lung

The chest is what is known as barrel-shaped The ribs are more horizontal than normally, the thoracic spine is bowed backwards (kyphosis) so that the anteroposterior diameter of the chest is as great as or exceeds the transverse The position of the chest is one of nearly full inspiration The midposition of the diaphragm is at a much lower level than usual and its excursions above and below this level are restricted The respiration is therefore mainly costal In some instances the diaphragm is practically fixed or indeed may be drawn up during inspiration (paradoxical movement) The residual air is

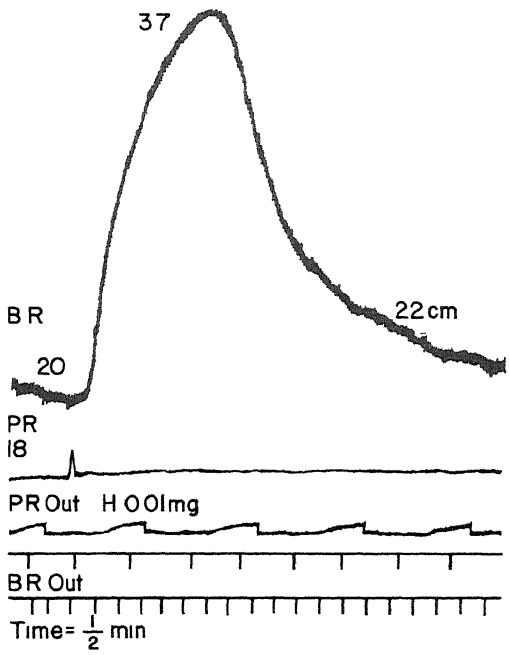

Fig 6 35 Guinea pig Reaction of bronchial muscle to 0 01 mg histamine

two or three times the normal, and the inspiratory reserve volume is reduced The tidal volume is normal or only moderately reduced and the vital capacity (Fig 6 34) is lowered by from 20 to 60% Owing to the loss of the elasticity of the lung, expiration is no longer simply a passive movement but is aided by a forcible contraction of the expiratory muscles When the patient is asked to make a deep inspiration, he does not expel all the air during the next expiration Several respirations occur before the chest returns to its original size Expiratory reserve volume is greatly decreased, and residual volume is markedly increased (Fig 6 34) These phenomena are due to the fact that the inelastic lungs have been overstretched and are brought back to their original volume with difficulty

In emphysema there are arterial hypoxia and retention of carbon dioxide The oxygen saturation of the arterial blood runs from a little below normal to around 75% or even less The carbon dioxide tension in the alveolar air in well-marked cases is from 50 to over 60 mm Hg (7 to 8%) and the carbon dioxide content of the arterial blood is correspondingly high

Owing to the obliteration of many capillaries in the lungs, the resistance in the pulmonary circuit is increased, thus a greater burden is put upon the right ventricle

The cause of the impaired gaseous exchange is not altogether clear Thickening of the alveolar and capillary walls and the obliteration of capillaries have been considered to be factors Yet if this were so one would not expect the retention of carbon dioxide which, owing to its greater solubility (30 times that of oxygen) has a much higher rate of diffusion through the pulmonary membrane, to be so much more pronounced than the anoxia The sharp rebound at the end of inspiration which occurs in the healthy lung causes mechanical mixing of the lung air and is an important factor in the efficient ventilation of the alveoli The absence of this effect in the emphysematous lung and its greater dependence, in consequence, upon the slower process of diffusion is probably an important factor leading to the defective aeration of the blood According to Christie, the impaired gaseous exchange is due mainly to the fact that, as a result of the loss of elasticity, the intrathoracic pressure is not distributed evenly throughout the lung As a consequence, the outlying alveoli which are largely functionless with obliterated vessels are ventilated to a greater extent than the relatively healthy ones more centrally placed Owing to the shapes of the respective dissociation curves such underventilation of the functioning alveoli will tend to have a greater effect in preventing the elimination of CO_2 than in interfering with the absorption of oxygen Other factors which may be concerned, are the slower rate of diffusion of CO_2, owing to its larger molecule, in the alveolar air, and the increased residual volume

The red cell count, hemoglobin content, and consequently the oxygen capacity of the blood, are increased above the normal in emphysema The cyanosis (p 6-78) is often pronounced, yet the patient's dyspnea is less than might be expected from his color and from the carbon dioxide retention which exists This is explained by the well-established fact that in emphysema the respiratory center is less sensitive to carbon dioxide A normal person when breathing a carbon dioxide rich mixture (8%) increases his pulmonary ventilation by 300% or more, the breathing of the emphysematous patient, on the other hand, shows relatively little change as a result of breathing a much stronger mixture (see Fig 6 36)

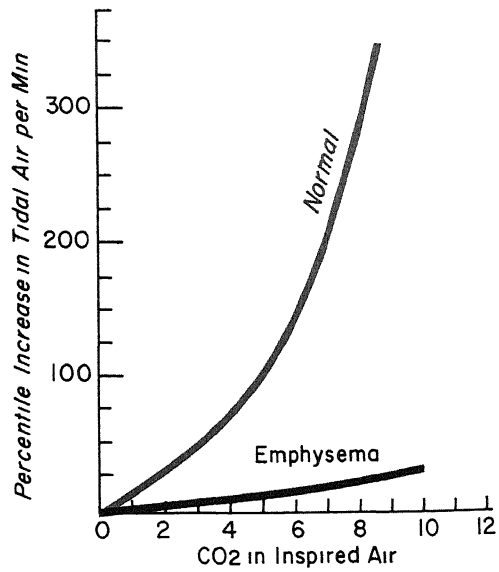

Fig 6 36 Chart showing the percentile increase in tidal air per minute as the percentage of inspired carbon dioxide is raised Note that when the normal subject inspires air containing 8% carbon dioxide the tidal volume is increased about 300% whereas in the emphysematous subject it is increased only about 25% (After R W Scott 1920)

CAUSATION

Two factors are concerned in the production of emphysema *a)* reduction in the elastic tissue of the lung, and *b)* increased distention of the alveolar spaces

It is very questionable whether, in the absence of some abnormality of the lung tissue itself, emphysema can result from increased intrapulmonary pressure, such as occurs in those following certain occupations, e g , glass blowers and the players of wind instruments The study of groups of men following such occupations does not indicate that emphysema is produced in this way Emphysema has, however, been induced in animals by stenosis of the trachea or bronchi or by the insertion of a valved apparatus into the trachea which allowed the free ingress of air but offered an obstruction to expiration

Asthma and chronic bronchitis frequently are forerunners of emphysema In the former condition the spasm of the bronchiolar muscle exerts a valvelike action In chronic bronchitis mucous plugs would act similarly Coughing, it has been supposed, places a strain upon the alveolar walls But during the phase of coughing when the glottis is closed the alveolar walls are supported When the glottis opens, the air escapes from the alveoli if the obstructing material has been dislodged, and no strain upon the alveolar wall would result If, however, the air remains entrapped its sudden re-expansion (rebound), as the pressure in the surrounding pulmonary tissue falls at the end of a cough, may injure the alveolar membrane and start the emphysematous process

What may be termed a physiological or *compensatory* emphysema occurs when part of the pulmonary surface is reduced as by the collapse of a part or the whole of one lung This is more in the nature of an hypertrophy A similar enlargement of both lungs occurs at high altitudes

A type of emphysema also occurs in the elderly—*senile or postural emphysema*—and is secondary to the change in the shape of the thorax which becomes more barrel-shaped and increased in capacity The lungs enlarge to fill the increased space This condition is associated with few symptoms There is little reduction in the vital capacity, and the oxygen saturation of the arterial blood is practically normal

Atelectasis

Any condition which lowers the pressure within the alveoli or increases the pressure upon the lung surface, may lead to collapse of the lung Thus pleural effusions, pneumothorax, tumors, etc , pressing from without or the isolation of the alveoli from their air supply by the obstruction of a bronchus will result in collapse of the lung or of the portion of the lung affected Atelectasis (Greek *ateles*, incomplete, *ektasis*, distention) is also the term applied to the condition in the newborn in which, as a result of the blockage of a bronchus or of a group of bronchioles by mucous secretion, or owing to weak inspiratory movements, a portion of the lung fails to become distended with air

Absorption of Air from Isolated Alevoli and Other Closed Spaces When a bronchus or bronchiole in a previously distended lung is obstructed the imprisoned air soon becomes absorbed from the affected alveoli Collapse of the air sacs cannot take place until this has occurred Absorption is brought about in the following way as pointed out by Henderson The air in the isolated alveoli has a total pressure of 760 mm Hg The partial pressures are in round numbers, O_2, 100 mm , N_2, 570 mm , CO_2, 40 mm , and aqueous vapor, 47 mm In the venous blood the total pressure is 703 mm , the nitrogen and aqueous vapor being the same as that of the alveolar air, but the partial pressure of oxygen is only 40 mm and of carbon dioxide 46 mm An interchange of the latter gases therefore occurs between the alveolar air and the venous blood It might be thought that the imprisoned air would then be in equilibrium with the blood and no further absorption occur But the alveolar air loses more oxygen than it gains carbon dioxide whereupon its volume is reduced The atmosphere acting upon the body surface and through the yielding soft tissues compresses the air so as to maintain its total pressure practically constant at 760 mm As a result of the absorption of oxygen the percentage and consequently the partial pressure of carbon dioxide and of nitrogen are increased These gases now diffuse into the blood The volume of the alveolar air is further reduced thereby, but its total pressure still remains unaltered The percentage and therefore the partial pressure of oxygen rises and more of this gas passes into the blood The process continues in this manner until no air remains, and the walls of the original space are ultimately approximated by the pressure of the atmosphere Air is absorbed from the pleural cavity or from any other closed cavity of the body in the same way (Henderson and Henderson, 1932) The absorption of the air confined within the pleural cavity permits the lung, if the air pressure had caused its collapse, to re-expand

The collapse and shrinkage of the lung which results from blockage of a bronchus increases

the intrathoracic negative pressure, since the closed thoracic box is less completely filled The diaphragm is therefore drawn upwards and uncollapsed portions of the lungs are expanded to a greater extent (compensatory emphysema) in order to fill the unoccupied space

Shunt

In the fetus the vessels of the airless lungs are bypassed by the greater part of the blood brought to the heart That is to say, most of the blood is shunted to the arterial side through channels which normally close at, or shortly after, birth It is clear that if one or more of these channels should persist after birth, or if the interventricular septum is defective so that a large part of the venous blood does not traverse the lungs, but is short circuited from the right to the left heart or directly into the aorta, the oxygen saturation of the arterial blood will be seriously reduced Arterial hypoxia evidenced by cyanosis (p 6-78) and dyspnea (p 6-59) will result (Fig 6 37) These will be especially pronounced upon exertion since the unsaturation of the polluting venous blood will be thereby increased

The Fetal Circulation Before the congenital abnormalities are described, the fetal circulation and the circulatory readjustments which occur at birth, or shortly thereafter, will be briefly reviewed

In the fetus the oxygenated blood from the placenta is carried by the *umbilical vein* to the liver, where it separates into two streams, one of which is distributed to the left two-thirds or so of the liver, the remainder passes directly via the *ductus venosus* into the inferior vena cava, thus mixing with blood returning from the lower part of the body The portal vein supplies the rest of the liver That portion of the blood from the umbilical vein which has traversed the vessels of the liver is also delivered by the hepatic veins into the inferior vena cava The hepatic veins are a number of small vessels and two much larger ones, the latter form a junction with the ductus venosus just before the latter joins the inferior vena cava The blood in the vena cava beyond this point is, therefore, partly oxygenated (from placenta via umbilical vein and ductus venosus) and partly reduced, having traversed the tissues of the lower limbs, intestines, and liver The caval blood, upon reaching the right auricle, separates into two unequal parts The much larger stream passes directly through the foramen ovale (*via sinistra*) into the left auricle, the smaller stream enters the right ventricle The blood which has reached the left auricle, after being joined by a small but by no means inconsiderable volume of blood returned from the pulmonary tissue, flows into the left ventricle, and is discharged into the aorta and distributed to the brain by the brachiocephalic artery, and to the myocardium by the coronary arteries The remainder flows down the aorta

The blood returned from the head and entering the right auricle by the superior vena cava, together with the small fraction of blood of the inferior vena cava which was not directed through the foramen ovale, enters the right ventricle and is ejected into the pulmonary artery A smaller part, yet, as shown by Franklin and his associates, more than has been generally supposed is conveyed to the lungs by two branches of the latter vessels The main stream, discharged from the right ventricle, passes by a wide vessel, the *ductus arteriosus*, into the aorta, and mixing with the blood coming from the left ventricle, is distributed throughout the body That portion which is supplied to the lower limbs is returned by two vessels—the *umbilical arteries*—to the placenta

During birth, or very shortly after, the three umbilical vessels close (even though the cord has not been tied or broken) by the contraction of smooth muscle in the vascular walls The flow through the ductus venosus ceases as a result of contraction of a smooth muscle sphincter at the point where it leaves the umbilical vein This occurs in the sheep fetus, according to Franklin and his associates, in from 5 to 25 min after the umbilical vessels have closed Within 5 min or so after the commencement of breathing the foramen ovale closes, and a little later (apparently never before the obliteration of the foramen ovale) the ductus arteriosus becomes occluded All the blood from the right side of the heart is nor-

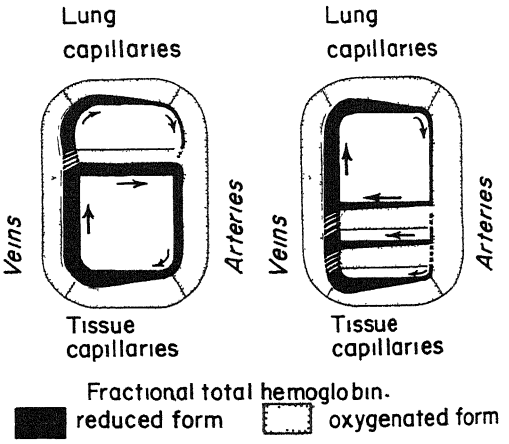

Fig 6 37 Diagram (*left*) showing the proportion of oxyhemoglobin to reduced hemoglobin in different parts of the circulation in an instance where a portion of the blood passes through unaerated channels (shunt) from the venous to the arterial system Righthand diagram represents a case in which the oxygen unsaturation of the blood is abnormally high in a part of the peripheral capillaries but normal in the arterial blood (hypokinetic type of anoxia) (After Lundsgaard and Van Slyke 1923)

mally from now on directed through the lungs Franklin and his associates found, however, in the case of the newborn lamb, that should the general condition of the later seriously deteriorate, the ductus arteriosus may open again The mechanism of closure of the ductus appears to be initiated in some way by the action of the oxygenated blood upon the vascular muscle and not through a nervous mechanism In the lamb this channel has never been observed to close before occlusion of the umbilical vessels (Barclay et al , 1945)

CONGENITAL CARDIAC DEFECTS

Patent ductus arteriosus, or foramen ovale, interventricular septal defects, stenosis of the pulmonary artery and coarctation of the aorta (narrowing of aorta in the neighborhood of the ductus arteriosus) are among the congenital defects most commonly met

The development of the direct Fick method (sect 3, chap 7) (utilizing catheterization of the right side of the heart) for determining the cardiac output has provided means of the greatest value in diagnosing congenital defects of the circulation It is now possible to obtain samples of blood for gas analysis from the right ventricle, the pulmonary artery, and many sites in the systemic circuit, including the left ventricle (See Fig 6 38)

Patent Foramen Ovale or Other Defect in the Interauricular Septum In patency of the foramen ovale, the opening is guarded by a valvelike membrane which prevents blood from passing from the left to the right auricle, and none passes in the opposite direction unless the pressure in the right auricle is high With other defects of the interauricular septum, a shunt from right to left with cyanosis may occur, but if there is mitral stenosis and a large defect (*Lutembacher's syndrome*) the high pressure in the left auricle causes a shunt from left to right

Patent Ductus Arteriosus Blood enters the pulmonary system from the arterial side, the oxygen content in the pulmonary artery is increased, but is normal in the right auricle and ventricle

If a *defect of the interventricular septum* exists alone, the oxygen content of the blood in the right ventricle and pulmonary artery is increased but not of that in the right auricle

Neither of these last two defects, if it exists alone, will cause cyanosis, since the shunt is from left to right (arteriovenous shunt) Rarely, however, in the case of a patent ductus arteriosus, the direction of flow is reversed temporarily at certain times (during crying or coughing), blood passing from the pulmonary artery into the aorta

Often the abnormalities are multiple For example, a patent foramen ovale, together with stenosis of the pulmonary artery, results in the passage of venous blood to the arterial side, i e , through the auricular defect, slight or moderate cyanosis is seen The combination of congenital defects, originally described by John Hunter and later by Fallot, and now generally known as the *tetralogy of Fallot*, consists of, *a*) an interventricular septal defect, *b*) narrowing of the pulmonary artery, or stenosis of its orifice, and *c*) dextroposition of the aorta, the orifice of this vessel being shifted to the right to straddle the septal defect *d*) The fourth element making up the tetrad is right ventricular hypertrophy The blood flow through the lungs and the pulmonary pressure are reduced Owing to the high pressure developed in the right ventricle blood is driven through the defect into the overriding aorta If the pulmonary stenosis is very severe, the ductus arteriosus must be patent in order to provide sufficient blood flow through the lungs to support life Cyanosis and dyspnea are usually pronounced Blalock and Taussig have devised an operation for the correction of the chief effects of these conditions It consists of anastomosing a large branch of the aortic arch (usually carotid or subclavian) to the right or left pulmonary artery

Another combination of defects has three features of the tetralogy of Fallot, namely, defect of the interventricular septum, dextroposition of the aorta and right ventricular hypertrophy, but pulmonary stenosis is absent It is known as *Eisenmenger's complex* The shunt is from left to right in early life, but later, when as a result of the large volume of blood entering the right ventricle from the left side as well as through the normal channels this chamber enlarges and hypertrophies, the high pressure developed may force venous blood into the overriding aorta, cyanosis then appears

In those congenital cardiac anomalies showing

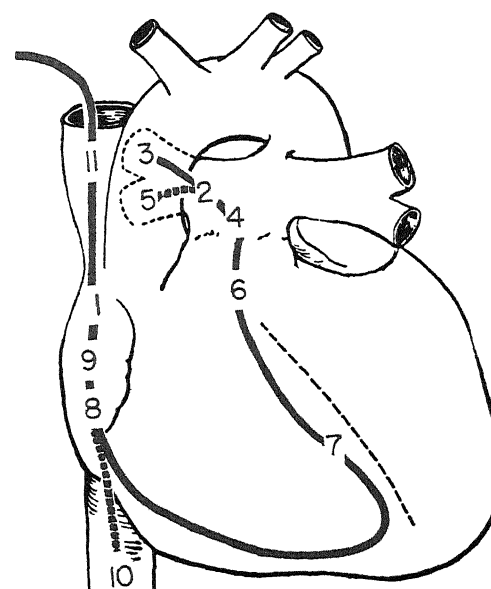

Fig 6.38 Numbers from 1 to 11 indicate the positions from which blood samples may be taken by means of the intracardiac catheter (After Groom et al 1948)

cyanosis, the arterial oxygen saturation is found to be, during rest, from 45% in severer degrees of cyanosis to 90% in the milder cases The red cell count, however, is likely to be increased, and the hemoglobin concentration may be high as 26 g % The arterial oxygen content, i e , the volumes of oxygen/100 ml of blood, in those with the higher hemoglobin concentration is, consequently, much higher than normal and may reach a value of 29 vol %, as against the normal maximum of 22 vol % (see "Cyanosis," below) Exercise, which in normal subjects causes little or no change in arterial oxygen saturation, produces a profound fall in the congenital heart cases, amounting in some to a reduction of over 30%

Carbon Monoxide Poisoning

References to carbon monoxide poisoning are contained in the earliest medical writings This gas was used by the Greeks and Romans for the execution of criminals and as a means of committing suicide Today, carbon monoxide is the most important gaseous poison against which physicians have to contend

The affinity of hemoglobin for carbon monoxide is approximately 300 times its affinity for oxygen Therefore, when the atmosphere contains only a very small percentage of CO, the hemoglobin takes up the poisonous gas and in so doing loses its ability to combine with an equivalent volume of oxygen

Recovery from carbon monoxide poisoning is usually complete when the exposure has not been too long or the concentration too high It is important that the carbon monoxide hemoglobin should be broken up as soon as possible since injury to the tissues is produced by the anoxia It is possible to displace the carbon monoxide by oxygen if the tension of oxygen is sufficiently high and that of carbon monoxide low Mixtures with a high percentage of oxygen and from 6 to 7% carbon dioxide combined with artificial respiration are used in the treatment of CO poisoning The carbon dioxide, as well as acting as a respiratory stimulant, reduces the affinity of hemoglobin for carbon monoxide Recently, administration of oxygen under pressures greater than 1 atm has been advocated by Smith (1965) Carbon monoxide, as well as its action in displacing oxygen from hemoglobin, has histotoxic properties, inhibiting the tissue respiratory enzymes This fact has no practical bearing, however, upon carbon monoxide poisoning in man, for the concentrations at which such action occurs is many times greater than could ever occur in the body

Cyanide Poisoning

No interference with oxygen carriage is caused by cyanide, but there is inhibition of tissue respiration Cyanide inhibits the action of cytochrome oxidase carbonic anhydrase and probably of other enzyme systems It follows from this that any antidote for cyanide poisoning must have one of two actions Either the cyanide must be removed or detoxified or the inactivated catalyst must be replaced Methylene blue does act as a catalyst for certain biological oxidations, and this led to its use as an antidote for cyanide poisoning When methylene blue is given to the intact animal, there is a marked rise in body temperature which is due to increased metabolism Sahlin in 1926 provided the first experimental demonstration that methylene blue antagonizes the action of cyanide in the intact animal He used rats and the observation has been confirmed on other animals—dogs, rabbits, mice The evidence suggests that methylene blue acts by removing the cyanide from tissue Methylene blue and cyanide do not combine directly, but methylene blue forms methemoglobin which combines with the cyanide to form cyanmethemoglobin The cyanmethemoglobin is relatively nontoxic and is broken down slowly, the detoxification probably being brought about by conversion of the cyanide to thiocyanate (Smith and Malcolm) Other substances which form methemoglobin (Hug, 1933, Wendel, 1933) such as sodium nitrite, amyl nitrite, pyrogallol, etc , are also effective in the treatment of cyanide poisoning Such methods of course are limited by the quantity of hemoglobin that can safely be converted to methemoglobin

A number of sulphur compounds have been found effective in cyanide poisoning Chen, Rose, and Clowes (1934) showed that sodium thiosulphate and sodium tetrathionate may protect dogs against as much as three times the lethal dose of cyanide

Cyanosis

Cyanosis (Greek, *cyanos*, blue) may be defined as the diffuse, dusky, or bluish color of the skin and mucous membranes caused by the presence in the blood of the superficial capillaries (subpapillary venous plexus) of reduced hemoglobin above a certain definite amount The presence of abnormal compounds of hemoglobin, e g , methemoglobin and sulfohemoglobin, resulting from the action of various toxic substances, causes a type of cyanosis (enterogenous cyanosis), but these will not be considered here (see sect 4, chap 4) Cyanosis may result from anoxia of either the arterial or hypokinetic type It obviously cannot occur in the anemic type, which is due essentially to a low hemoglobin concentration, in the histotoxic type in which the hemoglobin gives up less of

its oxygen store than in health, nor in the arterial and hypokinetic types if a severe grade of anemia exists The retention of carbon dioxide in the blood has no *direct* effect upon the production of cyanosis The blue color of the skin depends fundamentally upon the *absolute* amount of reduced hemoglobin in the capillary blood and *not* upon the *relative proportions* of reduced hemoglobin and oxyhemoglobin For example, in anemia the hemoglobin content of the blood may be only 20% of the normal In the capillary blood all of this could be in the reduced form, yet cyanosis would not result, since the absolute amount of reduced hemoglobin (i e , "blue" pigment) would be insufficient to produce any blue discoloration On the other hand, in polycythemia the hemoglobin may be 100% above normal Cyanosis will occur when the hemoglobin of the capillary blood is only 20% reduced, for the absolute concentration of reduced hemoglobin will then be raised to threshold value The greater quantity of the bright-colored oxyhemoglobin present exerts little or no influence, that is, it does not, as might be expected, tend to neutralize the color effect of the reduced hemoglobin

Normal blood contains about 15 g of hemoglobin/100 ml Lundsgaard found that the capillary blood must contain approximately 5 g of reduced hemoglobin/100 ml before cyanosis will appear When fully saturated (20 volumes %), ¾ g of hemoglobin will take up 1 ml of oxygen Five grams of hemoglobin, therefore, hold about 6 7 ml of oxygen, and 5 g of reduced hemoglobin are formed when the blood contains 13 3 volumes % of oxygen Cyanosis may therefore be expected to appear when the blood in the capillaries is on the average around 7 volumes % unsaturated As a result of certain modifying factors the precise level of capillary unsaturation at which cyanosis makes its appearance varies in different cases between 6 and 7 volumes per cent of oxygen

The oxygen unsaturation of the capillary blood does not of course occur abruptly at the arterial end but is progressive from point to point along the course of the vessel The loss of oxygen may be uniform from the arterial to the venous end of the capillary as shown in curve 1, Figure 6 39, or the desaturation may occur mainly toward the venous end (curve 2) when the capillary blood would approximate arterial blood in its content of reduced hemoglobin Under other circumstances the greatest oxygen loss may occur toward the arterial end (curve 3) when the unsaturation of the capillary blood throughout would approach that of venous blood It is difficult to obtain data from which the true curve may be drawn The simplest of these curves (curve 1) is assumed and the average unsaturation of the capillary blood is taken as midway between that of arterial and venous bloods respectively Thus

$$\tfrac{1}{2}(A + V) = C$$

where A and V represent the unsaturation in volumes per cent of arterial and venous bloods, respectively and C the average unsaturation of the capillary blood

For example, in a normal person the arterial unsaturation is 0 5 volume % (19 5 volumes % saturation), another 5 vol % are given up in the capillary, the venous unsaturation is therefore 5 5 volumes % So

$$\tfrac{1}{2}(0\ 5 + 5\ 5) = 3\ 0 \text{ volumes \% average unsaturation of capillary blood}$$

$$(3\ 0 \times 0\ 75) = 2\ 2 \text{ g reduced Hb}$$

We have seen that the average unsaturation of the capillary blcod must be between 6 and 7 volumes % (approximately 5 g of reduced Hb) before cyanosis appears This degree of unsaturation of the capillary blood may be brought about either by an increase in the arterial unsaturation (arterial type of anoxia) or as a result of a greater amount of oxygen being lost from the blood in its passage through the capillaries (hypokinetic type of anoxia) That is, by an increase in the venous unsaturation (V) alone

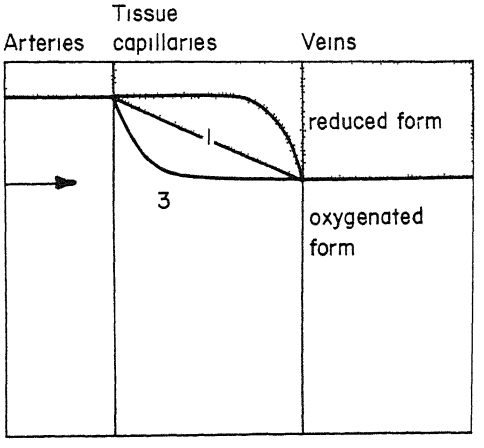

Fig 6 39 Diagram showing hypothetical variations in the shape of the reduction curve of oxyhemoglobin during the passage of the blood through tissue capillaries (After Lundsgaard and Van Slyke 1923)

In order to produce an average unsaturation of from 6 to 7 volumes % in the capillary blood the arterial unsaturation would need to be from 4 to 4 5 volumes %, or the unsaturation of the venous blood—that in the arteries being normal —11 to 13 volumes %. Meakins and Davies (1920) found that when the veins of the arm were obstructed in normal individuals cyanosis was just detectable when the venous blood reached an unsaturation of 11 4 volumes %.

These facts may be clarified by examples. If the blood as it leaves the lungs contains only 15 5 volumes % of oxygen, i e , if it has an unsaturation of 4 5 volumes % and the tissues abstract the usual quantity of oxygen, namely 5 volumes %, the unsaturation of the venous blood will be 9 5 volumes % and that of the capillary blood

$$\tfrac{1}{2}(4\ 5 + 9\ 5) = 7 \text{ volumes } \%$$

$$(7 \times 0\ 75 = 5\ 2 \text{ g Hb})$$

If on the other hand the arterial unsaturation is around the normal value of 0 5 volume % but as a result of slowing of the circulation each unit volume of the blood gives up a greater quantity of oxygen, and the venous unsaturation is increased to say 13 volumes %, the average unsaturation of the capillary blood will be

$$\tfrac{1}{2}(0\ 5 + 13) = 6\ 7 \text{ volumes } \%$$

In either of these instances slight cyanosis would be expected to appear.

Let us now consider what occurs when the hemoglobin percentage is above or below the normal value.

In *anemia* the amount of hemoglobin is below normal, and the oxygen capacity of the blood is correspondingly lowered. If the hemoglobin content be only 30% of the normal, the volumes per cent of oxygen in the arterial blood, though the latter be fully saturated, will be only about 6 volumes %, i e , the quantity of hemoglobin in 100 ml of blood is less than 5 g. It is obvious that such a person could not become cyanotic even if all his hemoglobin were in the reduced state. A patient whose hemoglobin was, say, 60% (oxygen capacity 12 volumes %) would, like one with a normal hemoglobin content, become cyanotic when his arterial blood reached an unsaturation of about 4 5 volumes %, that is when his capillary blood had an average unsaturation of around 7 volumes %. But the oxygen want of the anemic subject would be greater than that of the subject with a normal hemoglobin content since in the case of the former 4 5 volumes % constitute nearly 40% of the oxygen capacity of his blood. In a less enlightened age when bleeding was resorted to for the relief of cyanosis, the brilliant success of that procedure is not to be wondered at—nor that the patient died. In the hypokinetic type of anoxia the unsaturation of the venous blood of a subject with 60% hemoglobin content could not reach the value necessary to produce cyanosis until all the hemoglobin was in the reduced state. Thus ½(1 + 12) = 6 5 volumes % unsaturation of the capillary blood.

In *polycythemia*, in which the hemoglobin content is, say, double the normal (oxygen capacity 40 volumes %), cyanosis occurs in very mild degrees of anoxemia. At an arterial unsaturation of 4 5 volumes % the polycythemia subject would have the same degree of cyanosis as an ordinary person with this quantity (5 g) of reduced hemoglobin in his blood. But in the polycythemic subject with a hemoglobin content of 200%, 4 5 volumes % is only 11% of the oxygen capacity of his blood, in the person with a normal hemoglobin content it constitutes 22 5%. The oxygen want in the former would be relatively slight as compared with that of the latter. Or put in another way and including the anemic subject—if the anoxemia were of the same degree in each, the anemic person would show little or no cyanosis, the polycythemic, a cyanosis of high degree and the normal subject a color intermediate in intensity. In a person with an abnormally high blood count a degree of slowing of the peripheral blood flow which would be without effect upon one possessing a normal hemoglobin content will result in cyanosis. Thus in regions such as the face, ear lobes, and hands, where the cutaneous vessels are well filled with blood, cyanosis is readily induced in the polycythemic subject by exposure to cold. In certain conditions associated with arterial anoxemia, e g , emphysema (p 6-73) and congenital heart disease, the red cell count is increased, and the cyanosis, in consequence, enhanced. It will be evident from these examples that the presence of cyanosis indicates anoxia but the absence of cyanosis does not rule out the possibility of anoxia.

THE FACTORS WHICH INFLUENCE THE DEPTH OF CYANOSIS CAUSED BY A GIVEN QUANTITY OF REDUCED HEMOGLOBIN

The State of Cutaneous Capillaries When these are dilated more of the dark-colored blood will be present in the skin than when they are constricted In the former instance cyanosis will of course be more pronounced Increased carbon dioxide tension in the peripheral blood causes capillary dilation, therefore, when retention of this gas accompanies oxygen want, as in venous congestion of superficial regions, etc the cyanosis is intense If the peripheral vessels are strongly constricted, as in shock, cyanosis may be inconspicuous

Pigmentation and Thickness of the Skin These factors obviously will modify the depth of the cyanotic color Cyanosis is more clearly evident in regions where the skin is thin and unpigmented The yellow discoloration of the skin caused by an excess of bilirubin in the blood (jaundice) tends to modify the cyanotic tint, but since the former stains the skin itself, while the discoloration due to reduced hemoglobin is confined to the capillary vessels, jaundice is likely to be just as intense in regions where the skin is thick as in those where it is thin The cyanotic discoloration can be temporarily abolished by pressure upon the skin whereas the icteric staining cannot Cyanosis does not appear in the conjunctivae but these are deeply colored in jaundice

Therapeutic Procedures· Oxygen Therapy

Oxygen administration is of great value in combating acute arterial anoxia as may occur in pneumonia, pulmonary edema, or obstruction to breathing, as well as in states such as congestive heart failure, or coronary thrombosis when, though the arterial blood contains the usual amount of oxygen, the tissues, owing to impairment of the circulation, suffer from a deficiency of oxygen

The chronic anoxia due to anemia, in which the hemoglobin is saturated with oxygen to the normal degree, is treated preferably by measures directed to the disease itself rather than by oxygen therapy In failure of the circulation, the inhalation of 100% oxygen will increase the oxygen content of the blood to revive a flagging respiratory center But the anoxia due to a shunt of blood from the right to the left side of the heart (p 6-76) or through a similarly completely unaerated portion of the lung will not be much benefited by oxygen inhalations, it is not possible to make the blood supplying healthy and well-aerated alveoli absorb any important amount of *extra* oxygen and so compensate for the shunted blood

When, however, the diffusion coefficient of oxygen (chap 6 1) through the alveolar membrane is reduced as a result of edema, thickening, or a coating of fluid, oxygen administration by raising the pressure of the gas in the alveolar air will increase its rate of diffusion across the pulmonary epithelium The oxygen saturation of the blood flowing through the damaged pulmonary tissue is increased

Consequently, in broncho- or lobar pneumonia when such changes are responsible for the anoxemia, in emphysema or in pulmonary edema whether from cardiac or pulmonary disease or from gas poisoning, the success of oxygen administration is often spectacular Anoxemia possibly promotes an increase in transudation of fluid into the alveoli In other words, a vicious circle may be established—edema inducing anoxemia and the latter increasing the edema—which is broken by oxygen administration

Anoxemia due to rapid *shallow breathing* is relieved by oxygen treatment since the oxygen tension of poorly ventilated alveoli is raised thereby The shallow breathing itself is likely to persist since it is primarily due to the local process in the lung acting upon the nerve endings rather than to the anoxemia Therefore, this type of breathing could, no more than the pulmonary lesion itself, be expected to be abolished by oxygen treatment

It has been said that when the arterial blood contains the normal quantity of oxygen, namely about 19 5 volumes $^{c}_{o}$ (saturation 97 5$^{c}_{c}$) as in the hypokinetic type of anoxia of congestive heart failure, oxygen inhalation cannot be of any great value, since the oxygen saturation can be raised only to 100%, and the total oxygen content increased by 2 2 volumes $^{c}_{c}$ (an increase of 1 7 volumes in simple solution together with 0 5 volumes combined with hemoglobin) That is, the total oxygen content of a person breathing 100% oxygen will be 21 7 volumes %. But this increase of 2 2 volumes $^{c}_{c}$

(representing an increase in O_2 content of 11%) is as pointed out by Comroe and Dripps (1950) of the highest importance in anoxia, for it raises very considerably the pressure at which oxygen is delivered to the tissues For example, when a patient is breathing ordinary air, every 100 ml of blood in passing through the capillaries loses 7 volumes of O_2 (normal about 5 vol), and, therefore, leaves the venous end of the capillary with a content of 12 5 volumes %, is 63% saturated, and has a Po_2 of around 32 mm Hg Now when 100% oxygen is breathed the extra 2 2 volumes % in the arterial blood is given up on entering the capillaries, which reduces the oxygen saturation only to that existing under ordinary conditions in the arterial blood, namely, 97 5% But the tissues owing to the slowing of the circulation abstract a further 4 8 volumes % to satisfy their need of 7 volumes % The venous blood, therefore, contains 14 7 volumes % of oxygen, and is over 73% saturated, instead of about 63% without oxygen administration, the Po_2 is nearly 40 mm Hg Thus the tissues are supplied with oxygen at a virtually normal head of pressure In congestive heart failure, therefore, especially if there is generalized edema, the administration of oxygen is often of great benefit

METHODS OF ADMINISTRATION

Oxygen is given usually by means of a nasal or oral-nasal catheter, by a specially designed face mask, or the patient is placed in a hood-tent or airtight cabinet in which the O_2 percentage is maintained at the required concentration Carbon dioxide (5 to 10%) is sometimes added, especially in CO poisoning, persistent hiccough and postoperative atelectasis, in order to encourage lung expansion In an oxygen tent the patient's own breath may raise the CO_2 to the range of 1 to 2%

In normal persons the breathing of 100% oxygen often causes a slight initial reduction of breathing of about 3% In anoxia, a much more pronounced depression or even complete cessation of breathing may occur This so-called *oxygen apnea* may be very alarming, especially during anesthesia But it is a sure indication of the existence of anoxia and the need for oxygen therapy Before oxygen administration the center had been driven by impulses from the peripheral chemoreceptors, the relief of the anoxia has abolished this source of stimulation In chronic anoxia, such as may be seen in congestive heart failure and pulmonary emphysema, especially when there is also carbon dioxide retention, the patient may pass into coma when oxygen is administered The unfavorable effects following administration of O_2 under these conditions are attributable to the further rise in Pco_2 which occurs as a result of the depression of breathing

Another effect of oxygen inhalation is the elimination of nitrogen A man of average weight (70 kg) breathing oxygen eliminates about 18 ml of nitrogen/min The rate of removal of the gas from all tissues is not however the same, it is removed most rapidly from the blood and the most vascular parts of the brain Pure oxygen is, therefore, administered to divers to prevent decompression sickness, and to pilots before high altitude flights

Helium (atomic weight 4, ⅛ density that of nitrogen) is lighter than any other gas except hydrogen Barach has applied this physical fact to reduce the respiratory effort in asthmatic attacks, in those suffering from laryngeal or tracheal obstruction and in certain other types of dyspnea A gas mixture is used in which helium is substituted for nitrogen (oxygen, 21%, helium, 79%) For the relief of anoxemia the oxygen percentage may be increased to 60 or 70%

Effects of Prolonged Breathing 0 5 to 1 Atmosphere of O_2 Ill effects other than the "oxygen apnea" described above may result from prolonged administration of oxygen Commonly subjects complain of substernal distress in 4 to 16 hr after beginning to breathe 100% O_2 at sea level The symptom usually persists for some hours after the patient resumes breathing of atmospheric air The pain evidently is related to tracheobronchitis, and it is not a problem unless oxygen tension in inspired air is in excess of 0 5 of an atmosphere Other manifestations of toxicity produced by breathing 70 to 100% O_2 at a pressure of 1 atm include fatigue, paresthesias in the hands and feet, joint pain, anorexia, nausea, and vomiting The cause of these symptoms are unknown (Comroe and Dripps, 1950)

In the ordinary clinical management of patients when oxygen is given in a tent or by nasal catheter oxygen toxicity does not become a factor since the O_2 content in inspired air is rarely, if ever, increased to above 50% Higher levels can be achieved if a close-fitting mask is used in the absence of rebreathing or if the subject is placed in an enclosure into which oxygen is introduced.

Effects of Oxygen Pressures Greater Than 1 Atmosphere By placing the patient in a pressure chamber it is possible to administer oxygen under a pressure of more than 1 atm Recently this method has been used for treatment of carbon monoxide poisoning, and its usefulness for other purposes is being investigated extensively (see Lambertsen, Bond, and Jacobsen, II, 1965) When oxygen is breathed at pressures around 2 to 4 atm severe symptoms indicating dysfunction of the higher central nervous system are experienced These include mood swings, indifference, loss of judgment, somnolence, irrational apprehension, and finally convulsions of the grand mal type The latter are followed by automatism and amnesia Vertigo also is a common symptom of oxygen poisoning The cause of the symptoms is not clear Reduction in the CO_2 carrying capacity of the blood, with a corresponding rise in CO_2 tension and cH in the tissues and venous blood, has been shown to occur in experimental animals, but it is not known if the symptoms in man are related entirely to these changes (Bean, 1945)

Mice die within 20 to 25 min when exposed to an oxygen tension of 8 atm , whereas a pressure of 8 atm of air is tolerated well

Effects of Breathing Air at Very High Pressures (Nitrogen Narcosis) The inert gases, including nitrogen, at certain pressures display the typical properties of anesthetic agents Whereas surgical anesthesia is produced in patients breathing 80% of an atmosphere of nitrous oxide or xenon, about 38 atm of nitrogen has been calculated to be necessary to have this effect In experimental animals a pressure of 30 atm of nitrogen is required to abolish righting reactions However, symptoms referrable to impairment of function of the central nervous system occur in an individual exposed to 6 atm of nitrogen (the equivalent of about 200 ft below the surface of water) Helium-oxygen mixtures have less anesthetic action than nitrogen-oxygen mixtures, hence divers breathing helium-oxygen can descend to much greater depths without the development of mental aberrations

Resuscitation

Until the last few years Schafer's prone pressure method of artificially inflating the lungs was most widely practiced But today either the *Holger-Nielson* or the *mouth-to-mouth method* is preferred

HOLGER-NIELSON OR BACK-PRESSURE-ARM-LIFT METHOD

After loosening the clothing around the neck and chest, drawing the tongue well forward, and wiping fluid, mucus, etc , from the mouth and throat in order to allow free passage of air, the subject is laid in the prone position (chest down) The arms are abducted at the shoulders to lie at right angles to the trunk and bent at the elbows (see Fig 6 40) The head is turned to one side with a cheek resting on the hands The operator places himself in front of the subject with one knee resting beside his head and near his forearm The foot of the operator's other side is planted near the subject's opposite forearm Then the operator places his hands, with fingers spread apart, upon the subject's back, thumbs touching, and on an imaginary line joining the axillae He then sways forward, bringing his weight to bear through his arms and hands upon the subject's back The operator should hold his arms straight at the elbows This movement compresses the chest and imitates natural expiration The operator then seizes the subject's arm above the elbows and draws them forward, at the same time as he himself straightens up This position which expands the chest and simulates natural inspiration is held for 2 sec He then swings forward again and repeats the first phase The double movement is repeated about 12 times a minute

MOUTH-TO-MOUTH METHOD

In a symposium published in the May, 1958 issue of the Journal of the American Medical Association it is stated that mouth-to-mouth resuscitation is superior to all manual methods for all age groups It is reported to be the only

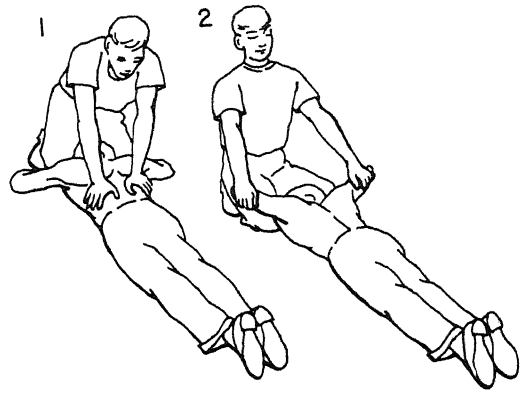

Fig 6 40 Illustrating the Holger-Nielsen method of resuscitation (From *First Aid Metropolitan Life Insurance Company*)

technique capable of producing adequate ventilation in all cases The single most important factor preventing adequate ventilation in this and some other methods, is mechanical obstruction of the airway by the tongue Proper extension of the neck and elevation of the jaw eliminates this obstruction To perform mouth-to-mouth resuscitation the subject is placed in the supine position with the head extended and the rescuer at the side of the head The rescuer grasps the lower jaw of the subject between his thumb and index finger and lifts it vertically upward The other thumb and index finger are used to clamp off the nostrils The rescuer then places his mouth over the subject's mouth and exhales into the airway a volume about two times the normal tidal volume (Fig 6 41) Volume and pressure required are easily judged by the rescuer He inflates the subject's lungs and thorax and notes the expansion of the chest The rescuer then removes his mouth from that of the subject to allow him to exhale The procedure should be performed about 12 to 20 times/min

The effectiveness and ease of performance of this type of resuscitation is improved by the use of an anesthesia face mask, or an oropharyngeal airway or an endotracheal tube

During recent years several methods have been developed for the long continued application of artificial respiration by various mechanical devices This work was begun by Thunberg in Lund, who devised an apparatus called the barospirator The subject was placed inside a metal chamber in which the pressure was raised and lowered rhythmically by means of the stroke of a large piston The interchange of air within the lungs was caused by a rise and fall of pressure of the air in the external atmosphere This apparatus was effective and a model was built large enough to accommodate patient, nurse, and doctor All three were ventilated without movement of the chest A certain amount of discomfort was experienced in this cabinet due to the change in pressure on the two sides of the eardrum during the increase and decrease of air pressure A more generally applicable model was produced by Drinker at Harvard In this type the patient's head remains outside the cabinet (Fig 6 42) The chest is expanded by reducing the pressure within the cabinet and as the pressure is raised again, the natural elasticity of the lung causes expiration Forced expiration, however, may be produced by raising the pressure above atmospheric Patients have been adequately ventilated with this apparatus for many months Some difficulty is occasionally encountered in the regulation of the rate and depth of respiration, but by determining the oxygen saturation of the arterial blood or watching for signs of cyanosis an observer can usually regulate the ventilation quite satisfactorily

Two other types of apparatus should be mentioned, *1*) the jacket model of Sahlin which operates like the Drinker machine but is applied only to the chest, and 2) the Bragg-Paul pulsator which consists of a hollow elastic bandage placed around the chest The bandage, when inflated by an electrically driven bellows, compresses the chest, which returns to the midposition by virtue of its own elasticity during the intervals between the compressions

The pulmotor and other similarly devised resuscitators, which force air into the chest and suck it out again as though the lungs were rubber bags, though so appealing in their mechanical efficiency, are physiologically unsound They are not only less effective than other methods but may be actually harmful The pulmonary tissue may be torn Those machines which inflate the lungs with an oxygen-carbon dioxide mixture, and permit expiration to take place simply by interrupting the air current and thus permitting collapse of the thorax, are sounder in principle, but precautions are necessary to insure that pressures produced in the lungs will not be excessive

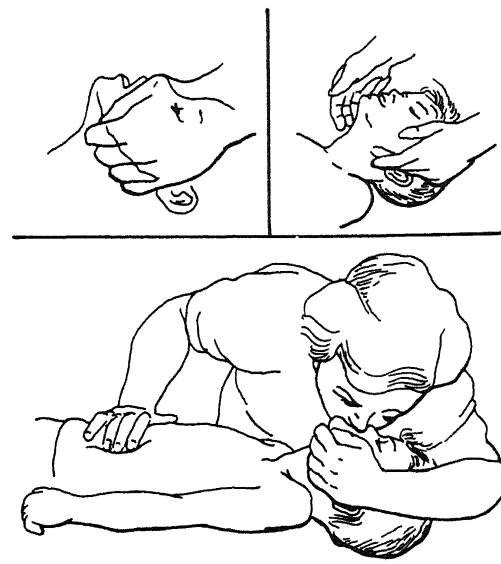

Fig 6 41 Mouth-to-mouth method of artificial respiration (Courtesy of Dr John Henderson and Duell Sloan, Pierce and Company Publishers New York)

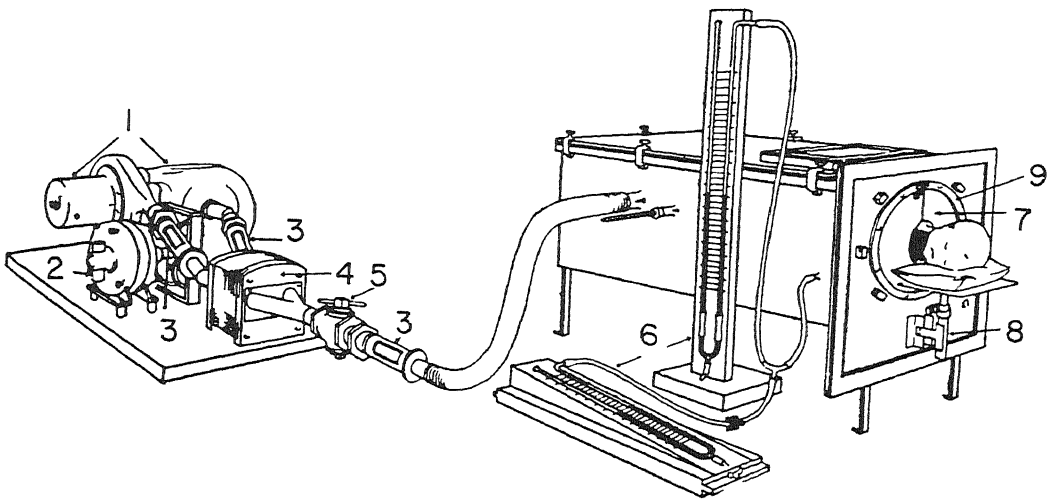

Fig 6 42 The Drinker respirator *1* pumps *2* motor *3* vents *4* alternate *5* valves *6* manometers *7* external shutters *8* adjustment for head rest *9* adjustable ring to hold collar in place

A mixture of oxygen and carbon dioxide (5% or 10% of the latter) commonly is used for resuscitation The high tension of CO_2 combined with the rhythmical inflation and deflation of the lungs, which presumably cause the discharge of afferent impulses, encourages the return of spontaneous breathing

RESUSCITATION OF THE NEWBORN

Asphyxia in the newborn infant is usually due to the failure of the lungs to expand fully, alveoli in areas of the pulmonary tissue remaining in the fetal state (atelectasis) The methods of resuscitation which may be effective in the adult are likely to fail Cutaneous stimulation, e g , slapping, hot or cold water, are time honored devices which are usually unsuccessful The object aimed at should be the expansion of the collapsed alveoli, and when the infant makes no respiratory effort this is best accomplished by the insufflation of the lungs with a carbon dioxide-oxygen mixture, carried out by the passage down the trachea of a tube, to the outer end of which a rubber bag filled with the gas mixture is attached When the breathing is not completely suspended but is weak, and the infant cyanosed, inhalations of a carbon dioxide-oxygen mixture are employed Also mouth-to-mouth resuscitation is quite effective in infants

Endocrine Control Systems

1 / INTRODUCTION TO ENDOCRINE CONTROL SYSTEMS

Signals that allow an animal to respond to changes in its environment are transmitted either by spread of depolarization through nerves or by release of hormones into the blood A hormone is a substance that is produced by a gland or specialized neurosecretory cell, is often stored in this cell, and is released into the blood in response to some specific stimulus Release may be triggered either by a nerve impulse or by a change in the concentration of some substance in the blood which is perfusing the gland (Fig 7 1) When the hormone reaches its target cells, it modifies the function of the cell to remove the stimulus that originally caused release of the hormone This "negative-feedback" system operates to maintain homeostasis within the organism Signals transmitted through nerves have the advantage of speed and localization to single cells within a large group of similar cells On the other hand, a hormone affects cells of varying type over longer times

The major endocrine glands and hormones that are of importance in controlling body function will be discussed in this section These include

Hypothalamus thyrotropin-releasing factor (TRF), corticotropin-releasing factor (CRF), growth hormone-releasing factor (GRF), follicle-stimulating hormone-releasing factor (FRF), leutinizing hormone-releasing factor (LRF), and prolactin-inhibitory factor (PIF)

Hypophysis thyrotropin (TSH), adrenocorticotropic hormone (ACTH), growth hormone (GH), follicle-stimulating hormone (FSH), leutinizing hormone (LH), prolactin, melanocyte-stimulating hormone (MSH), vasopressin, and oxytocin

Thyroid thyroxine, triiodothyronine, and calcitonin

Parathyroid parathyroid hormone

Pancreatic islets insulin and glucagon

Adrenal glucocorticoids, mineralocorticoids, androgens, epinephrine, and norepinephrine

Ovary estrogen and progesterone

Testes testosterone

Skin vitamin D

Hormones involved in control of the gastrointestinal tract, cardiovascular system, and kidney are discussed in other sections of this text

METHODS OF IDENTIFYING ENDOCRINE GLANDS AND HORMONES

Removal of a gland that is suspected of endocrine function is often an initial approach to defining its function For example, when the anterior lobe of the pituitary is removed, there are important abnormalities in the animal These are *a*) arrested growth, *b*) atrophy of the gonads, and indirectly of the accessory organs of sex, *c*) suppression of milk secretion and involution of the mammary glands, *d*) atrophy of the thyroid and adrenal cortex, *e*) lowered metabolic rate, *f*) a tendency to hypoglycemia and reduction in liver and muscle glycogen, and *g*) depression of spontaneous activity and diminished resistance to infection and shock Since this gland secretes hormones that control other endocrine glands, effects of hypophysectomy are widespread This example emphasizes the range of functions that depend upon endocrine function

The second step in identifying the function of an endocrine gland is to make an extract of the tissue and to administer the extract to a hormone-deficient animal in the hope that it will correct the abnormalities that are present One of the classical demonstrations of the effect of an extract on such an abnormality was provided by F G Banting and C H Best, one of the original editors of this textbook When the pancreas is removed from dogs, the glucose content of the blood begins to rise within a short time, the urine gives a positive test for sugar, nitrogen excretion is elevated, and death occurs within 2 or 3 weeks Banting and Best (1922) were the first to obtain an extract

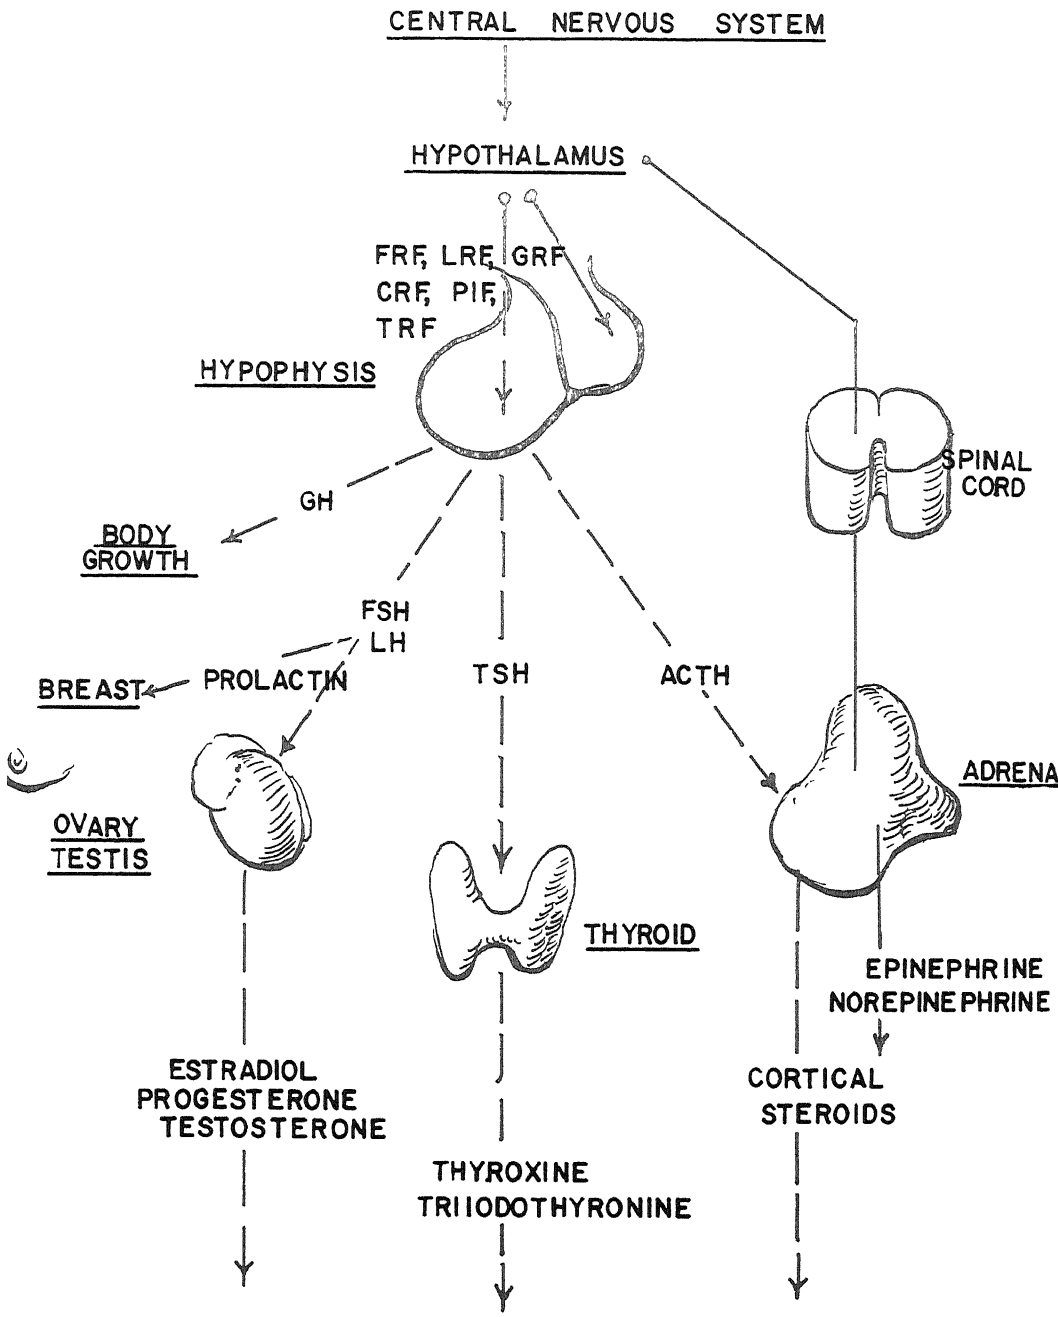

Fig 7 1 The relationship between the nervous system and the endocrine system ——nerve pathway ---- -- vascular pathway Note that neurosecretory structures the hypothalamus neurohypophysis and adrenal medulla are regulated by a direct nerve supply whereas the activity of other glands is controlled by humoral or hormonal agents carried in the blood

of the pancreas that would reverse these abnormalities of diabetes in the completely depancreatized dog (Fig 7 2) Subsequently, Abel et al (1927) crystallized insulin from extracts of pancreatic tissue

Once a hormonal activity has been identified in an extract of a gland, the substance responsible for the activity must be purified and the chemical structure determined Since many of the hormones are peptides or proteins, struc-

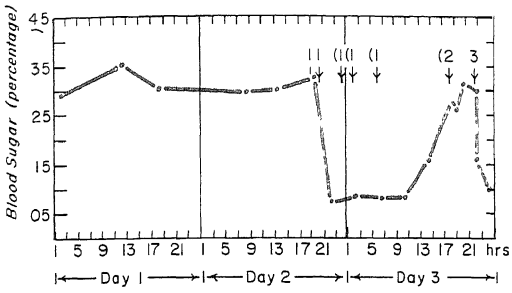

Fig 7 2 Effect of insulin of the blood sugar curve of a depancreatized dog *1*) Injection of extract of degenerated pancreas *2*) extract after incubation with pancreatic juice and *3*) extract incubated without pancreatic juice (Redrawn from Banting and Best 1922)

tures of this class of hormones have been determined only in the past 20 years Structures of the steroid hormones yielded more rapidly to chemical analysis and these structures have been determined during the past 50 years In these regards, endocrinology is a science of the 20th Century since E H Starling first used the word "hormone" in 1905 in referring to the activity of secretin, a gastrointestinal hormone

SYNTHESIS AND RELEASE OF HORMONES

Endocrine glands have certain anatomical features in common *1*) They are typical glands (except for the hypothalamus and neurohypophysis which belong to a special class of neurosecretory organs) in that they are composed of masses of secretory cells arranged in columns or clumps These cells may occasionally, as in the case of the thyroid, be arranged in alveoli or acini with their secretory product stored in the lumen More commonly, however, the hormones or their parent substances are stored as granules or droplets in the cells *2*) Although glandular in nature, no ducts are present *3*) Since the blood functions as a "duct" and carries off secretory products, they are richly vascularized

Protein hormones are synthesized on ribosomes that are attached to the endoplasmic reticulum The hormone is packaged into storage or "zymogen" granules in the Golgi apparatus The type of granule that is formed varies from one cell to another and serves as a means of identifying the hormone that is in the granule Release of hormone involves a process known as *emiocytosis* or reverse pinocytosis The membrane of the storage granules fuses with the plasma membrane of the cell and the product is released into the interstitial space

Steroid hormones are synthesized from cholesterol by a complicated series of reactions that occur in both the cytoplasm and mitochondria of these cells These cells are particularly rich in mitochondria and in some instances adaptations of mitochondrial structure to facilitate steroid synthesis are present In these glands the substrate for steroid synthesis, cholesterol is stored in lipid droplets as cholesterol esters When the gland is stimulated to produce hormone, it is synthesized either from this stored precursor or from cholesterol that is present in the plasma

ASSAY OF HORMONES

Hormones have effects when present in extremely low concentrations As a result, assay methods that are sufficiently sensitive and specific have been difficult to develop Initially, all hormones were measured by bioassays that were dependent upon the effect of a hormone on either a living animal or tissue preparation These assays are often insensitive and nonspecific When the structure of some hormones was determined, chemical assays were devised Thyroid hormone and adrenal and gonadal steroids are satisfactorily estimated by these methods

A particularly difficult problem is the estimation of peptide hormones in the concentrations normally found in plasma, millimicrogram per milliliter Since other proteins are present in the range of milligrams per milliliter, it is not possible to purify and quantitate peptide hormones by the usual techniques of fractionation A special method of assay was devised by Berson and Yalow (1964) and is known as a radioimmunoassay In order to use this method, a pure hormone must be prepared by the gland which synthesizes the compound This hormone is injected into an appropriate species of animal Since the animal reacts to the hormone in the same manner as it does to other foreign protein, antibodies against the hormone are formed After repeated injections of hormone are given, the serum of the animal contains a high titer of antibody against the purified hormone This serum can be used to measure the immunoreactive hormone in plasma and other body fluids It should be

stressed that immunological reactivity rather than biological activity is measured If inactive fragments of hormone react with the antibody or if hormone is bound to components in the plasma that prevent its interaction with antibody, these activities may not be the same

Once a potent antibody to a pure hormone is available, it can be used to measure plasma levels of peptide hormones An example of the use of this method to measure plasma levels of growth hormone is shown in Figures 7 3–7 5 The basic principle is to set up competitive reactions between radioactively-labeled hormone and unlabeled hormone for this specific antibody (Fig 7 3) Radioactive hormone is prepared by reaction of a portion of the tyrosine residues of the protein with ^{131}I After incubation of the mixture of labeled and unlabeled hormone with the antibody, labeled hormone which is antibody-bound is separated from free hormone by electrophoresis (Fig 7 4) The fraction of labeled hormone that is antibody-bound decreases as more unlabeled hormone is added to compete for the antibody

Free labeled-HGH (F)	Unlabeled-HGH (*in known standards or in body fluids*)
+	+
specific antibody	specific antibody
↓↑	↑↓
Antibody-bound labeled-HGH (B)	Antibody-bound unlabeled-HGH

Fig 7 3 Competing reactions that form the basis of the radioimmunoassay of human growth hormone (HGH) (From Yalow and Berson 1968)

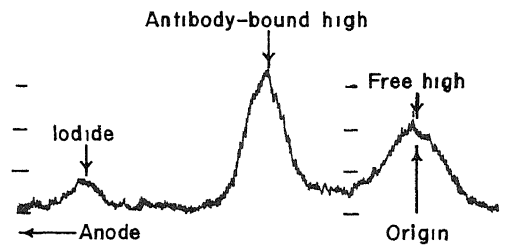

Fig 7 4 Paper radiochromatoelectrophoretogram of mixture of HGH-^{131}I diluted HGH antiserum and human plasma after incubation at 4° C Free HGH-^{131}I is absorbed to the paper at the origin antibody bound hormone has migrated with the plasma protein and iodine-131 released from the labeled hormone during incubation has migrated farther than the plasma proteins (From Yalow and Berson 1968)

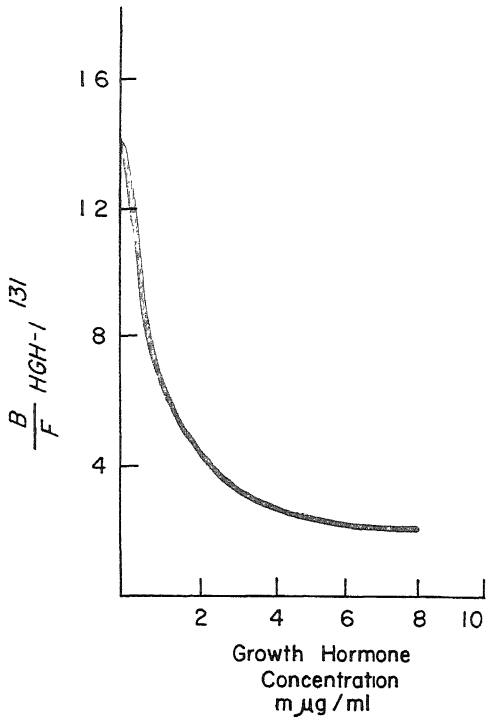

Fig 7 5 Standard curve for HGH assay B/F ratio in standard solutions is plotted as a function of human growth hormone concentration (From Yalow and Berson 1968)

The ratio of bound/free human growth hormone (HGH)-^{131}I is a function of the quantity of unlabeled hormone that is added (Fig 7 5) Once this relationship is established with hormone standards, it can be used to assay plasma levels Radioimmunoassays have been established for insulin, glucagon, FSH, LH, prolactin, TSH, adrenocorticotrophic hormone (ACTH), α-MSH, β-MSH, vasopressin, parathyroid hormone, and calcitonin in addition to growth hormone

Recently, the principle of radioimmunoassay has been applied to the assay of nonprotein hormones This method is based on the presence of specific binding proteins for steroid and thyroid hormones in plasma In normal plasma, a large fraction of these hormones are specifically bound to carrier proteins Competition between labeled and unlabeled hormone for binding has been used and standard curves similar to those of Figure 7 5 have been described Using this method, sensitive assays for thyroid hormone, adrenal steroids, and gonadal steroids have been established

MECHANISM OF HORMONE ACTION

When a hormone reaches its target cell, it must affect the intracellular metabolism in order to modify cell function Peptide and protein hormones are large molecules, however, and will not enter cells readily unless specialized transport systems are present In the case of insulin, the hormone appears to affect cell metabolism by binding to receptors on the surface rather than by entering the cell itself If the hormone is restricted to surface binding, two mechanisms of action suggest themselves, *1)* a hormonally-induced change in membrane permeability for substrates or ions, and *2)* production of a "second messenger" within the cell that will transmit the signal of the hormone (Fig 7 6)

Hormonal control of permeability is well-documented for ions, glucose, and amino acids Increased entry of glucose into cells, which is mediated by a special transport system, is the major way in which insulin controls glucose utilization by muscle Other hormones that change membrane permeability include growth hormone, glucagon, glucocorticoids, estrogen, testosterone, and vasopressin Whether changes in membrane permeability are primary or secondary effects of these hormones is uncertain

Many hormones regulate intracellular metabolism via a second-messenger, 3′-5′-cyclic adenosine monophosphate (cyclic AMP) Sutherland and co-workers (1965) discovered this compound and established its role in hormone action In this system (Fig 7 7), the hormone binds to a receptor on the cell surface that is part of adenyl cyclase, the enzyme involved in formation of cyclic AMP Adenyl cyclase uses ATP as substrate and produces cyclic AMP

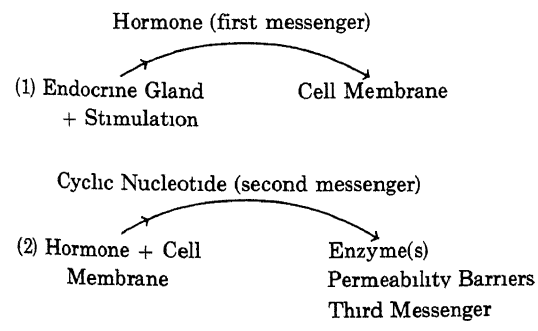

Fig 7 6 The two-messenger system (From Sutherland Oye and Butcher 1965)

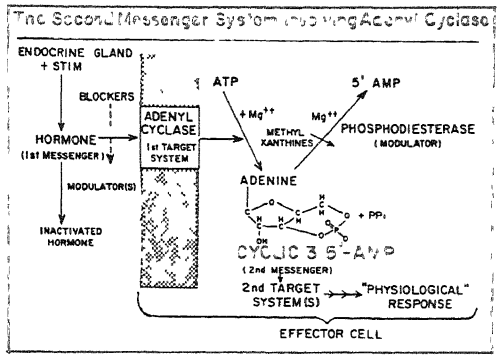

Fig 7 7 The two messenger system involving adenyl cyclase (From Sutherland Oye and Butcher 1965)

and inorganic pyrophosphate as products Intracellular levels of cyclic AMP are most commonly controlled by changes in the activity of adenyl cyclase Destruction of the messenger by phosphodiesterase also effects cyclic levels This enzyme is inhibited by methyl xanthines, such as caffeine, which results in much higher cyclic levels in response to activation of adenyl cyclase Mechanisms involved in the regulation of cell metabolism by cyclic AMP are under intensive study Effects of the second messenger on the following types of events have been described *1)* changes in membrane permeability to ions, water, and amino acids, *2)* release of stored hormone from endocrine glands, *3)* modification in the rate of enzymatic reactions, and *4)* induction of enzyme formation Recently a cyclic AMP-dependent protein kinase has been identified This enzyme may be involved in a number of these effects When protein kinase is activated by cyclic AMP, it catalyzes the phosphorylation of either enzymes or controls transcription of deoxyribonucleic acid (DNA) by histones The wide range of effects which involve cyclic AMP is listed in Table 7 1 As a result of the diverse role of the second messenger, it will be discussed to some extent in every chapter of the endocrine section

Steroid hormones are able to penetrate the cell membrane due to their smaller size and lipid solubility As a result, these compounds are able to modify intracellular metabolism directly A model for the effect of estrogen on the uterine cell is shown in Figure 7 8 The hormone penetrates the cell membrane and binds to a receptor protein in the cytoplasm Estrogen is transported to the nucleus where it

Table 7 1
Extent of regulation by cyclic AMP

Known Effects of Cyclic AMP		
Enzyme or process affected	Tissue	Change in activity or rate
Phosphorylase	Several	Increased
Glycogen synthetase	Several	Decreased
Protein kinase	Several	Increased
Phosphofructokinase	Flatworm	Increased
Tyrosine transaminase induction	Liver	Increased
PEP carboxykinase induction	Liver	Increased
Serine dehydratase induction	Liver	Increased
β-Galactosidase induction	Bacteria	Increased
Overall protein synthesis	Several	Decreased
Glyconeogenesis	Liver	Increased
Ketogenesis	Liver	Increased
Lipolysis	Adipose	Increased
Steroidogenesis	Several	Increased
Water permeability	Epithelial	Increased
Ion permeability	Several	Increased
Calcium resorption	Bone	Increased
Renin production	Kidney	Increased
Contractility	Cardiac muscle	Increased
Tension	Smooth muscle	Decreased
Membrane potential	Smooth muscle	Hyperpolarized
Amino acid uptake	Liver and uterus	Increased
Amino acid uptake	Adipose	Decreased
Clearing factor lipase	Adipose	Decreased
Amylase release	Parotid	Increased
Insulin release	Pancreas	Increased
ACTH release	Anterior pituitary	Increased
TSH release	Anterior pituitary	Increased
GH release	Anterior pituitary	Increased
LH release	Anterior pituitary	Increased
Thyroid hormone release	Thyroid	Increased
Calcitonin release	Parafollicular	Increased
Acetylcholine release	Nervous	Increased
Histamine release	Leukocytes	Decreased
HCl secretion	Gastric mucosa	Increased
Fluid secretion	Insect salivary glands	Increased
Discharge frequency	Cerebellar Purkinje	Decreased
Melanocyte dispersion	Skin	Increased
Aggregation	Cellular slime mold	Increased
Aggregation	Platelets	Decreased
RNA synthesis	Bacteria	Increased
DNA synthesis	Thymocytes	Increased
Cell growth	Tumor cells	Decreased

From Sutherland, 1970

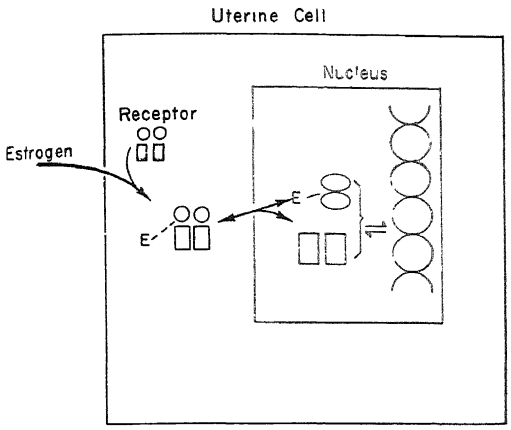

Fig 7 8 Model of estrogen interaction with the uterine cell The steroid binds with a cytoplasmic receptor which transfer it to the nucleus The nuclear receptor facilitates the role of steroids in controlling DNA transcription (Adapted from Gorski et al 1968)

is transferred to a nuclear receptor protein Steroid hormones appear to modify cell metabolism by inducing new enzyme formation This type of control is exerted by regulating the transcription of portions of DNA resulting in formation of messenger ribonucleic acid (RNA) Messenger RNA leaves the nucleus and is translated by the protein synthesis pathway in the cytoplasm Effects of steroid hormone usually require an hour or so to be exerted and may be blocked by inhibitors of RNA and protein synthesis

Steroid hormones are known to exert "permissive effects" on the action of other hormones This term means that the effect of rapidly acting hormones, such as glucagon, depend upon the presence of normal levels of steroid hormones in order to exert their effects Since steroid hormones modify enzyme levels and other cell components, effects of other hormones will change in steroid hormone-deficient animals Control of cell metabolism by rapid acting hormones depends upon the cell constituents that are already present, suggesting that the permissive action of steroids may also depend upon effects on transcription

2 / CONTROL OF THE ANTERIOR LOBE OF THE PITUITARY GLAND

The concept of control of anterior pituitary gland by higher brain centers has crystalized only within the last 10 to 15 years, although elements of the portal vessel-chemotransmitter hypothesis were appreciated as far back as the late 1930's This hypothesis holds that neurosecretory cells in various areas of the hypothalamus secrete chemical substances into hypophysial portal blood vessels whose primary capillary bed lies in the median eminence region These substances called hypothalamic-releasing factors, are carried by the portal vessels and enter pituitary sinusoids where they promote release of hormone from pituitary cells

The anterior pituitary gland probably contains a specific type of hormone-producing cell for each of the following six protein trophic hormones—follicle-stimulating hormone (FSH), luteinizing hormone or interstitial cell-stimulating hormone (LH or ICSH), prolactin (LTH) in some species), adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and somatotrophin or growth hormone (STH or GH) Structures, effects of these hormones on target glands, and general metabolic effects will be dealt with in chapters that follow At the present time, six releasing factors have been identified—FSH-releasing factor (FRF), LH-releasing factor (LRF), corticotropin-releasing factor (CRF), TSH-releasing factor (TRF), GH-releasing factor (GRF), and prolactin-inhibitory factor (PIF) These releasing factors apparently provide a means for a precise set of controls that permit the secretion of trophic hormones in a highly specific and selective way

Some years ago, workers in several laboratories set out to isolate and define the chemical nature of the releasing factors by extracting and purifying minute quantities of biologically active principles from literally millions of fragments of hypothalamic tissue In the last months of 1969, the structure and artificial synthesis of the first releasing factor, TRF, was achieved (Burgus et al , 1970, Folkers et al , 1969) Structures of the remaining factors and their mode of action are under study in a number of laboratories

It is the purpose of this chapter to *a*) briefly review the submicroscopic anatomy of the anterior pituitary, *b*) describe salient features concerning the physiology and chemistry of the releasing factors, *c*) discuss possible modes of action of the hypothalamic factors on the pituitary cell, and finally *d*) indicate the paths that recent studies in this area are taking It is important to note that many comprehensive and excellent reviews on the physiology and chemistry of the releasing factors are available to the interested reader Especially good are Meites (1970), Burgus and Guillemin (1970b), and Schally et al (1968) for the chemistry of releasing factors, Meites (1970), Ganong and Martini (1969), McCann and Porter (1969), and Meites and Nicoll (1966) for various physiological aspects, and Geschwind (1969, 1970) for mechanism of action

Cytophysiology of the Anterior Pituitary

The diversity of cell types in the anterior pituitary gland was first recorded by Schonemann (1892) Since that time results of many hundreds of cytological studies make it clear that the three major groups of cell types, i e , chromophobes, acidophils, and basophils each have subclasses within The chromophobes, which are devoid of any stainable cytoplasmic granules by light microscopy, make up approximately 55% of the cells in the gland The acidophils and basophils constitute the remaining 35% and 10%, respectively These proportions vary depending upon age, sex, and physiological state The acidophils contain cytoplasmic granules which take on acid dyes while the basophils contain granules which stain readily with basic dyes With the excep-

tion of the gonadotropins, the experimental evidence that one cell type produces one particular hormone is convincing

ELECTRON MICROSCOPY

Studies of Smith and Farquhar (1966, 1970) have clearly demonstrated that it is possible to identify at least four of the six cell types primarily on the basis of secretion granule size in their cytoplasms These studies involved examination of subcellular changes in pituitary tissue removed from animals that had been physiologically altered in some predictable fashion For example, thyrotrophs have been identified in normal glands as cells that contain cytoplasmic granules 140 mμm in diameter In glands from thyroidectomized animals, these cells are degranulated and vesiculated Similarly, after castration, cytoplasmic vesicles coalesce to form "signet ring cells" in those cells containing 200-mμ diameter granules These cells are therefore considered gonadotrophs In the lactating female rat, LTH secretion is suppressed if the young are separated from the lactating mother Some 10 to 12 hr after separation there is an accumulation of mature secretion granules (600 to 900 mμm) in cells considered to be responsible for LTH secretion Studies such as these provide not only convincing evidence for the identity of a spe-

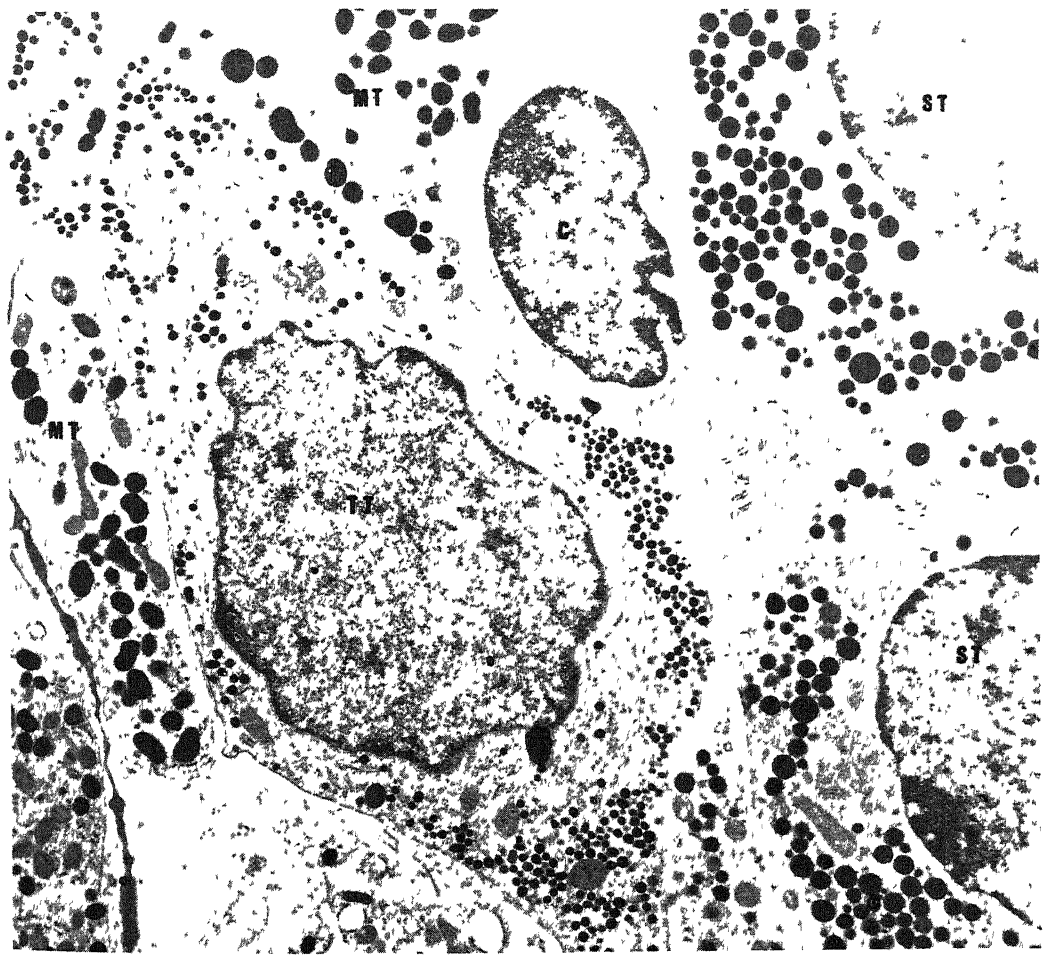

Fig 7 9 Electron micrograph showing a field of cells from the anterior pituitary gland of the rat Several cell types are seen which can be distinguished by differences in the nature of their secretion granules Mammotrophs (*MT*) or prolactin-secreting cells have the largest granules (600 to 900 mμ) and thyrotrophs (*TT*) the smallest (150 mμ) Those of somatotrophs (*ST*) or growth hormone-producing cells are of intermediate size (350 to 400 mμ) A small chromophobe (*C*) or nongranulated cell is also present (× 20 000) (Courtesy of M G Farquhar)

cific hormone-producing cell, but also indicate that hormone synthetic and secretory activity can be correlated with the ultrastructural appearance of the cell (Figs 7 9 to 7 11)

Immunohistochemical techniques have also been used for hormone localization Initially, a fluorescent compound was conjugated to the hormone antibody but more recently an enzyme, horseradish peroxidase, has been used as a conjugate Using this technique Nakane (1970) has found that STH, ACTH, LTH, and TSH were localized in separate cells (see Fig 7 12) FSH and LH, however, were frequently found in the same cell In general, the results from this method confirm that secretion granule size serves as a useful marker for the identification of pituitary hormone-producing cell types

SUBCELLULAR SITES OF HORMONE SYNTHESIS STORAGE AND RELEASE

The rough, endoplasmic reticulum is highly developed in active pituitary cells, suggesting that hormones are synthesized at this site A cell-free pituitary ribosomal system has been found to incorporate labeled amino acids not only into protein, but also into ACTH, STH, and LTH fractions Furthermore, biosynthesis of LTH and STH was found to be most effective in polysomes containing six to seven ribosomal units This finding is in good agreement with the predicted polysome size requirement for the synthesis of proteins with molecular weights of approximately 20 000 (Adiga et al , 1968)

It seems reasonably clear that packaging of

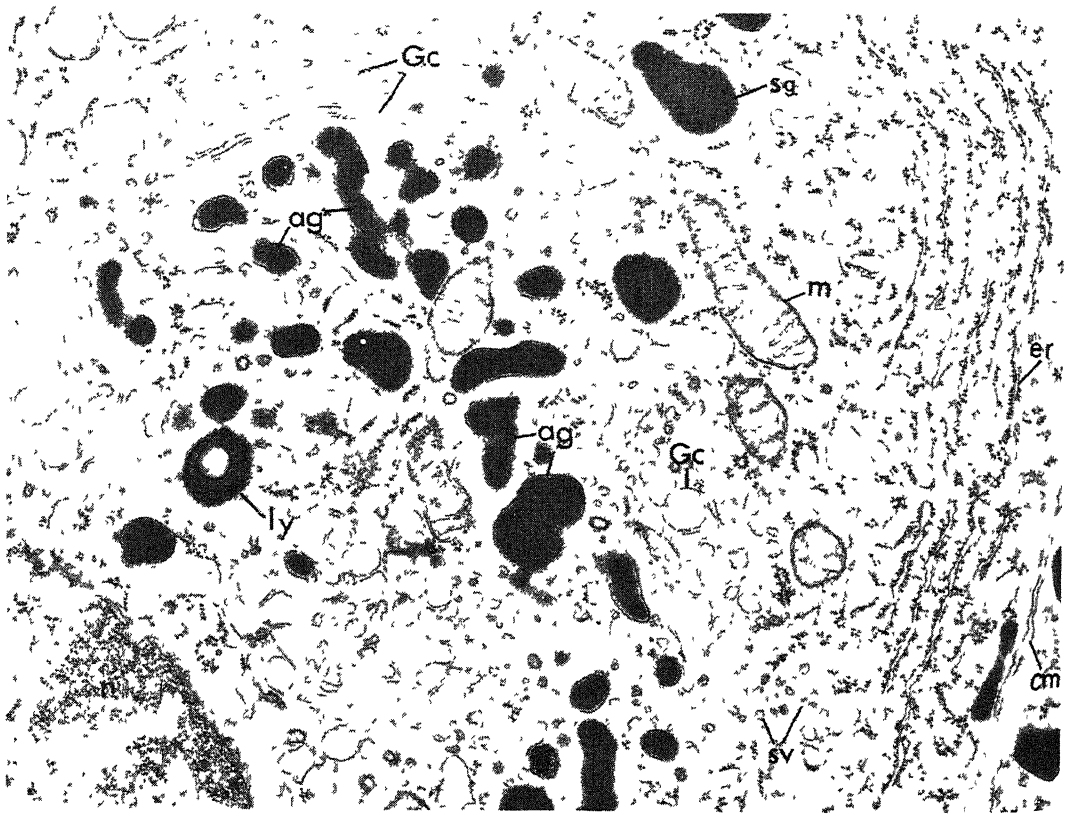

Fig 7 10 Portion of a mammotroph (prolactin secreting cell) from the anterior pituitary of a lactating rat These cells are rapidly synthesizing concentrating and discharging prolactin or lactogenic hormone They show abundant peripheral arrays of rough-surfaced endoplasmic reticulum (*er*) parallel to the cell membrane (*cm*) a large juxtanuclear Golgi complex (*Gc*) and many profiles of forming granules (*ag*) Secretory granules are formed in several steps small (100 to 200 mμ) granules arise within the inner Golgi cisterna pinch off and are found along the concave Golgi face Several small granules merge to form larger aggregates (*ag*) of variable shape and the polymorphous images round up to form ovoid or elliptical mature granules (*sg*) which measure 600 to 900 mμ (× 21 500) (Courtesy of M G Farquhar)

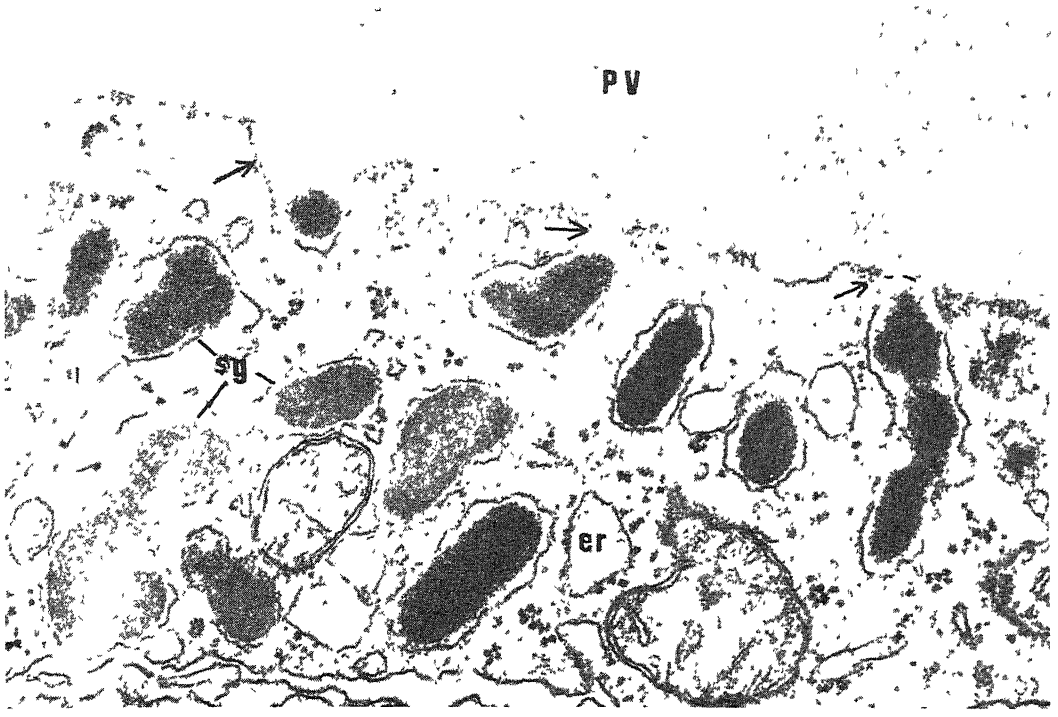

Fig 7 11 Portion of a mammotroph or lactogenic hormone producing cell from a lactating rat A number of secretory granules (*sg*) are lined up facing the perivascular spaces (*PV*) Several are undergoing discharge by exocytosis or fusion of the granule membrane with that of the cell membrane (*arrows*) (× 42 000) (Courtesy of M G Farquhar)

newly synthesized hormone into secretion granules occurs in the Golgi region of the cell Several ultrastructural studies suggest that the development of the Golgi apparatus is directly related to the secretory activity of the cell Since the granule size and form seem to be characteristic for a given cell type, some specificity must exist in the Golgi system of the different cells to determine the arrangement and size of the emerging packet After completion, the granule consists of an electron dense core surrounded by a membrane derived from the Golgi Although there is no direct evidence, it seems likely that some of the carbohydrate moieties of the FSH, LH, and TSH molecules are also attached in the Golgi region Enzymes derived from the Golgi, primarily phosphatases, are also packaged in the secretion granule (Smith and Farquhar, 1970)

Secretion granules of different sizes have been isolated in highly purified form and a major portion of each trophic hormone has been associated with an individual granule fraction (Fig 7 13) There granules, which retain their membrane on isolation, contain biologically active hormone when injected into bioassay animals It is of interest that gonadotropins, associated with granules isolated from basophils, are in a form which makes them extractable in 0 15 M saline Isolated STH granules are stable in saline, however, but unstable in the presence of ethylenediaminetetraacetic acid (EDTA), a chelating agent These results suggest that divalent cations are required for stability of the STH granule Finally, purified granule preparations have been analyzed by polyacrylamide gel electrophoresis Hormones in the isolated granules have mobilities similar to those reported for crude pituitary homogenates or extracts (Hodges and McShan, 1970) Thus, individual hormones are associated with granules of different sizes in a highly specific fashion

On the basis of electron microscopic findings, Farquhar reported some 10 years ago (1961) that hormone discharge from the pituitary cell involved exocytosis or reverse pinocytosis (Figs 7 11, 7 14) This process involves fusion of the granule membrane with the apical cell membrane The electron dense com-

Fig 7 12 Localization of growth hormone in thin section by treatment of section with peroxidase-labeled antibody to growth hormone Reaction products from the substrate 4-Cl-1-naphthol are deposited primarily on secretion granules of growth hormone (*GH*) cells (× 6000) (From Nakane 1970)

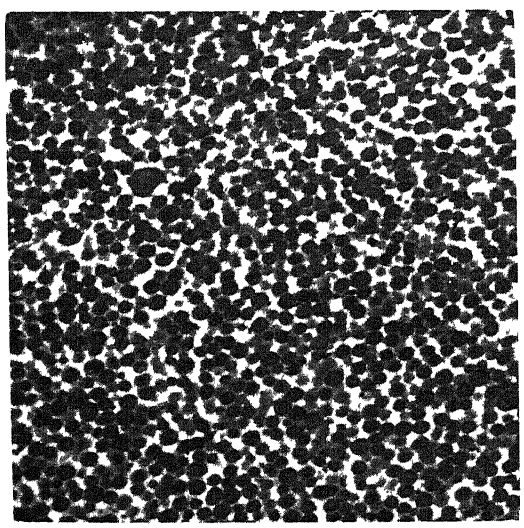

Fig 7 13 Electron micrograph of a thin section through a pellet consisting largely of isolated pituitary secretion granules which are 350 mμ in diamter A majority of the growth hormone activity in the original rat pituitary homogenate was recovered with these isolated granules (× 9000) (From Hymer and McShan 1963)

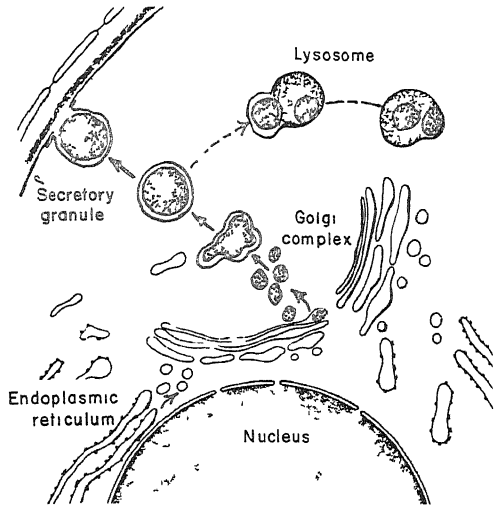

Fig 7 14 Diagram depicting formation of large (600 to 900 mμ diameter) prolactin granules in a pituitary mamotroph by coalescence of smaller granules formed in the Golgi complex During normal lactation the granules are released as shown in Figure 7 11 Upon weaning of the young however demands for LTH secretion are diminished and the granules follow the path indicated by the dotted line Here they are incorporated into autophagic vacuoles and digested by lysosomal enzymes (From Fawcett et al 1969 Redrawn after Smith and Farquhar 1966)

ponent of the granule is released into the pericapillary space Since none of this dense component is found lying free in the perivascular connective tissue or within the vascular endothelium, it has been assumed that the hormone rapidly dissolves or undergoes some physiochemical change prior to transport into the blood A system for degradation of mature hormone is also present in pituitary cells Smith and Farquhar (1966) have shown breakdown of granules containing LTH by lysosomes under conditions where hormone is no longer required

The time required for synthesis and release of hormone molecules has recently been examined Radioautographic studies with the electron microscope indicate that 10 min after administration of radioactive amino acid, label is found in the endoplasmic reticulum Some 30 min later it is concentrated in the Golgi complex, and after 90 min labeled secretion granules are dispersed in the cytoplasm (Racadot et al, 1965) Since the time required for synthesis of a hormone molecule on a polysome is probably no more than 2 min, the above results imply that a relatively long time

must elapse before newly synthesized hormone can be released into the circulation It would be of interest to know if, under conditions of rapid hormone release, intracellular packaging might not be bypassed

Neurchumoral Control

Among the first experiments to provide support for neurohumoral control of anterior pituitary function were those involving *a*) electrical stimulation or lesioning of the hypothalamus, *b*) interruption of the blood vessels between the hypothalamus and the pituitary, or *c*) transplantation of the pituitary gland In 1952, Harris and Jacobsohn transplanted pituitaries into either the median eminence or temporal lobe of hypophysectomized rats Rats with transplants in the median eminence mated and delivered young, but those with transplants under the temporal lobe were anestrus and had atrophic reproductive organs As another example, pituitary cells grown in tissue culture quickly lose their distinctive staining characteristics, but if extracts of hypothalamic tissue are added to the culture vessel, the cells regain normal staining properties (Meites, 1970) Many other experiments could be cited, but all point to the required integrity of the portal blood supply for proper pituitary function (Fig 7 15)

As pointed out by Harris, the region where hypothalamic nerve terminals come into contact with the primary capillaries of the portal vessels is the median eminence Examination of this area with the electron microscope shows a number of granules of varying sizes (1000 to 2100 Å) in addition to the typical synaptic vesicles Preliminary evidence based on gradient centrifugation suggests that these granules may contain releasing factors (Kobayashi and Tokuzo, 1969) Areas of the hypothalamus responsible for synthesis and secretion of individual releasing factors have not been clearly identified Hence, hypothalamic areas, rather than discrete nuclei are discussed when considering control of anterior pituitary function

The following criteria must be satisfied for ultimate proof of the releasing factor hypothesis

1) Secretory elements in the brain must be demonstrated to elaborate a substance within diffusion distances of the primary capillary plexus of the hypophyseal portal vessels

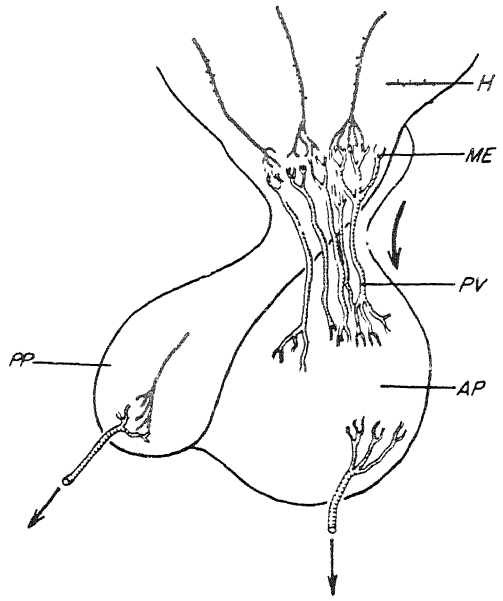

Fig 7 15 Diagram of a midline sagittal section through the base of the hypothalamus and pituitary gland to show the structures concerned in the regulation of anterior pituitary activity Nerve fibers from the hypothalamus (stippled *H*) enter the median eminence (*ME*) of the tuber cinereum to end on the primary plexus of the hypophyseal portal vessels (*PV*) It is postulated that releasing factors pass from these nerve terminals into the portal vessels and are carried into the anterior pituitary (*AP*) to regulate its secretory activity This is probably a similar mechanism to that found in the posterior pituitary gland (*PP*) where peptides are discharged from nerve endings into the general circulation (Diagram and description from Harris 1970)

2) Identification and characterization of this substance in hypophyseal portal blood is required Furthermore, the concentration of the substance should be *a*) greater in portal blood than systemic blood, and *b*) related to varied secretion rates of one of the pituitary hormones

3) When the substance enters the pituitary sinusoids, it causes an alteration in release rate of one tropic hormone

Although only minute amounts of releasing factors would be expected in portal blood, recent experimental evidence suggests that such activity can be detected Porter et al (1970) devised a procedure for collecting stalk blood from the anesthetized rats that involves exposure of the ventral surface of the pituitary via a parapharyngeal approach A dural flap over the gland is cut and the veins draining the pituitary are broken The pituitary stalk is transected and the gland removed The short stump of the pituitary stalk is left protruding

through the diaphragm of the sella, and a polyethylene tube is placed over the stalk in such a manner as to form a tight seal Portal blood can be collected for 4 to 6 hr by applying negative pressure on the cannula In large male rats, 6 μl of blood is collected per minute As indicated above, releasing activity can be demonstrated in this blood

RELEASING FACTOR ACTIVITY IN DIFFERING PHYSIOLOGICAL STATES

Knowledge of the effects of physiological stimuli on secretion rates of releasing factors would aid in an overall appreciation of the regulation of hypothalamohypophysial axis activity This work is difficult because of uncertainties involved in isolation and bioassay of releasing factors and in interpretation of the data In most of these studies, hypothalamic content of releasing factors is measured Tissue content of a hormone represents the balance between rates of synthesis and release It is usually considered that an increase in hypothalamic content of releasing factor represents increased synthesis and secretion if changes of the corresponding hormone in the anterior pituitary and target gland are also observed In those cases where target gland hormones may act directly at the pituitary level, hypothalamic content of releasing factor should remain unchanged Most stimuli, however, appear to act through the hypothalamus and involve changes in secretion rates of releasing factors Experimental data suggest the presence of two feedback mechanisms which modify secretion rates *1*) the "long" loop which involves peripheral target hormones, and *2*) the "short" loop which involves pituitary hormones acting directly on the hypothalamus

Evidence for the long-loop feedback mechanism in the control of FSH and LH secretion stems from the observation that hypothalamic LRF and FRF content is greatly increased after castration This is especially true for the male, but has also been seen to some extent in the female These changes parallel increased synthesis and release of FSH following castration Interestingly, administration of testosterone or estrogen to the castrate male results in a marked depletion of FRF stores Some specificity is indicated by the fact that progesterone administration has no effect on FRF stores in the hypothalamus (Martini et al, 1968) These data argue for the idea that testosterone decreases secretion of pituitary FSH by way of the hypothalamus Results from similar kinds of studies for other hormones have been reported by Meites (1970)

The evidence for the existence of short-loop feedback control has involved systemic administration of pituitary hormones For example, injection of 20 μg FSH/day/5 days to castrated male rats causes a significant drop in pituitary FSH and hypothalamic FRF The specificity of this response is indicated by the finding that injection of LH or ACTH has no such effect In this kind of experiment, the FSH is believed to act directly back on the hypothalamus to prevent secretion of FRF Furthermore, implantation of relatively large doses of pituitary hormones in the median eminence region also results in reduced content of the hypothalamic factor and decreased output of the pituitary hormone Thus, implantation of LH in the hypothalamus decreases LRF and LH, and implantation of ACTH into median eminence significantly depress blood corticosterone levels This method has been criticized because diffusion of hormone from the implantation site undoubtedly occurs, and in fact probably reaches the anterior lobe Electrophysiology has also been used to advantage in some of these problems Work by Beyer and Sawyer (1969) indicates that *1*) "patterns of hypothalamic neural activity can be correlated with pituitary secretion, and *2*) various hormones, including the pituitary trophins, influence the basal level of activity and the responsitivity of hypothalamic neurons " Finally, hypothalamic releasing factors are detectable in the systemic circulation of hypophysectomized rats 1 month after the operation This condition, which is never encountered in the intact animal, is explained by the lack of inhibiting messages from the anterior pituitary Taken together, the results from experiments utilizing these different techniques strongly support the notion that a "short" feedback mechanism functions in the regulation of pituitary secretion It is an attractive mechanism for the control of secretion of those hormones that do not have a peripheral target gland and are therefore not regulated by the more traditional feedback mechanisms It is not clear whether this system operates by the systemic circulation or by transport up the pituitary stalk

In the case of regulation of ACTH and TSH secretion, fairly good evidence can be mustered for an additional feedback control directly at the pituitary level Data on regulation of gonadotropin secretion are controversial, but a basomedial hypothalamic receptor for testosterone inhibitory feedback seems fairly well-established Estrogen may also have a primary action on the basomedial hypothalamus, with additional secondary effects on the anterior pituitary (Davidson, 1969) In the case of growth hormone secretion, a number of studies point to the existence of a specific glucose-sensitive growth hormone regulatory system Thus, hypoglycemia or falling blood glucose will stimulate STH secretion Other stimuli, such as sleep, or those related to protein metabolism (e g , arginine and several other amino acids) will also stimulate STH secretion, but whether these stimuli are specific or merely act as stressors is debatable While it is clearly accepted that STH secretion is under control of the hypothalamus, the relationship of the above stimuli to the hypothalamus remains to be defined (Glick, 1969)

There is a considerable body of evidence to indicate that brain catecholamines participate in the regulation of gonadotropin secretion Fuxe and Hokfelt (1969) have demonstrated, by a histochemical technique, the presence of dopamine-containing neurons whose cell bodies lie in the arcuate nuclei Axons from these neurons project to the external layer of the median eminence in close proximity to the portal blood vessels Interestingly, their dopamine content fluctuates under conditions of altered gonadotropin secretion Dopamine could participate in gonadotropin secretion by *a*) directly stimulating release of pituitary FSH and LH, *b*) potentiating the effect of the gonadotropin releasing factors, or *c*) functioning as a synaptic transmitter to produce the release of FRF or LRF Data from Kamberi et al (1970) indicates the latter possibility is most likely For example, basal release of FSH from pituitaries incubated in flasks containing median eminence fragments was unaltered when serotonin, epinephrine, or norepinephrine were added However, FSH release was significantly stimulated by addition of dopamine Furthermore, addition of dopamine to pituitaries incubated alone failed to alter FSH release In more recent experiments, utilizing an in vivo approach, injection of dopamine into the third ventricle of hypophysectomized rats caused dramatic and specific increases in plasma levels of LRF (Schneider and McCann, 1970) Furthermore injection of estradiol into the third ventricle 2 hr prior to dopamine administration would block this response

Finally, it should be obvious to the reader that the loop systems discussed in this section are extremely complex In future work it will be important not only to identify sites of feedback action and multiple actions of loops, but also the relative importance and interplay of each of the loops in the physiological regulation of anterior pituitary function

ASSAY OF RELEASING FACTORS

An in vitro pituitary incubation system, sometimes called the short-term incubation system, was originated by Saffran and Schally (1955) and was later modified by Guillemin, Meites, and others Basically the method involves incubation of rat anterior pituitary glands in small flasks or beakers placed in a Dubnoff metabolic shaker maintained at 37° C with continuous oxygenation Under these conditions, tissue and cell viability appears relatively normal after 1 or 2 hr incubation It is also possible to maintain explants of pituitary tissue in organ culture Tissues handled in this manner remain functional for a week or longer

The results of studies with the short-term incubation system show that addition of crude acid extracts of hypothalamus causes the release of biologically detectable quantities of all the anterior lobe hormones with the exception of LTH Since LTH levels are high in media taken from glands incubated in the absence of hypothalamic extracts, it was concluded by Meites (1970) that the hypothalamus contained a prolactin-inhibiting factor (PIF) This idea is entirely in keeping with the observations that when pituitaries are transplanted to the kidney capsule, *a*) the predominant surviving cell type is the mammotroph, and *b*) that since the gland has been removed from its hypothalamic control, there is an enhanced release of LTH from the graft

Hypothalamic extract-induced release of hormone from the in vitro pituitary is specific as suggested by the following lines of evidence First, the quantity of released hormone is dependent upon the concentration of extract used, i e , it follows a dose response curve

Second, if crude acid extracts of cerebral cortex tissue are added, the amount of hormone released is often no greater than "basal" or endogenous release levels Furthermore, no PIF is found in cerebral cortical extracts Third, only one hormone is released from the tissue when a single purified factor is added The experiments of Guillemin and Vale (1970) demonstrate this important point If purified TRF is added to the in vitro system, TSH output is greatly increased above endogenous release levels while ACTH and LH are not (Fig 7 16) This specificity is further demonstrated by the findings that *a*) thyroxine inhibits the TRF effect on release, *b*) TSH release is related to dose of TRF, *c*) oxygen is required for the full effect of TRF, and *d*) pituitary response to TRF is decreased at 0° C

Although hormone release is clearly demonstrated in the in vitro procedure, the method provides only a static view of the process A potentially useful method for studying the kinetics of hormone release in vitro has recently been proposed (Serra and Midgley, 1970) In this method a single anterior pituitary gland is incubated in a 350-μl capacity vial constructed in such a way that the gland can be superfused in continuous fashion and the perfusate analyzed for hormone content (Fig 7 17) With this set-up, it has been shown that a single pituitary gland will respond to hypothalamic extract by release of LH, that the response is dose related, that the response consists of a brief release essentially limited to the time of extract administration followed by a fall to a constant basal release rate and finally

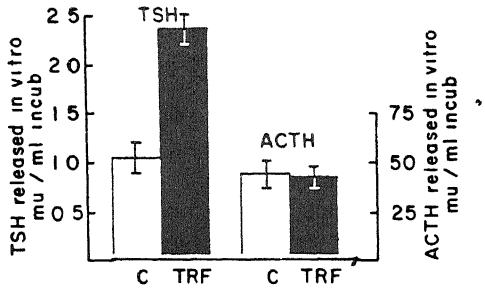

Fig 7 16 Specificity of the response of the rat pituitary incubated in vitro With the use of paired hemipituitaries addition of *TRF* stimulates release of *TSH* whereas no increase in the release of *ACTH* is observed when both *TSH* and *ACTH* are measured in aliquots of the same incubation medium Sensitivity of the assay method for *TSH* 0 02 mU, for *ACTH* 0 1 mU (From Guillemin and Vale 1970)

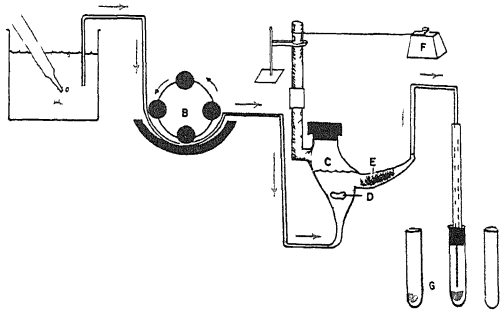

Fig 7 17 Incubation design *A*) buffer container with 95% oxygen and 5% carbon dioxide continuously bubbled *B*) peristaltic pump *C*) incubation chamber containing 200 μl of buffer *D*) intact rat anterior pituitary gland *E*) glass wool filter *F*) mixer producing vibrations of the incubation chamber and *G*) test tubes (From Serra and Midgley 1970)

that the same gland can be repeatedly stimulated to release measurable quantities of hormone (Fig 7 18) Techniques such as these clearly permit new approaches to the study of release kinetics of the pituitary trophic hormones

IN VIVO ASSAY FOR RELEASING FACTORS

A number of different in vivo assay methods have been used to check for the presence of releasing factor activity One type, the "pituitary depletion assay" is based on the general principle that injection of a preparation containing one or more releasing factors brings about a depletion of pituitary hormone content related to the amount of factor injected (Motta et al, 1970) Another general type of assay utilizes the principle that in vivo administration of a releasing factor causes an increase in the blood level of a particular pituitary hormone A modification of this method involves measurement of the change in target gland hormones Each assay method that is used, in vitro as well as in vivo, has advantages as well as disadvantages Lack of precision, due not only to variability in pituitary response to a releasing factor but also to variability in assay of released pituitary hormone, is a common problem

Recently Gay et al (1970) have developed a method for constant monitoring of plasma LH concentrations in individual animals Using a sensitive radioimmunoassay for rat LH, these workers have been able to analyze the dynamics of LH release following one or more

injections of crude rat hypothalamic extract In this method, the castrated female rats are treated for 3 days with estrogen and progesterone Increases in circulating LH in response to injection of hypothalamic extracts occur within the first 2 min after injection and maximal values occur 8 min after extract administration (Fig 7 19) These preparations are capable of responding to repeated injections of hypothalamic material Moreover, it is possible

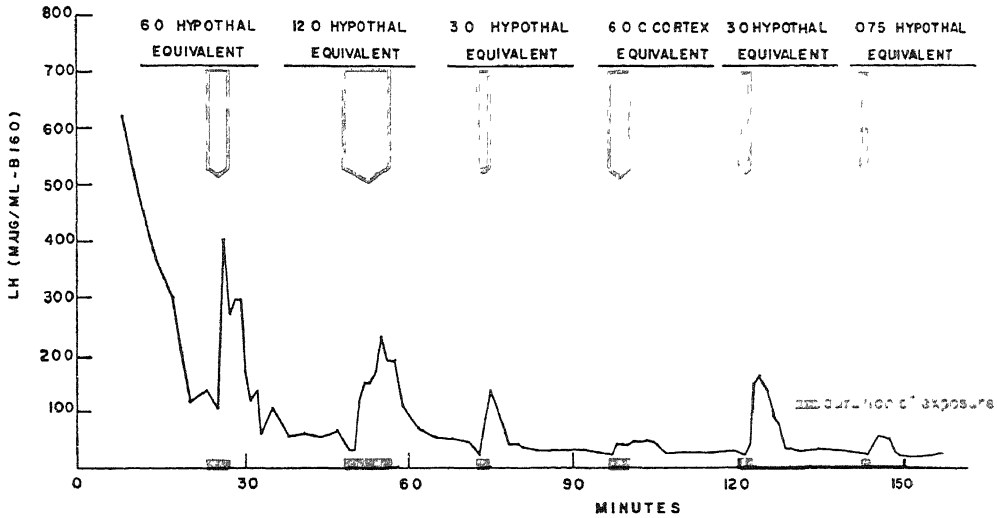

Fig 7 18 Concentration of LH in the superfusate following exposure in vitro to hypothalamic extracts for 4 8 2 and 0 5 min Exposure to 6 cerebral cortex equivalents was done during a 4-min period Samples were collected and measured at 1- or 3-min intervals Superfusion rate using the apparatus shown in Figure 7 17 was constant at 200 μl /min LH was measured by radioimmunoassay in 10 or 20 μl aliquots of superfusate (From Serra and Midgley 1970)

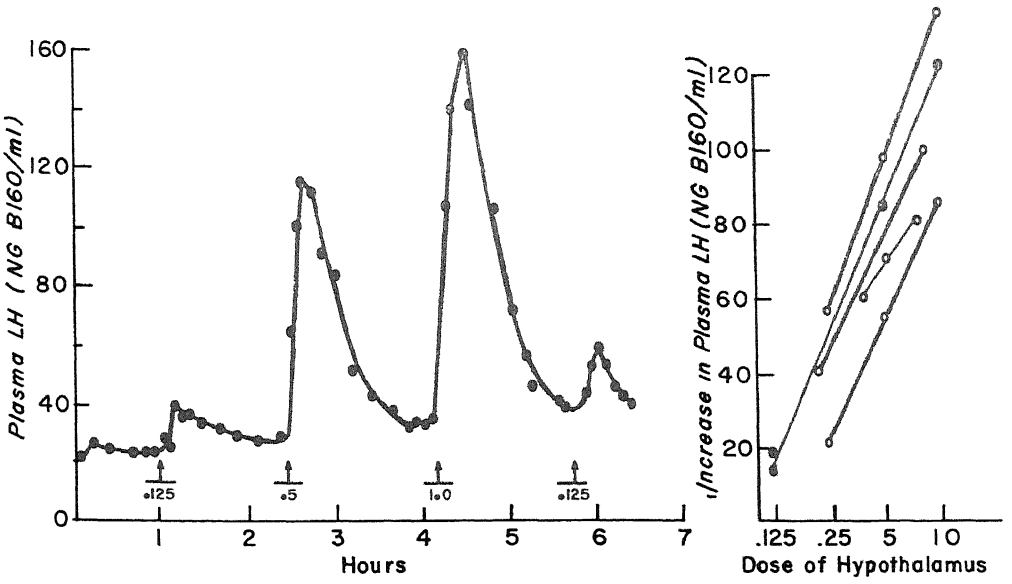

Fig 7 19 Demonstration of the dose related increase in plasma LH following 4 successive injections of 0 125 0 5 1 0 and 0 125 hypothalamic equivalents into an estrogen progesterone-treated castrate rat The observed responses of the animal have been replotted in the right hand portion of the figure to illustrate the linear relationship between the increase in plasma LH and the log-dose of hypothalamic extract injected Responses observed in other similarly prepared rats are indicated by the open circles in the right-hand portion of the figure From data obtained in these experiments it is calculated that LH has a half-life (or disappearance rate) of 23 min (From Gay et al 1970)

to show an increase in plasma LH which is related to dose of extract administered This method, which clearly provides a useful way for evaluating the kinetics of hormone release in vivo, will most certainly be used in future work

CHEMISTRY OF THE RELEASING FACTORS

Purification and chemical isolation of the releasing factors is currently a major goal in a number of different laboratories This approach has recently led to determination of the structure and synthesis of TRF As the initial purification step, it is a common procedure to extract frozen tissue or acetone powders of lyophilized hypothalamic tissue with dilute acid Glacial acetic acid is used most frequently Such extracts are then subjected to preparative gel filtration on columns of Sephadex G-25 The order of elution from the column is GRF, CRF, TRF, FRF, PIF, and LRF Vasopressin emerges last (McCann and Porter, 1969) In some cases there is considerable overlap of activities Further purification is often obtained by chromatography on ion exchange cellulose In the final stages electrophoresis, partition chromatography, or counter current distribution techniques have been used The enormity of the tasks involved can be appreciated when one considers that a typical yield of "highly purified" releaser material is on the order of 1 to 10 mg from a starting material of several hundred thousand hypothalami

The procedures listed above are those commonly used for the isolation of peptides From their behavior, it seems clear that the releasers are low molecular weight peptides, probably on the order of 1000 MW Except for TRF, all of the releasers are inactivated by proteolytic enzymes Most of the partially purified factors are stable when heated to 100° C for a few minutes Highly purified materials are exceedingly potent in terms of biological activity It is not uncommon to find that doses in the nanogram or picogram range will have measurable effects As a result, hypothalamic factors will release many times their own weight of pituitary hormones, i e , they show a so-called "multiplier effect " The [(amount of hormone produced)/(amount of releasing factor added)] is often several thousand, or higher

TRF. The structure of both procine and ovine TRF is (pyro) Glu-His-Pro (NH_2) (Fig 7 20) Pyroglutamic acid, (also known as 2 pyrrolidone-5-carboxylic acid) forms the N terminus while proline amide forms the C terminus portion of the molecule (Burgus et al , 1970a, Folkers et al , 1969) Synthetic and natural TRF have essentially identical biological activities Both the in vivo and in vitro responses to synthetic TRF are inhibited by administration of triiodothyronine (Bowers et al , 1970a) Finally, in a number of recent studies (Bowers et al , 1970b, Martin and Reichlin, 1970), a dramatic rise in plasma TSH was seen 2 to 5 min after intravenous injection of the synthetic molecule into mice or rats (Fig 7 21)

Minor modifications in the chemical structure of TRF decrease or eliminate biological activity For example, simple tripeptides of glutamic acid, histidine, and proline in all

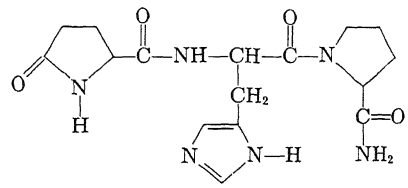

Fig 7 20 Structure of TRF (From Burgus et al 1970)

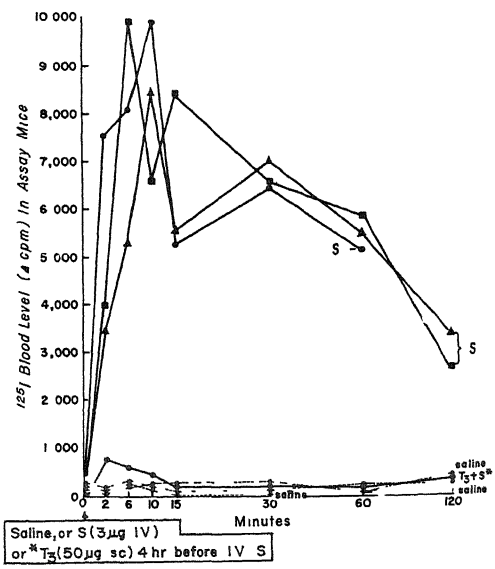

Fig 7 21 Effect of (pyro) Glu His Pro (NH_2) (S) on plasma TSH levels of adult male rats Plasma TSH levels determined by bioassay in mice and recorded as ^{125}I blood level (c p m) Each result is the mean obtained from 3 to 4 mice ± S E Note how prior administration of T_3 blocks the response to (S) (From Bowers et al 1970a)

their possible sequences are not biologically active The addition of a single CH_3 group on the amide of proline reduces the activity to approximately 1/8 that of the synthetic compound The synthetic tripeptide (pyro) Glu-His-Asp (NH_2) is not active, nor is (pyro) Glu-His (NH_2) or (pyro) Glu-Pro (NH_2) All of these findings (Bowers et al , 1970a) clearly show that the entire structure is required for full biological activity The importance of the artificial synthesis of TRF cannot be overemphasized The following is taken from a recent paper (Bowers et al , 1970b) "The simplicity of the structure engenders delight as well as amazement It is noteworthy that this is the first known chemical structure of one of the hypothalamic hormones which have been sought for so long Studies of procine and ovine TRH are equally exciting since the results have been obtained independently and confirm one another and also because they represent once more unequivocal evidence that the hypothalamus secretes specific neurohormonal substances which control the release of anterior pituitary hormones It is hoped that the structure of TRF is a key which will help reveal the structure of the other hypothalamic releasing hormones "

GRF A peptide with GRF activity has been purified and appears to be homogeneous by thin layer chromatography and electrophoresis (Schally et al , 1970a) Ninety-eight per cent of its dry weight could be accounted for by the amino acids shown in Table 7 2 GRF is an acidic polypeptide with a molecular weight of about 1600, that is split by trypsin, chymotrypsin, or papain into small fragments which are not biologically active Schally reports that as little as 0 1 picogram of this material will cause release of growth hormone from pituitaries incubated in vitro Purified GRF is active in vivo as determined by the pituitary depletion assay method The active dose administered to the assay animal was 1 ng

During the course of screening fractions from Sephadex columns for GRF activity by in vitro assay, fractions adjacent to the GRF peak which would diminish output of bioassayable growth hormone by approximately 50% were found (McCann and Porter, 1969) This material was called growth hormone inhibiting factor (GIF) A dual control for growth hormone release by GRF and GIF can thus be easily envisaged Whether release of all pituitary hormones are under such dual control is unknown at the present time

Table 7 2
Amino acid composition of porcine GRF

Amino Acid[a]	Molar Ratio[b]	Probable Residues[c]
Lysine	1 0	1
Histidine	0 9	1
Ammonia	2 1	2
Serine	1 4	1
Glutamic acid	4 9	5
Alanine	3 8	4
Valine	1 1	1
Leucine	2 0	2

From Schally et al , 1970
[a] Amino acids account for 98% dry weight
[b] Accepting lysine as 1 0
[c] To the nearest integer, assuming 15 amino acid residues

Gonadotropin Releasing Factor. There is little doubt that there are substances in extracts of median eminence tissue which will induce release of LH and FSH from pituitaries in vitro or raise plasma levels of these hormones in vivo Until recently it was generally held that release of these gonadotropic hormones was controlled by discrete molecules, viz FRF and LRF, which could be chemically separated (Fig 7 1) However, Schally et al (1971) has recently suggested that a single hypothalamic factor controls the secretion of both FSH and LH His most highly purified preparation has both LRF and FRF activity, yet only one amino acid sequence (pyro) Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2 The structure was confirmed by chemical synthesis The synthetic decapeptide apparently shows the same kinds of responses in biological activities as the natural material Thus it *a*) raises the concentration of LH in the plasma of ovariectomized rats pretreated with estrogen and progesterone, *b*) raises plasma levels of FSH and LH in castrated male rats pretreated with testosterone propionate, and *c*) stimulates release of FSH and LH from the in vitro pituitary

PIF. Certain fractions obtained from Sephadex and ion exchange columns contain prolactin-inhibitory-factor activity The most commonly used assay procedures have been either the inhibition of prolactin release from the in vitro pituitary or prevention of suckling-

induced depletion of pituitary prolactin Essentially nothing is known about the chemistry of PIF Data from the laboratories of MacLoed and Daughaday (In Meites, 1970) indicate that epinephrine and norepinephrine may inhibit prolactin secretion in vitro, however, as pointed out by Meites (1970) there are many reasons to believe that catecholamines themselves are not PIF

CRF CRF has not been prepared in pure form Two difficulties have impeded this work *1)* CRF activity appears to decrease, rather than increase, in the later stages of purification, and 2) bioassays are difficult since the stress of the assay procedure interferes with the determination of CRF activity (Vernikos-Danellis and Marks, 1970) In fact, McCann and Porter (1969) claim that much of the confusion concerning regulation of ACTH release can be attributed to the indirect methods used in evaluating release rate

In spite of these reservations, there appears to be little question that fractions containing CRF activity can be isolated from median eminence tissue Most of the evidence indicates that the active molecule is a small polypeptide Data from a number of different kinds of experiments also show that this material is not vasopressin

Experiments performed by Saffran et al (1955) clearly indicated that there were substances in neurohypophyseal extracts, distinct from vasopressin, which also stimulated release of ACTH from the anterior pituitary These workers found activity in two types of CRF preparations from porcine posterior pituitary powders and they were designated α and β CRF β CRF contains serine and histidine, in addition to the amino acids of lysine vasopressin It is not known at this time whether α or β CRF constitutes a "true physiological" corticotropin-releasing hormone

HYPOTHALAMIC RELEASING FACTOR ACTIVITY IN MAN

Releasing factor activity does not appear to be species specific, since highly purified ovine and porcine-releasing factors are active in humans Moreover, active extracts have been prepared from human hypothalami. As examples, a single injection of FRF into amenorrheic or anovulatory women induced a rise in plasma FSH within 30 min after administration; plasma LH levels rise rapidly following infusion of LRF in children or adult patients, small amounts of procine TRF administered to human athyreotic cretins cause a significant elevation in plasma TSH 3 min later and circulating and urinary 17-hydroxycorticoids are raised following intravenous perfusion of hog and beef CRF extracts in the human (Harris, 1970, for detailed references)

Two recent abstracts from Schally's laboratory (Schally et al, 1970a, Bowers et al, 1970b) provide more information on this subject In one study, extracts from 339 human hypothalami were separated on Sephadex G-25 GRF was further purified by free-flow electrophoresis and chromatography on carboxymethylcellulose (CMC) TRF, LRF, and FRF were concentrated by phenol and then chromatographed on CMC The results prompted Schally to claim "It is concluded that in man the release of pituitary hormones is regulated by hypothalamic hormones and that the chemical characteristics (molecular weights, isoelectric points, etc , and in the case of TRF probably the structure) of human hypothalamic hormones are very similar to those of domestic animals "

In the other study (Bowers et al, 1970b), the effect of synthetic TRF was evaluated in 12 normal males One to 800 μg were injected intravenously, blood collected, and levels of TSH, FSH, LH, and STH determined by radioimmunoassay The results showed that *a)* the response was specific in that only serum TSH was elevated, *b)* TSH levels were significantly raised 10 min after injection and reached a maximum at 30 min , and finally *c)* pretreatment with 100 μg T_3 5 to 7 hr before injection of TRF partially or completely inhibited the response to TRF

Taken together, the results clearly point to a new field in which studies with purified and synthetic releases in humans could be usefully applied toward correcting a number of endocrine disorders in man

Mechanism of Action

The study of the mechanism of action of releasing factors on the synthesis and release of hormone by the pituitary cell was a logical and inevitable outgrowth of the physiological and chemical studies described earlier in this chapter In spite of obvious difficulties (e g , availability of pure or purified factors and the

cellular heterogenity of the anterior pituitary), a few consistent findings emerge

RELEASE

Since injection of purified releasing material results in a rapid release of hormone into the circulation, it is generally accepted that a primary action of the releasing factor is the stimulation of hormone release Secretion of catecholamine from the adrenal medulla under the control of acetylcholine or high (K^+) has served as a model for experiments on the anterior pituitary (Douglas, 1968) In the adrenal medulla *a*) Ca^{++} was required for catecholamine release, *b*) acetylcholine stimulated uptake of ^{45}Ca, and *c*) Mg^{++} inhibited the stimulatory response Douglas proposed that catecholamine release was initiated by a decrease in the transmembrane potential of the cell that led to increased membrane permeability allowing a net flux of Ca^{++} into the cells An increase in intracellular Ca^{++} would then somehow promote hormone release Because of the analogy to excitation-contraction in muscle, the entire process was termed "stimulus-secretion coupling" Douglas found that membrane depolarization could be uncoupled from secretion, i e , membrane depolarization could still be induced by high [K^+] under conditions where hormone release was blocked, e g , in a Ca^+-free medium This suggested that the entry of Ca^{++} was a crucial event in the secretion process

When similar experiments were done on anterior pituitaries in vitro, high [K^+] in the incubation medium was found to stimulate release of all the pituitary hormones Calcium was required for "normal" as well as high [K^+]-induced hormone release Measurements of pituitary cell transmembrane potentials from pituitaries incubating in high [K^+], as well as crude hypothalamic extracts, have recently been made As predicted, treatment with high [K^+] produces a reversed, positive transmembrane potential in more than half the cells These positive potentials are explained by a preferential permeability to calcium ions triggered by an initial depolarization of the cell membrane to high [K^+] (Milligan and Kraicer, 1970) It would, therefore, appear that the "stimulus-secretion" coupling model can be usefully applied to problems of hormone release from the anterior pituitary As suggested by Geschwind (1970), the role of Ca^{++} in hormone release may involve *1*) conformational changes in the hormones in the granule and/or plasma membrane, resulting in a change in membrane permeability, *2*) interaction between the membrane of the secretion granule and the inner surface of the cell membrane, *3*) changes in the colloidal state of the cell cytostructure so as to induce granule movement toward the plasma membrane, and *4*) stimulation of contraction of a system composed of microtubules and filaments of actomyosin-like material that links secretion granules to the plasma membrane Kraicer has suggested the term 'excitation-contraction coupling" for this situation

Cyclic adenosine monophosphate (AMP) has been established as a second messenger which mediates many of the actions of a variety of different hormones The following experiments suggest that cyclic AMP may be involved in releasing factor-induced pituitary hormone secretion *1*) Addition of crude stalk median eminence extracts to pituitaries in vitro significantly increased pituitary cyclic AMP levels Specificity in this response was apparent since cerebral cortical extract or lysine-8-vasopressin were without effect *2*) Blockage of cyclic AMP degradation by theophylline augmented hormone release *3*) Purified releasers increased pituitary cyclic AMP levels *4*) Hormone release followed addition of cyclic AMP or its *O'*,*N*-dibutyryl derivative to isolated pituitaries *5*) Calcium ion, although required for release, was not required for releasing factor-induced stimulation of pituitary cyclic AMP

Rasmussen and Tenenhouse (1968) have pointed out that the secretion of a number of stored peptides is mediated by cyclic AMP and that Ca^{++} is required for the action of this nucleotide They suggest that the conversion of a small pool of adenosine triphosphate (ATP) to cyclic AMP decreases calcium chelation, making more calcium available for stimulation of peptide secretion These observations have prompted Geschwind to propose the following useful scheme for releasing factor action "an adenophypophysiotropic factor activates adenyl cyclase and/or modifies the cell membrane to allow Ca^{++} entry If the only effect is on adenyl cyclase, then either cyclic AMP modifies the membrane to allow Ca^{++} entry

or membrane Ca^{++}, by being freed from a Ca^{++}-ATP complex and entering the cytosol, passively allows the entry of extracellular Ca^{++} Cyclic AMP then acts, in some still un-

known fashion, to promote release, and for this effect both Ca^{++} and energy are required Cyclic AMP is hydrolyzed by an intracellular cyclic nucleotide phosphodiesterase whose synthesis may be induced in specific cells by the appropriate target organ hormones (e g , dexamethasone and thyroxine) "

Finally, addition of target hormone to pituitaries in vitro has been shown to inhibit high $[K^+]$-induced hormone release This has been shown for thyroxine (Vale and Guillemin, 1967) and corticosterone (Kraicer et al, 1969) on release of TSH and ACTH, respectively Furthermore, thyroxine will inhibit TRF-induced release of TSH, and incubation of rat adenohypophysis in the presence of physiological concentrations of corticosterone (0 25 to 50 μg /ml) suppress hypothalamic extract-induced release of ACTH (Kraicer and Milligan, 1970) Such experiments indicate that these hormones may exert additional feedback control directly on the pituitary cell membrane

SYNTHESIS

In general, two experimental approaches have been used to examine the possibility that releasing factors act within the pituitary cell by controlling the rate of hormone synthesis In one approach, the bioassayable hormone content of the pituitary is measured after in vivo or in vitro administration of a releasing factor to determine if *a*) the amount released, *b*) the pituitary content itself, or *c*) the sum of the two exceed the amount originally present in the gland Evidence from experiments of this kind indicate that hypothalamic factors stimulate hormone synthesis For example, *1*) extracts of median eminence stimulate release of TSH and ACTH from pituitary autografts implanted beneath the kidney capsule 67 days previously although the gland presumably contains little or no TSH or ACTH, *2*) intracarotid injection of rat median eminence extract produces a 5-fold increase in pituitary ACTH content 2¼ min later, *3*) pituitaries taken from ovariectomized rats pretreated with estradiol and progesterone contain 40% more FSH (in the gland + medium) after treatment with RFR than that recovered in control incubations of 4-hr duration, and *4*) incubation of pituitaries from estrogen-progesterone-blocked ovariectomized female rats for 2 hr in LRF caused a maximum release of approximately 5 μg /mg pituitary, almost twice that originally found in the glands

The results of experiments involving changes in bioassayable content are subject to criticism because of the possibility that one is measuring the activation of a precursor hormone molecule rather than its de novo synthesis As an example, peptide bond cleavage occurs in the conversion of proinsulin to insulin Since a number of specific proteases are encountered in pituitary tissue, and since their levels fluctuate depending upon the physiological state, a similar conversion could occur under the influence of a releasing factor Moreover, in the case of the glycoprotein hormones, one could also imagine a control step in which attachment of carbohydrate to inactive polypeptide would be sufficient for activation (Geschwind, 1969, 1970)

The other approach to studying the effects of releasing factors on hormone synthesis has been to measure the incorporation of radioactive amino acid into a pituitary hormone The majority of such experiments have yielded negative results The careful study of Salmi and Geschwind (1967) is representative Pituitaries from ovariectomized rats pretreated with estrogen and progesterone were incubated for 4 hr in the presence of hypothalamic extract and L-^{14}C-leucine or D-^{14}C-glucosamine Although the extract promoted definite release of LH, the incorporation rate of both labeled precursors into LH was not different from that found in control incubations In one of the few positive experiments of this type, Wilber (1970) has reported that addition of synthetic TRF to rat pituitaries in vitro results in a 4-fold increase in incorporation rate of ^{14}C-glucosamine into pituitary plus medium TSH At the present time, the question of whether a releasing factor may increase hormone synthesis as a primary or secondary event remains difficult to answer Many workers believe that synthesis occurs only after substantial hormone release suggesting that synthesis of new hormone is triggered by simple mass action

Future Studies

What are the directions that future studies in this area will take? First, it must be obvious that improved procedures for the bioassay of the releasing factors will be crucial for advancement In this regard, the use of quantitative and sensitive radioimmunoassays are be-

coming more routine Secondly, it is highly desirable that the activity of a releasing factor preparation be defined in some sort of standard unit Not only would this yield more comparable results in individual laboratories, but would also be extremely useful in the quantitation of hypothalamic contents of releasing factors in a variety of physiological states Thirdly, work on the purification and isolation of the releasing factors will continue to dominate the field The successful synthesis of TRF has been a major accomplishment to date Announcements of the structures of other factors should be forthcoming Burgus and Guillemin (1970b) have, in fact, observed "the hypothalamic-releasing factors may all be members of a closely related series of small polypeptides, possibly with a protected N terminus and an amidated C terminus " Some initial work on the effects of these factors in humans has been done, and the possibilities for extensive clinical investigations look promising indeed Tests of pituitary function, induction of ovulation in certain patients or induction of growth in selected individuals with growth hormone deficiency may be possible with improved knowledge of releasing factor chemistry Antagonists of releasing factors can be synthesized, and such diseases as diabetes or carcinoma of the breast may be treatable by a "medical" hypophysectomy If antagonists to the gonadotropin releasing factors could be synthesized it should, of course, be also possible to prevent conception Finally, the mechanism of action of these factors on the pituitary cell will continue to be an important area of investigation In this regard, attempts are being made in the authors' laboratory to isolate relatively homogenous populations of different types of pituitary cells An example of fractions containing primarily small chromophobes, and acidophils is shown in Figure 7 22 *a*, *b*, respectively Basically the method used involves sedimentation of a trypsinized cell suspension through a shallow (1 to 3%) gradient of bovine serum albumin maintained at unit gravity Under these conditions, the sedimentation rate depends largely on the size of the cell Such isolated cells are viable, they synthesize protein and ribonucleic acid (RNA) and contain detectable quantities of hormone It will be of interest to determine the physiological and biochemical effects of purified releasing factors on each preparations

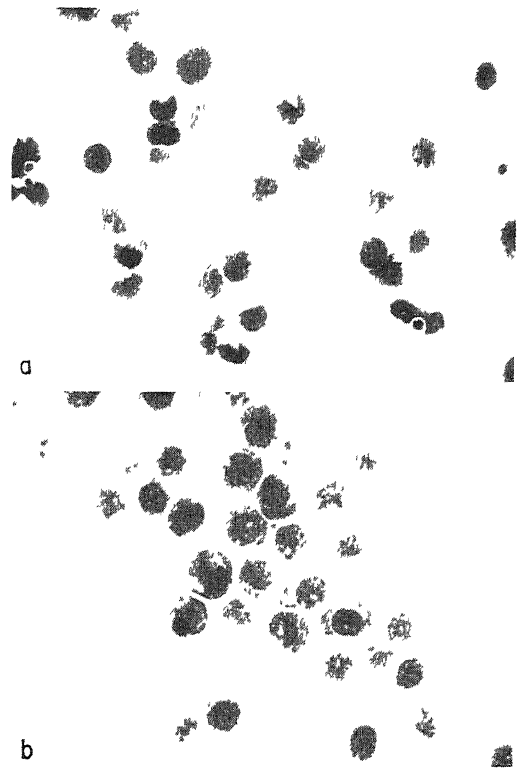

Fig 7 22 Photomicrographs of pituitary cells separated by sedimentation through a shallow protein gradient (1 to 3% bovine serum albumin) maintained at unit gravity according to the method described by Peterson and Evans (1967) Cells in (*a*) are primarily small chromophobes while those in (*b*) are primarily acidophils (× 900)

3 / CONTROL OF THE POSTERIOR LOBE OF THE PITUITARY GLAND

The neurohypophysis is responsible for production and release of two hormones, vasopressin and oxytocin Vasopressin, sometimes called antidiuretic hormone or ADH, is involved in control of water excretion by the kidney and in control of blood pressure Oxytocin stimulates contraction of smooth muscle in the uterus and in the ducts of the mammary gland In this chapter, control of the neurohypophysis and the effects of its secretory products will be described

ORIGIN AND STRUCTURE

The pituitary has a dual origin in the embryo—from the ectoderm in the roof of the primitive mouth as well as from the base of the brain In the early embryo the ectoderm pouch, Rathke's pouch, extends to meet a corresponding hollow diverticulum prolonged downward from the floor of the third ventricle The original cavity of the neural lobe of the pituitary disappears completely in man, so that the pituitary stalk becomes solid The part of the pituitary which originates from Rathke's pouch has a glandular structure and is called the adenophyophysis (anterior pituitary gland) The portion developed from the brain is known as the neurohypophysis (posterior pituitary gland) Each division is subdivided into three parts (Fig 7 23) Thus, the neurohypophysis consists of the expanded distal portion, the infundibular process or neural lobe, the nervous part of the stalk known as the infundibular stem or neural stalk, and the expanded upper end of the stalk, which is the median eminence of the tuber cinereum It is important to realize that all three parts of the neurohypophysis may liberate hormone into the blood stream The adenohypophysis consists of the pars tuberalis, the pars intermedia, and the pars distalis or anterior lobe The neural stalk, together with its sheath, the pars tuberalis, is known as the hypophysial or pituitary stalk The major innervation of the neurohypophysis is derived from the supraoptic and paraventricular nuclei In the infundibular process the fibers of the hypophysial tract branch and interweave and end in close association with capillaries These nerve terminals are loaded with aggregations of a cystine-rich neurosecretory material

A neurosecretory role for nerve cells in the hypothalamoneurohypophysial system was established by the studies of Bargmann (1949, 1954) These cells synthesize vasopressin and oxytocin, transport these substances down their fibers, store them in nerve endings of the infundibular process, and release them into the blood (Fig 7 24) The criteria on which a neurosecretory role is assigned are as follows *1)* identifiable neuronal inclusions share the same distribution as biological activity of the hormones, *2)* interruption of the secretory pathway results in accumulations of secretory material on the hypothalamic side of the lesion, and *3)* appropriate stimuli cause changes in both the number of granules and the biological activity of stored hormone Additional support for synthesis of hormone in the cell body followed by transport down the axon is provided by autoradiographic studies of incorporation of radioactive methionine and cysteine into these nerve cells After injection of the radioisotopes, the cell bodies label rapidly, but the infundibular process does not Ten hours after injection of radioactive cysteine but not methionine, the infundibular process contains large amounts of radioactivity Since vasopressin is rich in cysteine, but contains no methionine, these studies support the concept of synthesis in the cell body followed by axonal transport to nerve endings Neurosecretory material in the storage granules contains hormone bound to a carrier protein Release of hormone from the infundibular process is trig-

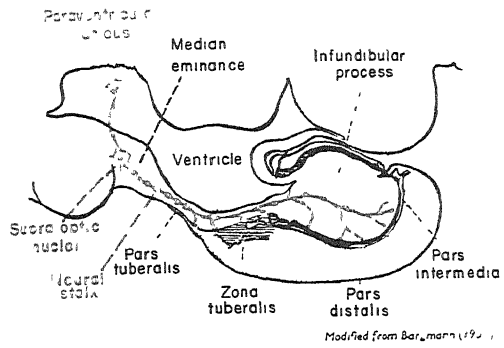

Fig 7 23 Diagram of sagittal section of pituitary and hypothalamus of cat (From Sloper 1966)

gered by an action potential that is transmitted from the cell body As a result, electrical stimulation of the severed stalk of the isolated pituitary can cause secretion (Douglas and Poisner, 1964) After stalk section, about 13% of the total neurohypophysis remains intact and innervated and can release hormone into the blood at a slow rate

HORMONES OF THE NEUROHYPOPHYSIAL SYSTEM

Vasopressin and oxytocin are found in the infundibular process and in the hypothalamus When extracts of the hypothalamus were reported to possess antidiuretic, pressor and oxytocic action (Abel, 1924, Trendelenburg, 1928, and Sato, 1928), considerable skepticism was expressed This reaction was due to the fact that the neural lobe was not recognized as a hormone-storing rather than a hormone-producing gland However, hypothalamic extracts contain only 0 5 to 2 0% of the activity of the neural lobe Analysis of the supraoptic and paraventricular nuclei indicate that the supraoptic nucleus is responsible for production of vasopressin while the paraventricular nucleus accounts for synthesis of oxytocin Synthesis of these hormones in separate nuclei helps to account for differential release under certain conditions, such as suckling and dehydration

Neurohypophysial hormones are of similar structure, consisting of a pentapeptide ring closed by an S-S bridge and a tripeptide side chain (Table 7 3) Almost every vertebrate group has a characteristic hormone or combination of hormones Two hormones are usually found, one resembling oxytocin with a neutral amino acid in the eighth position and another resembling vasopressin with a basic amino acid in this position The hormone combination found in man is oxytocin and arginine vasopressin Vasotocin having the ring of oxytocin and the side-chain of vasopressin produces both antidiuresis and milk ejection when injected into mammals

CONTROL OF VASOPRESSIN SECRETION

Preparation of highly purified and synthetic oxytocin and vasopressin has made possible the analysis of the physiological activities of the whole posterior pituitary extract in terms of these two compounds It seems clear that oxytocin is responsible for the action of pituitary extracts on uterine muscle and on the mammary gland, while vasopressin acts on the blood pressure and water excretion by the kidney Vasopressin has some slight oxytocic activity and oxytocin has slight pressor and antidiuretic action Pressor effects of vasopressin occur only when large amounts of the hormone are administered

Levels of vasopressin in plasma and other body fluids must still be measured by bioassay techniques Antibodies against vasopressin have been produced and a radioimmunoassay procedure has been reported (Permutt et al, 1966) However, this assay is not sensitive enough for measurements of plasma levels Prior to bioassay, hormone must be extracted and concentrated The effect of this extract on urine flow in a hydrated, ethanol-anesthetized rat is the usual method employed Effects of the extract are compared with effects of known amounts of vasopressin

Vasopressin release is controlled by the osmolality of the plasma and by the volume of the blood (Fig 7 25) Osmolality is sensed by osmoreceptors within the hypothalamus The localization of the osmoreceptors to the brain was first demonstrated by Verney (1947) Intracarotid injection of hypertonic saline was found to cause antidiuresis in dogs while similar volumes of hypertonic saline injected into the peripheral circulation had no effect An increase of 1 to 2 m Osm /kg is sufficient to raise vasopressin secretion provided that the osmolality is above 290 m Osm /kg Whether the osmoreceptors are the same cells that synthesize and secrete vasopressin is uncertain, they may be different cells When plasma osmolality increases, vasopressin is secreted

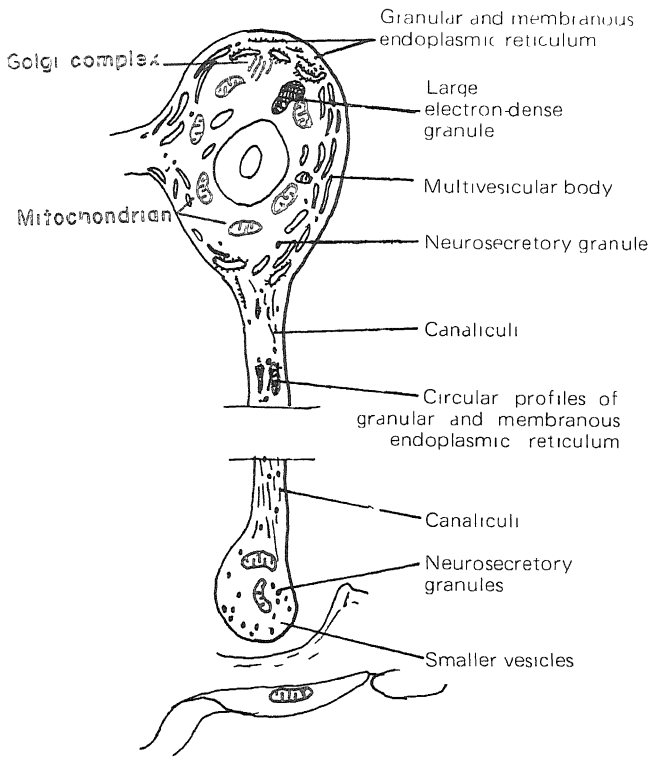

Fig 7 24 Diagrammatic representation of neuronal cell body in hypothalamus and nerve ending in infundibular process (From Sloper 1966)

Table 7 3
Neurohypophysial hormones of known chemical constitution and their distribution

Name	Chemical Constitution									Phyletic Distribution
	1	2	3	4	5	6	7	8	9	
Oxytocin	Cys	Tyr	Ile	Glu (NH_2)	Asp (NH_2)	Cys	Pro	Leu	Gly (NH_2)	Mammals, birds
Vasotocin	Cys	Tyr	Ile	Glu (NH_2)	Asp (NH_2)	Cys	Pro	Arg	Gly (NH_2)	All vertebrates except mammals
Arginine vasopressin	Cys	Tyr	Phe	Glu (NH_2)	Asp (NH_2)	Cys	Pro	Arg	Gly (NH_2)	Mammals except pig
Lysine vasopressin	Cys	Tyr	Phe	Glu (NH_2)	Asp (NH_2)	Cys	Pro	Lys	Gly (NH_2)	Pig

From Heller, 1966

and water reabsorption by the kidney is increased As a result, osmolality is restored to the initial value

Hemorrhage amounting to as little as 10% of blood volume results in an inhibition of water diuresis (Rydin and Verney, 1938) This response is due to an increase in the plasma vasopressin level (Fig 7 26) The response depends upon the degree of blood loss When blood loss approaches 50% of blood volume, vasopressin levels reach 600 μU /ml The release of vasopressin in response to hemorrhage is impaired in animals whose vagus nerves are cut Vagotomy interrupts the afferent pathway

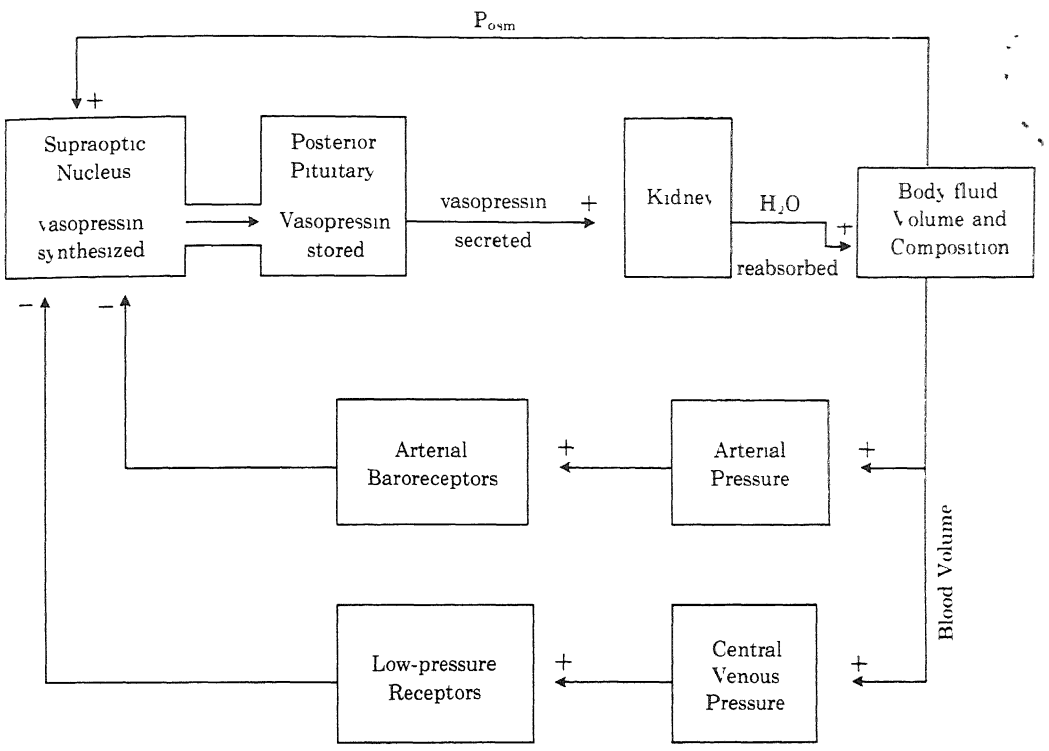

Fig 7 25 Control of vasopressin secretion by plasma osmolality and blood volume + increase or stimulation − decrease or inhibition (Modified from Share 1969)

from low-pressure receptors in the left atrium and perhaps other portions of the low-pressure side of the circulation Stretching of these receptors by distension of the left atrium generates afferent impulses which inhibit vasopressin release (Baisset and Montastruc, 1957, Share, 1965, Johnson et al, 1967) During hemorrhage, atrial pressure falls due to a drop in central venous pressure and fewer impulses arise from the low pressure receptors As a result, inhibition of vasopressin release is relieved and hormone appears in the blood

Carotid sinus baroreceptors are involved in control of vasopressin release When these receptors are stretched by normal or elevated blood pressure, impulses arise that are inhibitory to vasopressin release During hemorrhage, arterial pressure falls and fewer inhibitory impulses arise from the arterial receptors These receptors are probably responsible for the increase in plasma vasopressin seen in the vagotomized dog subjected to a large blood loss (Fig 7 26)

Interaction of the atrial and arterial pressure receptors in control of vasopressin release was suggested by Gauer and Henry (1963) In the normal animal, the first receptors to sense a change in blood volume are in the low-pressure system As hemorrhage becomes more marked, arterial blood pressure also falls and the arterial receptors participate in the increase in vasopressin secretion

Effects of vasopressin appear to be mediated by changes in intracellular levels of cyclic adenosine monophosphate (cyclic AMP) (Robinson et al, 1968) Addition of vasopressin increases cyclic-AMP levels while addition of cyclic-AMP mimics effects of vasopressin on water and sodium transport In addition, vasopressin stimulates the activity of adenyl cyclase found in preparation of kidney cell membranes The mechanism of action of vasopressin on the kidney is described elsewhere in this volume

CONTROL OF OXYTOCIN SECRETION

The major stimuli for release of oxytocin are *a*) suckling, and *b*) distension of the cervix and vagina (Cross, 1966) Increased milk ejection following oxytocin administration does not involve increased milk secretion but rather ejection of milk already present within the

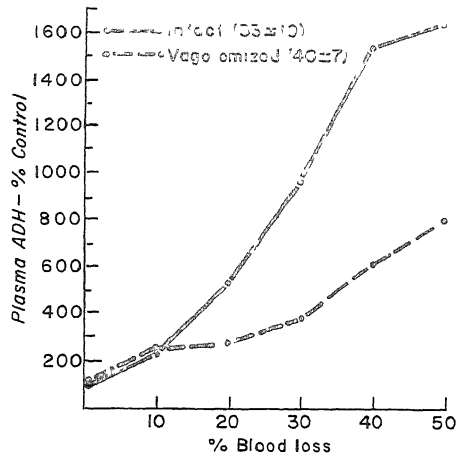

Fig 7 26 Effects of successive bleedings of 8 ml/kg body weight on the plasma vasopressin concentration in intact and vagotomized dogs The dogs were bled at 5-min intervals Blood samples for the determination of vasopressin were taken 3 min after the midpoint of each hemorrhage The plasma vasopressin concentration on the ordinate is expressed as per cent of the concentration of vasopressin in the plasma just prior to the first hemorrhage The abscissa is the degree of blood loss expressed as per cent of the initial blood volume which was taken to be 8% of the body weight The figures in parentheses are the concentration of vasopressin in microunits per milliliter of plasma in the initial blood samples (mean ± S E) (From Share 1969)

gland Ejection depends upon contraction of the myoepithelium present in the alveoli and lactiferous ducts Oxytocin levels have been measured in jugular vein blood before, during, and after suckling or milking and have been found to increase from about 5 μU /ml before suckling to 20 to 100 μU /ml during suckling Injection of 50 mU of oxytocin duplicated the normal milk-ejection response to suckling

The role of oxytocin in normal labor is still unclear Labor is a complicated process involving softening and dilation of the cervix, loosening of pelvic ligaments and contractions of abdominal muscles Oxytocin has no effect on these events On the other hand, blood levels of oxytocin in ewes were found to increase from about 3 μU /ml during pregnancy to 3,000 μU /ml during delivery of the lamb (Fitzpatrick, 1961 a,b) Similarly oxytocic activity of human systemic blood increased from 50 μU /ml during pregnancy to 150 μU /ml in the second stage of labor (Caldeyro-Barcia, 1961) Lesions that interrupt the supraopticohypophyseal tract in the anterior portion of the median eminence grossly impair labor (Fisher et al, 1938 b) Oxytocin, then, appears to serve an important but not vital role in labor It stimulates the frequency and duration of contractions in the uterine myometrium The hormone frequently is given by obstetricians to induce or intensify uterine contractions

Plasma levels of oxytocin are about the same in men as women, but the function of the hormone is uncertain Acceleration of sperm transport to the epididymis has been reported in rabbits

DISORDERS OF POSTERIOR PITUITARY FUNCTION

Diabetes insipidus is a condition in which large quantities of urine of very low specific gravity, 1 002 to 1 006, and low chloride content are excreted In an ordinary case the daily output of urine is 4 or 5 liters, but daily amounts several times these figures have been reported A corresponding increase in fluid intake occurs and thirst is often intense The condition frequently accompanies tumors of the pituitary or hypothalamic region, and is essentially due to lack of posterior pituitary hormone Ranson and his colleagues (Fisher et al , 1938a) were able to produce a similar picture in cats and monkeys by placing bilateral electrolytic lesions in the supraopticohypophysial tract in the hypothalamus Their cats developed a permanent polyuria of 300 to 500 ml of urine per day, which could be reduced to normal levels by replacement therapy with posterior pituitary extracts It may be pointed out that animals deprived of the pars distalis of the adenohypophysis, as well as the neurohypophysis, develop only a slight polyuria if any at all The pars distalis exerts a general diuretic effect which is necessary for the development of a marked polyuria This may be observed in human patients with an expanding lesion in the sella turcica Destruction of the neurohypophysis results in diabetes insipidus, but further development of the lesion may destroy the pars distalis with amelioration of the diabetes

Administration of vasopressin is the only available means for control of diabetes insipidus, but the hormone is not effective in some cases These individuals show a familial tendency to the disease which is thought to be due to an inherent defect of the renal tubules with respect to renal reabsorption of water

4 / CONTROL OF THYROID FUNCTION

The thyroid gland, as a distinct anatomical entity, has been known for at least 300 years, but its relationship to the clinical states we know as hyper- and hypothyroidism was not recognized until the latter part of the 19th century. At this time many of the features of cretinism and adult myxedema were noted to resemble changes which appeared after surgical removal of the thyroid. This suggested to physicians that the thyroid gland may secrete a humoral substance which is essential for the maintenance of well-being. A short time later Baumann discovered the presence of large amounts of iodine in the thyroid. Most of this was found to be incorporated within a protein which upon hydrolysis yielded a material that was effective in relieving the symptoms of myxedema. The physiologically active substance was isolated and chemically defined by Kendall (1915) who gave it the name thyroxin. In 1952, the second of the two presently known thyroid hormones, triiodothyronine, was discovered in thyroid glands by two English workers, Gross and Pitt-Rivers.

These two hormones, which are generally referred to as thyroxin or T_4 (3,5,3′,5′-tetraiodothyronine) and triiodothyronine or T_3 (3,5,3′-triiodothyronine), are both derived from the amino acid tyrosine, and are unique in that their biological activities are dependent on the presence of iodine, a trace element (Fig. 7-27). This particular structural feature has greatly aided our understanding of thyroid physiology and biochemistry. Since the radioactive isotope, ^{131}I, is incorporated readily into the hormones during their biosynthesis in the thyroid, it has been possible to study many aspects of the formation, distribution and metabolism of the thyroid hormones in a relatively straightforward way by measuring the isotope in vivo or in tissue samples.

HISTOLOGY

The thyroid tissue is composed of cuboidal epithelial cells arranged in a single layer around spaces roughly spherical in shape. These spaces variously known as follicles, vesicles, acini or alveoli contain a homogenous gelatinous material, the colloid substance which is the stored secretion of the gland. Connective tissue fibers support the alveolar walls and form septa which divide the gland into smaller masses. The cells lining the alveoli contain numerous mitochondria and a well-defined Golgi apparatus. Studies with the electron microscope have shown that the luminal or apical borders of these cells possess microvilli, which are characteristic features of cells engaged in absorption or secretion. When the gland becomes active, the Golgi apparatus hypertrophies and droplets of colloid appear in its proximity. Other histological changes typical of increased activity in the thyroid are increase in the epithelial cell height, increase in mitotic figures, decrease in amount of colloid in the follicles (with a tendency to become basophilic rather than acidophilic in staining properties), and an increase in vascularity. The maximal normal weight of the human thyroid is, according to Marine, from 20 to 35 g or around 0.4 g/kg of body weight. The thyroid tissue of the early fetus consists of masses of epithelial cells showing little or no arrangement into follicles. The latter appear about the 3rd month in the human but are small and contain little colloid. Functional activity first appears in the fetal gland at about this time. Concentration of inorganic iodide is demonstrable before the appearance of colloid, but organic binding (formation of iodinated amino acids) is not observed until colloid is demonstrable histologically.

Synthesis, Storage and Secretion of Thyroid Hormones

Iodine is a relatively scarce element in the earth's crust and animals have had to develop extremely efficient means to extract enough for biological purposes. Ultimately, all of the iodine taken into the body is derived from soil

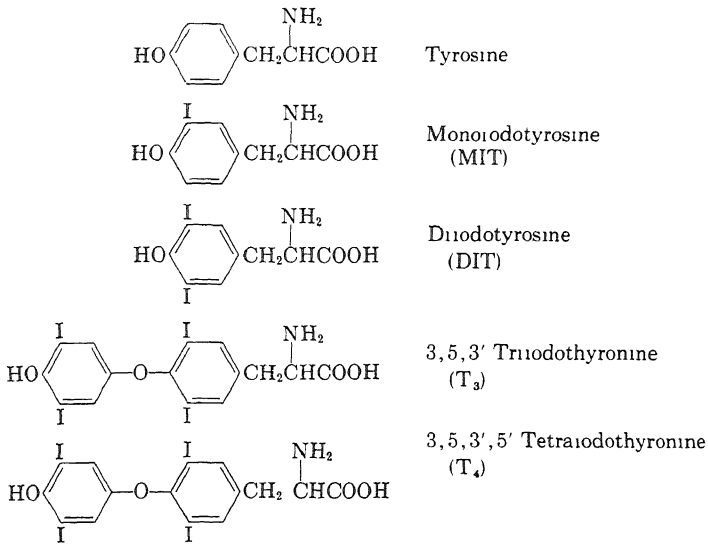

Fig 7 27 Structure of tyrosine and its important iodinated derivatives

and water and it is the content of iodine in these natural sources which determines the amount normally ingested Iodine taken in with food in organic form is released as iodide (I^-) and it is absorbed into plasma in this form (Fig 7 28) The major route of excretion of iodide is urine although small amounts are lost in the feces, mainly in organic form

IODIDE TRAPPING (Halmi, 1964, Wolff 1964)

Nearly one-half of the total body iodine is normally sequestered in the thyroid gland This is a truly remarkable accomplishment when one considers the extremely small amounts of iodine present in plasma and in the water and food that are consumed The ability of the thyroid cell to take up iodide from plasma and concentrate it is a prerequisite for the optimal synthesis of thyroid hormone In geographic areas where the content of iodine in soil and water is low, iodide trapping efficiency by the thyroid may become greatly increased In laboratory animals, such as the rat, the ratio of thyroid to serum iodide (T/S ratio) often reaches values of 100 when iodine depletion is rigorously maintained by the combination of a low iodine diet and the administration of propylthiouracil, a drug that blocks synthesis of thyroid hormone

The trapping of iodide against an electrochemical gradient, like active sodium transport, has been shown to require a steady input of energy from adenosine triphosphate (ATP) Transport is strongly inhibited under anaerobic conditions or following the administration of agents such as dinitrophenol which reduce ATP by uncoupling oxidative phosphorylation Inhibition of Na-K ATPase by the cardiac glycoside, ouabain, also interferes with iodide transport in thyroid slices, and the suggestion has been made that trapping may be linked in some way to cation transport

As in other carrier-mediated transport systems, the trapping of iodide can be inhibited competitively by other ions The strongest inhibitory effects are exerted by univalent anions of similar ionic size and shape Thiocyanate, perchlorate and nitrate ions are among the common ones which exhibit inhibitory properties Other halides such as fluoride and chloride do not react, although the heaviest halide, astatide, which is naturally radioactive, is accumulated by the thyroid to about the same extent as iodide The blocking effect of thiocyanate and perchlorate on iodide uptake by the thyroid will reduce the synthesis and subsequent release of thyroid hormones and, for this reason, both agents have been employed clinically in the treatment of hyperthyroidism

Although iodide trapping is a characteristic feature of the thyroid, it is not limited to this organ Other tissues such as the salivary glands, intestinal mucosa, mammary gland, the ciliary body and choroid plexus concentrate iodide to some extent and may even form small amounts of monoiodotyrosine (MIT), but

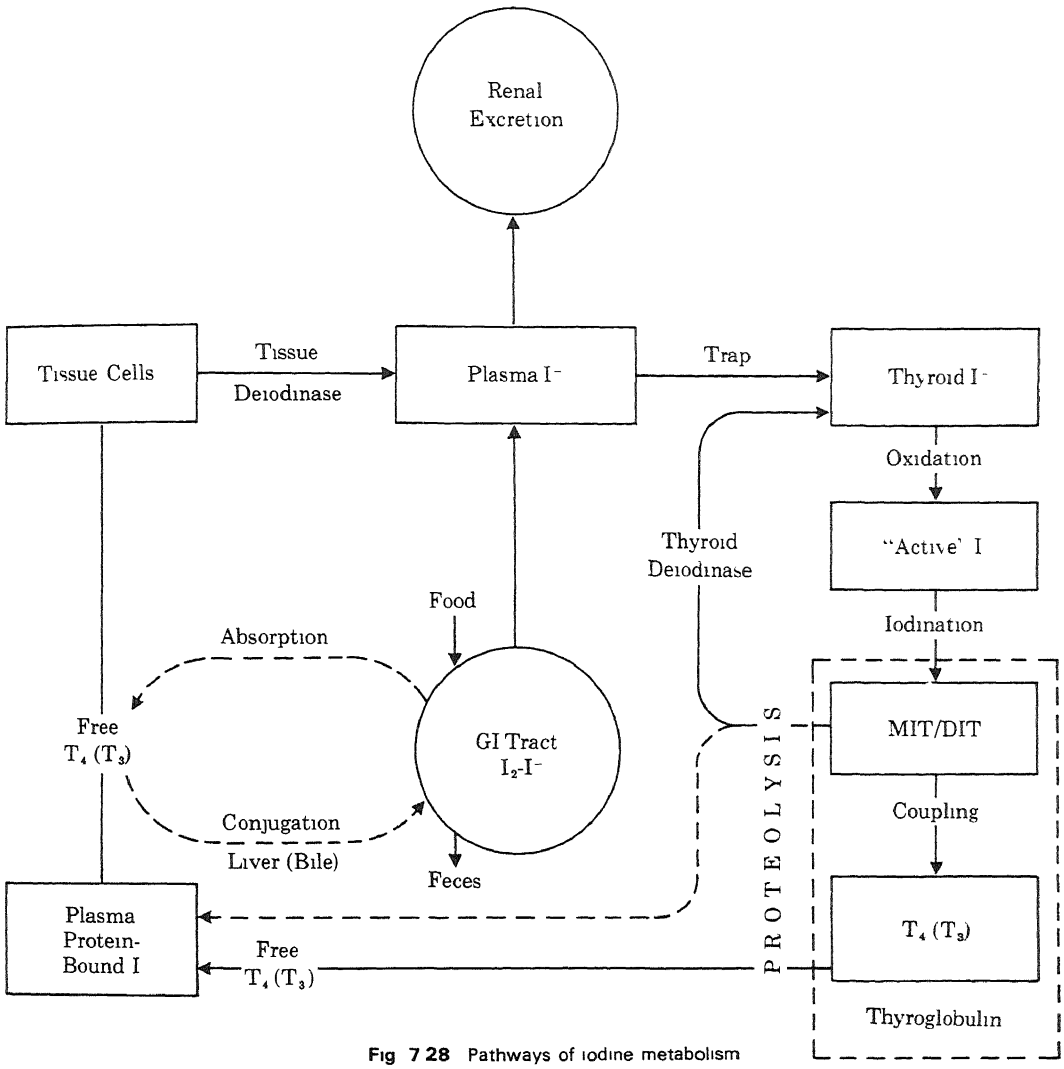

Fig 7 28 Pathways of iodine metabolism

these tissues do not possess the ability to synthesize thyroid hormones, and thus the total quantity of iodine stored is negligible It is of interest that iodide transport in these tissues can be inhibited competitively by the same anions that are effective in the thyroid However, trapping is not regulated according to the need for thyroid hormone as is the case in the thyroid gland

The mechanism of regulation of iodide transport in the thyroid is not clearly understood but one of the factors which may be involved is an adaptive response to thyroid-stimulating hormone (TSH) Iodide transport is greatly reduced in hypophysectomized animals and can be stimulated by the administration of TSH in vivo The response, however, is achieved only after several hours of treatment and attempts to stimulate iodide transport in vitro with TSH have been unsuccessful Thus, the effect appears to be indirect and a number of intermediate steps are undoubtedly involved in its regulation The notion has also been advanced that iodide transport is to some degree self-regulating As presently viewed, this regulation involves the inhibition of transport by some intracellular iodine product which as yet remains unidentified

ORGANIFICATION (Pitt-Rivers and Cavalieri, 1964, Rall et al 1964 Stanbury, 1966, Murray and McGuirr 1964 Greer et al, 1964, Taurog, 1970)

The second phase of thyroid hormone biosynthesis represents the iodination of tyrosine

residues in peptide-linkage within the intact thyroglobulin molecule a process known as organification or organic binding Since thyroglobulin is stored within the acinar space of the follicle iodide which is transported across the membrane at the base of the cell must move through the cell to the opposite or apical pole in order to reach the site of organification This apparently happens very quickly since in radioautographic studies in rats the first appearance of ^{131}I is in the colloid adjacent to the epithelial membrane at the apical pole Monoiodotyrosine (MIT) can be detected shortly after the injection of ^{131}I The formation of diiodotyrosine (DIT) and the coupling of the iodotyrosines to form T_4 and T_3 occur somewhat later

The mechanism of thyroglobulin iodination is not clearly understood but it is probable that most of the reactions involved are enzymatic in nature It is generally agreed that iodide is first oxidized at a site on the cell membrane adjacent to the acinus Biochemical and histochemical studies have revealed the presence of an enzyme, peroxidase, and it is also known that the organic binding of ^{131}I is strongly inhibited by the addition of catalase to preparations of isolated thyroid cells While these findings strongly suggest that hydrogen peroxide is an intermediate, the oxidation product of iodide has not been identified with certainty The iodination reaction, which involves the incorporation of oxidized or "active" iodine into the phenolic ring of tyrosine, is probably enzymatic as well and may represent an intrinsic function of the same peroxidase system

The final step in organification involves the coupling or condensing of two iodotyrosines, which are in peptide linkage within the thyroglobulin molecule to form the iodothyronines, T_3 and T_4 The reaction transfers the phenolic group from one iodotyrosine to another and splits out alanine which remains in peptide linkage The amount of T_4, as opposed to T_3, depends to some extent on the relative amounts of MIT and DIT present With extensive iodination of thyroglobulin, the ratio of DIT to MIT is increased and hence the yield of T_4 would be proportionately greater In man, as in a number of other animals, T_4 is the predominant iodothyronine It should be mentioned, however, that the much smaller quantity of T_3 does not necessarily lessen its physiological importance since the biological activity of T_3 is considerably more intense than that of T_4 Whether by design or by accident, this quantitative difference in effectiveness between T_3 and T_4 is useful from the standpoint of iodine conservation In deficiency states, when iodine must be efficiently reutilized, the proportion of T_3 increases, thus adding further protection against hormone deficiency

A number of cases have been reported in which spontaneous defects in coupling have resulted in goiter and hypothyroidism Only traces of T_4 and T_3 were found in these individuals although ^{131}I was rapidly taken up by the thyroids and incorporated into DIT and MIT which, in a few instances, could be detected chromatographically in the plasma

Blocking of Organification A number of organic compounds, including thiourea, propylthiouracil, the sulfonamide drugs, and mercaptoimidazoles, are known to interfere with organification and to cause goiter Owing to their effectiveness in blocking thyroid hormone synthesis, a number of these chemicals, especially propylthiouracil, and one of the mercaptoimidazoles, Tapazole, have been widely used clinically in the treatment of hyperthyroidism Naturally-occurring goitrogens, which exert similar effects on the thyroid, are found in the seeds of many plants of the cabbage family and in the rutabaga and turnip

The mode of action of these compounds has not been established but it is clear that all steps in organification are affected The coupling reaction is strongly inhibited, DIT and MIT formation are inhibited also although small amounts of MIT continue to be formed in the presence of a high concentration of blocking agent These agents exert no inhibitory effect on iodide trapping and in fact very high T/S ratios of iodide are usually observed following their administration This may result in part from the high levels of endogenous TSH which follow the reduction of thyroid hormone secretion

THYROID HORMONE STORAGE AND RELEASE (Rall et al, 1964, Wollman, 1969, Murray and McGuirr, 1964)

Thyroid hormone is stored within the gland as iodothyronines incorporated in peptide linkage within the protein, thyroglobulin The

latter is a protein of about 680,000 molecular weight which is synthesized by the epithelial cells and then secreted prior to its iodination into the lumen or acinus of the follicle where it accumulates as a material known grossly as colloid Since the acinar space is separated from the extracellular space by a layer of epithelial cells, the high molecular weight of the colloid serves to keep the osmotic pressure and, hence, the volume of the colloid space within reasonable limits

It is evident from the foregoing that the problem of hormone release becomes one of transporting the iodinated thyroglobulin back into the epithelial cell and digesting it The series of events which encompass this process have been dramatically unfolded with the use of the electron microscope Experimentally, as early as 5 min after TSH administration, the microvillous border of the epithelium adjacent to the colloid becomes extensively folded and cytoplasmic projections move out into the colloid Small vesicles, known as colloid droplets, appear within the cytoplasm This endocytic process resembles phagocytosis closely and is one of the earliest manifestations of TSH action As the vesicles move toward the basal membrane of the cell, they fuse with lysosomes which contain proteolytic enzymes The proteolysis of thyroglobulin and subsequent release of free T_4 and T_3 is presumed to take place within these vesicles Although this process can be visualized best under maximal TSH stimulation, it is thought to represent the normal route of thyroglobulin digestion and hormone release under normal physiological conditions

Thyroid deiodinase. In addition to its content of T_4 and T_3, thyroglobulin normally contains variable quantities of MIT and DIT which remain uncoupled These iodotyrosines are freed as a result of thyroglobulin digestion and, except for small amounts which escape into the circulation, they are rapidly deiodinated by a potent thyroid deiodinase This important function tends to conserve thyroidal iodide for reutilization in iodinating new thyroglobulin There are on record cases of hypothyroidism in which there is a genetic absence of thyroid deiodinase From this clinical evidence it may be presumed that without a mechanism for conserving thyroidal iodide the gland would lose more iodide than it could regain by augmented iodide trapping. The intracellular pool of iodide generated by this deiodination reaction does not mix readily with the transport pool of iodide and is thus portected against loss from the cell at sites of iodide exchange with the plasma This pool has been termed the second iodide pool as distinguished from the first or transport pool

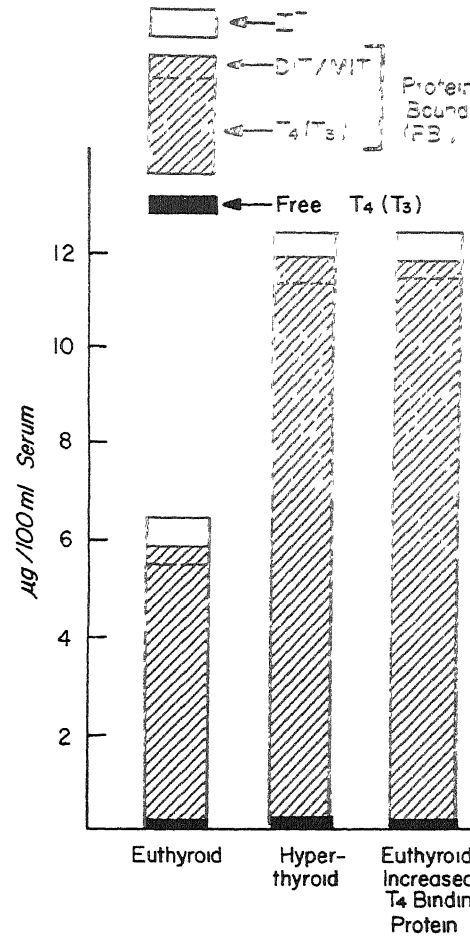

Fig 7 29 Iodine fractions in plasma

Distribution and Metabolism of Thyroid Hormones[1]

PLASMA IODINE

The iodine content of plasma exists in a number of discrete fractions and the analysis of these fractions in one way or another has been used extensively in diagnostic tests for hyper- and hypothyroidism (Fig 7 29) Of the

[1] Rall et al , 1964, Robbins and Rall, 1960, Tata, 1964, Sterling, 1964 and 1970

total amount of iodine in plasma, which in a healthy individual averages about 6 μg/100 ml, 90% represents iodine in organic form and the remainder is free iodide Of the organic fractions, more than 95% is bound to protein Since these protein-bound fractions, collectively called protein-bound iodine or PBI, largely comprise bound T_4 and T_3, the PBI has been used extensively as a diagnostic test for hyper- and hypothyroidism The normal range for the PBI is 4 to 8 μg/100 ml of serum, and values above and below this range are consistent with the diagnosis of hyper- and hypothyroidism, respectively Protein-bound T_4 and T_3 can be separated from iodide and small amounts of MIT and DIT by extracting the serum proteins with butanol and then washing the butanol with alkali This method has been used to improve the diagnostic capability of the PBI in instances, for example, where the PBI may be falsely elevated after the ingestion of large amounts of iodide

From the standpoint of the physiological effects of the thyroid hormones on body tissues, the most important fraction is the very small amount of free T_4 and T_3, estimated to be in the range of 5×10^{-11} M The quantity is too small to measure by direct chemical means, but it has been quantitatively assessed after equilibrium dialysis of plasma Most of it consists of T_4, but small amounts of T_3 are also present This free fraction is thought by most investigators to represent the physiologically-active fraction of circulating thyroid hormone and to correlate with the clinical states of hyper- and hypothyroidism

THYROXIN BINDING PROTEIN (TBP)

The small fraction of free thyroxin in serum is in equilibrium with a much larger protein-bound fraction Most of the bound thyroxin migrates during electrophoresis with a protein located between α_1 and α_2 globulin A smaller portion is bound to a prealbumin fraction In general terms, the quantity of T_4 that is bound can be predicted from mass action equations if the total number of sites that are available for binding are known In clinical situations, such as pregnancy or after estrogen administration, where the TBP is known to increase, the amount of thyroxin bound will also increase This might cause a significant reduction in the amount of free thyroxin were it not for the efficient operation of the thyroid-pituitary servomechanism which increases the output of thyroxin from the thyroid gland to maintain a physiological level of free thyroxin (see below) It should be pointed out that when the TBP is elevated, the PBI is also increased It is for this reason, among others, that the PBI has been largely supplanted by improved methods of diagnosis

FATE OF THYROID HORMONES

Free T_4 and T_3 in plasma are thought to be in equilibrium with free iodothyronines within tissue cells, and there is considerable indirect evidence suggesting that the cell membrane does not play an active role in the transport of the free hormone from the vascular to the tissue compartments, but rather the hormones gain access to the intracellular compartment by simple passive diffusion In ^{131}I label studies, the iodothyronines have been found to bind firmly but reversibly to subcellular constituents such as the nuclei, mitochondria, and the rough endoplasmic reticulum Owing to the mass of skeletal muscle, the largest fraction of tracer doses of T_4 and T_3 can be recovered from this tissue However, the most intense binding and highest rates of turnover are found in the liver It is of interest that virtually no intracellular binding of the thyroid hormones occurs in the brain or the gonads, tissues which are also unresponsive to the direct metabolic effects of these hormones

The iodothyronines are known to undergo at least three major types of reactions according to the tissue involved First, an appreciable fraction is taken up by the liver and conjugated The conjugated products appear in the bile largely as the β-glucuronide The product may undergo hydrolysis in the intestine followed by reabsorption of the free hormone This circuit from blood to liver to the intestine and back to blood again is known as the enterohepatic circulation A certain fraction of the β-glucuronide fails to be reabsorbed and is excreted in the feces

Like their amino acid cousins, the iodothyronines also undergo oxidative deamination and transamination These reactions occur both in the kidney and liver but are more prominent in the former and represent the major metabolic pathways for T_4 and T_3 in this tissue

The final and most important metabolic fate of the thyroid hormones is their deiodination

Eventually, iodine is irreversibly lost from all of the hormones secreted by the thyroid except for that fraction which is excreted intact in the feces The deiodination is accomplished by a tissue deiodinase activity which differs from thyroid deiodinase in that it has a high specificity for T_4 and T_3 Once iodide is liberated it may be retrapped by the thyroid or excreted in urine An interesting question may be raised as to whether T_3 is generated within tissue cells by the partial deiodination of T_4 While most investigators have felt that any T_3 present in tissue cells gets there by inward transport from the free T_3 pool in plasma, there is now evidence that an appreciable fraction of circulating T_3 is formed by the extrathyroidal deiodination of T_4

Control of Thyroid Function[2]

The thyroid gland is directly under the control of the anterior pituitary and the loss of pituitary function by hypophysectomy or disease, such as postpartum necrosis or tumor, results in striking involutional changes in the thyroid These changes include flattening of the follicular epithelial cells and decreases in rates of iodide uptake, hormone biosynthesis and release The PBI is often low and patients exhibit a low basal metabolic rate (BMR) and complain of extreme intolerance to cold All these features are directly attributable to the loss of thyroid-stimulating hormone (TSH) Under appropriate conditions, it is possible to reverse these changes and completely restore thyroid function It should be emphasized at this point that while thyroid function is greatly reduced in the absence of TSH, it does not entirely disappear and there remains a low intrinsic basal activity Thus, TSH does not appear to bring into existence any of the essential thyroid processes, but it simply accelerates their rates

THYROID-STIMULATING HORMONE TSH) (Bates and Condliffe, 1966 Odell et al, 1967, Field, 1968, Freinkel 1964)

TSH is a glycoprotein secreted by basophilic staining cells of the anterior pituitary It has a molecular weight of about 30,000 and has been purified sufficiently to permit the development of an immunoassay for endogenous TSH

Effects of TSH. The action of TSH is limited to the thyroid gland, but in this tissue the manifestations of its activity are numerous and they encompass nearly all phases of cellular function In general the effects are stimulatory and appear to be directed toward speeding-up the intrinsic processes that are evident in glands from hypophysectomized animals

For purposes of description, the effects of TSH may be divided into two major categories The first is concerned with iodine metabolism and includes all the steps involved in the transport of iodide from the plasma into the cell, its organic binding and the events leading to the hormone release Among the earliest effects of TSH is the stimulation of hormone release As mentioned earlier, the addition of TSH to thyroid slices or isolated cells is followed within minutes by the appearance of colloid droplets near the apical membrane of the cell This process which results in the secretion of T_4 and T_3 can be observed in the absence of any evident stimulation to organification or iodine trapping It is clear from other types of experiments however, that iodine binding is stimulated by TSH This effect is thought to be an independent response since it may be elicited under conditions where the trapping of iodide is blocked The stimulation of iodide trapping by TSH is the slowest of the responses and has not been directly observed in isolated thyroid tissue

Included in the second category are a large number of responses relating to energy metabolism, synthetic processes and cell growth Increases in oxygen utilization, glucose uptake, and oxidation are early responses to TSH Nicotinamide adenine dinucleotide phosphate (NADP) levels also rise in association with the stimulus to glucose oxidation While this alteration has given rise to considerable speculation, its significance has not been established Other early effects are the stimulation of ^{32}P incorporation into phospholipids and an increase in net Na^+ and water uptake Effects relating to cell growth are somewhat slower to appear These include the stimulation of protein and ribonucleic acid (RNA) synthesis, an increase in mitotic activity and an increase in the height of the epithelial cells Along with these changes, the gland often shows increased vascularity

Attempts to explain this diversity of effects by a single site of action has been a frustrating

[2] Purves, 1964, Dobyns, 1964, Brown-Grant, 1966

experience for many investigators in this field, especially since it has been shown that TSH does not enter the cell but probably is bound to receptor sites on the cell membrane As a result, TSH is spatially separated from the many locations of functions that it controls The answer to this problem may be the second messenger, cyclic AMP TSH has been shown to stimulate the adenyl cyclase activity in isolated thyroid cell membranes and to increase tissue levels of cyclic adenosine monophosphate (cyclic AMP) in intact cells Moreover, addition of the dibutyrl derivative of cyclic AMP, which penetrates the cell membrane, evokes many of the early responses to TSH, notably the stimulation of colloid droplet formation and glucose oxidation Whether all of the effects of TSH, particularly those relating to cell growth, are mediated to cyclic AMP yet remains to be established

PITUITARY-THYROID FUNCTIONAL RELATIONSHIP (Fig 7 30) (Purves, 1964 Dobyns 1964, Brown-Grant 1966 Odell et al , 1967)

It has long been recognized that the release of TSH by the pituitary is strongly inhibited by T_4 and T_3 It is generally thought that the inhibitory response is sufficiently sensitive to physiological concentrations of hormone that any significant tendency for the level of free T_4 to deviate from a set point would be buffered by appropriate changes in the secretion of TSH This in a few words describes the basic mode of regulation of thyroid secretion by the pituitary In operation, it is identical to the type of negative feedback control or servomechanism found in many different control systems and serves to maintain the level of hormone in plasma at a constant value When the constant inhibitory play of free T_4 and T_3 on the pituitary is decreased or abolished following thyroidectomy or the administration of agents such as propylthiouracil which interfere with hormone secretion, TSH release increases The subsequent rise in plasma TSH can be measured in samples of plasma by immunoassay methods and will differentiate hypothyroidism resulting from a primary interference with thyroid hormone production in the thyroid from that arising secondarily as a consequence of the loss of TSH secretion by the pituitary There is some evidence, largely from studies of cold adaptation, that T_4 also exerts an inhibitory effect on TSH secretion via the hypothalamus This effect, however, does not play a prominent role in the feedback control of the thyroid

INFLUENCE OF THE HYPOTHALAMUS ON THE PITUITARY-THYROID RELATIONSHIP (Brown-Grant, 1966 Burgus and Guillemin 1970b)

The basic feedback relationship between the pituitary and thyroid can operate independently of the central nervous system, but it is clear from a number of physiological studies that higher centers do influence this relationship to a significant degree If the neurovascular link between the hypothalamus and pituitary is interrupted experimentally, either by transplanting the pituitary to another site such as the renal capsule or anterior chamber of the eye or by transecting the pituitary stalk and inserting an impermeable barrier to prevent growth of the portal vessels, the activity of the thyroid declines somewhat, but is still significantly higher than that found in hypophysectomized animals Although the amount of TSH that is secreted is smaller than that secreted when the pituitary is in its normal position, the secretion can be inhibited by T_4 Thus, the basic servomechanism remains intact, but it appears as though the set point has been adjusted downward One of the more striking features of animals with transplanted pituitaries is their failure to release TSH with cold stress as occurs in normal animals

An exciting recent development has been the chemical identification and synthesis of a small peptide serving as the humoral link between the hypothalamus and the anterior lobe of the pituitary The substance which had been recovered from hypothalamic extracts is called thyrotropin releasing factor or TRF It is thought to be synthesized by neurons in the hypothalamus and secreted at nerve endings in the median eminence where it is picked up by vessels of the hypophysial portal circulation and then carried to the anterior lobe There it acts to stimulate the release of TSH Although much has yet to be learned about the relationship of the hypothalamus to the anterior pituitary, it may be assumed that much of the regulatory activity that has just been discussed is a result of the interplay between the stimulatory

effect of TRF and inhibitory influence of T_4 and T_3 on TSH secretion by the anterior lobe It follows from this that the level of TRF stimulation determines the set point or "thermostatic setting" about which the pituitary-thyroid servomechanism operates There is already considerable evidence that the setting is increased in homeothermic animals when they are exposed to cold

THYROID REGULATION IN SOME COMMON SITUATIONS

Goiter. Any agent or condition which interferes directly with thyroid hormone production will promote increased TSH secretion by decreasing the inhibition of TSH release If the interference is prolonged, thyroid enlargement or goiter may result This is the usual mechanism of goiter formation associated with the administration of thyroid blocking agents such as propylthiouracil or thiocyanate, or following ingestion of naturally occurring goitrogens In all of these instances, the thyroid enlargement is dependent on continued TSH secretion since, in animal experiments, removal of the pituitary or suppression of TSH release by the administration of T_4 will prevent goiter formation

Thyroxin-Binding Proteins (TBP) It was mentioned earlier in this chapter that the physiological activity of thyroid hormone on tissues is more likely related to the free fraction in plasma than to the much larger amount bound to protein The quantity of binding-protein is known to increase considerably in such situations as pregnancy or following the administration of estrogens and may decrease where there are abnormal urinary losses of protein as in nephrosis It is of interest then to consider the consequences of changes in the level of binding proteins on the regulatory mechanisms As the level of binding protein rises for any reason, more T_4 will be bound and the free fraction of T_4 will tend to fall Owing to the operation of the pituitary-thyroid servomechanism, any reduction in free T_4 will evoke an increase in the rate of secretion by the thyroid This response will take place concurrently with the rise in TBP and when the rise ceases, many of the additional binding sites on the protein will be occupied by T_4, thus contributing to an elevation in the PBI

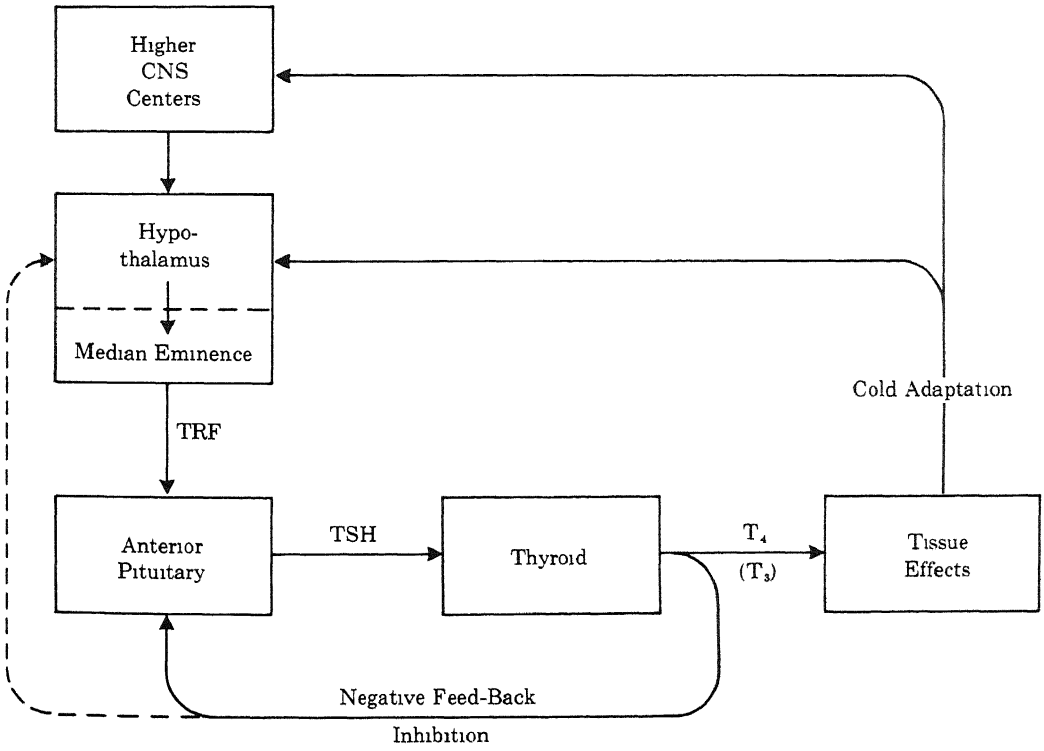

Fig 7 30 Scheme showing major regulatory influences on the thyroid

The concentration of free T_4, however, will remain the same since it is adjusted by the setting of the servomechanism Thus, the end result of the physiological adjustment to a rise in TBP is a larger pool of T_4, most of which is bound Hyperthyroidism does not occur in this situation since tissue effects of T_4 are related to the free fraction, not the amount bound

The opposite changes occur when the level of TBP falls, as for example following pregnancy An effect similar to an actual fall in the level of binding protein may be obtained by the administration of drugs such as salicylates which compete with thyroxin for the binding sites

Tissue Effects of Thyroid Hormone

The mechanism of action of the thyroid hormones at the tissue level is not known It is clear, however, that the iodothyronines T_4 and T_3 exert numerous effects on nearly every tissue of the body While the diversity of these effects seems endless and limited only by the imagination and energy of the investigator, most of the effects appear to participate in the regulation of two general types of processes *a*) growth and differentiation, and *b*) oxidative or energy metabolism Aside from purposes of discussion, there are reasons for believing that these two categories of responses may represent different actions of thyroid hormone It is known, for example, that T_4 will stimulate oxygen utilization in all homeothermic vertebrates, but little or no response is seen in poikilothermic animals On the other hand, metamorphosis in amphibia and other poikilothermic vertebrates is strongly dependent on the presence of a functioning thyroid The basis for such a differentiation may be more apparent than real, however, since investigators have now begun to recognize that the effect of thyroid hormone on oxygen utilization may depend on an alteration at the level of gene expression

GROWTH AND DIFFERENTIATION (Shallabarger, 1964)

Early studies have shown a clear dependence of metamorphosis in frogs on thyroid hormone The administration of thyroid extract to frog tadpoles results in rapid metamorphosis and the production of small but otherwise normally developed frogs Contrarily, thyroidectomized tadpoles fail to develop legs although general somatic growth continues Thus, very large larval forms are produced in this way Mammalian development is also influenced by thyroid hormone Hypophysectomy in very young rats treated with growth hormone will show general growth of bone, but striking abnormalities in the epiphyseal structure will appear While T_4 alone in these animals has little apparent effect on general somatic growth, it is required for the normal pattern of bone maturation Development of the central nervous system is also affected by the thyroid, a response which is thought to account for the mental retardation in cretinism where thyroid function is lacking early in life

CELLULAR METABOLIC PROCESSES (Barker 1964 Wolff and Wolff 1964

In 1895 Magnus-Levy observed a low basal oxygen consumption in hypothyroid patients and was able to reverse this defect by the administration of thyroid extract It has been shown subsequently that basal oxygen consumption in the range of 50% below normal to twice the normal rate is directly influenced by the level of circulating thyroid hormone Both T_3 and T_4 have qualitatively the same effect on tissue respiration and other metabolic processes, although there are quantitative differences that were alluded to earlier Investigation has shown that mole for mole the effect of T_3 on oxygen consumption is quicker to appear and gives a greater peak response than does T_4 However, since the total duration of effectiveness of T_3 is shorter than T_4, both drugs are thought to give about the same overall response

Alterations in oxidative metabolism are also evident in isolated tissues taken from hyper- and hypothyroid animals Large changes in O_2 utilization are seen in liver, muscle, kidney, heart, salivary glands, and the pancreas, while other tissues such as brain, spleen, lymph nodes, and the gonads, are apparently unresponsive to the hormone It is of interest to note, as was mentioned earlier, that labeled T_4 does not bind appreciably to subcellular particles from the latter group of tissues

The mode of action of thyroid hormone on oxygen consumption has been the subject of extensive investigation for many years In general, all oxidative processes are speeded up in

tissues from hyperthyroid animals The utilization of energy yielding substrates, such as glucose and fatty acids, are greatly increased but it is clear that the effect is not simply the result of an increase in the availability of these substrates for oxidation Some basic change has occurred in oxidative machinery of the cell In view of the similarity between hyperthyroidism and the hypermetabolism which results from the administration of uncouplers of oxidative phosphorylation, such as dinitrophenol, the notion has been put forth that thyroid hormone acts as an uncoupling agent It is true that some deficiency in ATP formation does occur, particularly in very severe hyperthyroidism, but in slight or moderate hyperthyroidism ATP levels may be normal or even increased Furthermore, since it is not possible to couple oxidative phosphorylation more tightly than one sees in euthyroid states, it is difficult to explain the decreased oxygen consumption in hypothyroidism Most of the evidence clearly points to the regulation of oxidative metabolism within the mitochondria, with or without effects on the coupling of oxidation to ATP formation

While the biochemical mechanism of the thyroid hormone-induced hypermetabolism is still not clear, it does seem probable that the effect is dependent on some fundamental alteration of the cell which involves new protein synthesis This alteration could represent enzyme protein, structural components or a cluster of changes It has long been known that the effects of T_4 and even the faster-acting T_3 on O_2 consumption are slow to appear, often requiring days of treatment before optimal increases have been established One may presume, of course, that other changes occurred much earlier since it is known that the hormones attach themselves to cellular sites soon after they penetrate the cell membrane Earlier effects have in fact been measured and one of the first recorded is an increase in the synthesis of nuclear RNA in livers of hypothyroid rats This is followed by the stimulation of protein synthesis in certain fractions of cell protein, including mitochondrial protein Of interest is the further finding that when protein synthesis is inhibited, the enhancement of O_2 consumption following T_4 fails to appear Such an apparent dependence of tissue respiration on protein synthesis in this instance does not imply that all metabolic effects of T_4 and T_3 are related to protein synthesis, but it does implicate one or more of the key steps leading to hypermetabolism

A number of other metabolic changes are seen in hyper- and hypothyroidism Owing to the need for large quantities of oxidizable substrate in hyperthyroidism, glycogen stores in liver may become rapidly depleted in the postabsorptive state and the breakdown of body protein, especially skeletal muscle, may be increased to provide carbon for gluconeogenesis The oxidation of fatty acids and cholesterol is increased in hyperthyroidism The opposite effect is seen in hypothyrodism where hypercholesterolemia is a prominent feature Because of this blood finding and the high incidence of angina and ischemic heart disease in hypothyroidism, considerable effort has been expended in synthesizing thyroid hormone analogues which will lower serum cholesterol without producing significant calorigenic effects Despite the prominent catabolic effect of thyroid hormone on protein metabolism that is evident clinically in severe hyperthyrodisim, thyroid hormone does exert significant anabolic effects on tissue and body growth The effect is clearly seen from the retardation of growth that occurs when adequate amounts of thyroid hormone are lacking during development

Physiological Aspects of Thyroid Disorders[3]

THYROID ^{131}I UPTAKE (Goolden 1964)

A variety of tests have been devised to measure thyroid function by the amount of ^{131}I-iodide taken up in the thyroid under specified conditions By and large these have proven to be useful not only in the diagnosis of thyroid disorders but in extending our knowledge of the basic functioning of the thyroid As is so often the case, the two objectives are inseparable since an intelligent understanding of disease requires a full knowledge of the working of the system in health Most of the tests have employed external counting of radioactivity over the thyroid region in the neck from 10 min to 48 hr after the test dose Since plasma iodide is cleared almost exclusively by the thyroid and the kidneys, the quantity of radioactivity excreted in the urine

[3] MacGregor, 1964, Morgans, 1964

will provide an indirect assessment of uptake Other modifications have included the measurement of ^{131}I in PBI after 24 to 48 hr as an assessment of hormone secretion The average range of values for the 24-hr thyroid uptake in normal subjects is 10 to 40% of the test dose Values above 50% are indicative of hyperthyroidism (Fig 7 31)

The ^{131}I uptake is influenced by many factors, some of which should be considered in the interpretation of clinical data The ingestion of iodides will reduce uptake by dilution of the label in plasma and by a direct, but not well understood, suppression of thyroid activity Thyroid blocking agents, of course, exert inhibitory effects Since the pool of free iodide in the thyroid is small compared with the pool of organified iodine, ^{131}I uptake in the presence of a block in organification will not be large The administration of perchlorate will discharge this pool of ^{131}I, however, but will not reduce any radioactivity that has been organically bound This method has proved useful in differentiating defects in organification from other forms of hypothyroidism

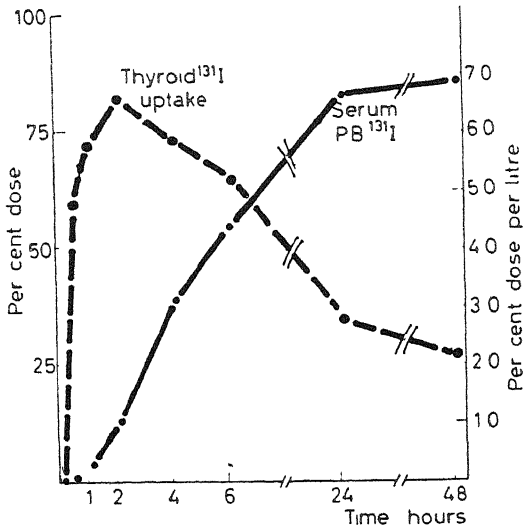

Fig 7 31 The accelerated turnover of iodine in thyrotoxicosis demonstrated by ^{131}I studies in a thyrotoxic woman following an intravenous dose of 25 μc The thyroidal uptake of ^{131}I was very rapid the thyroidal clearance rate being 302 ml/min/1 73 m ^{2} a spontaneous release of radioactivity beginning after 2 hr was reflected by a steady increase of protein-bound radioactivity in the serum at all times more than 90% of this PB ^{131}I was extractable with butanol chromatographic analyses confirmed the presence of iodothyronines from 2 hr onwards (From Murray and McGirr 1964)

The change in uptake after the test administration of TSH or T_4 (T_3) has on occasion proved to be extremely useful diagnostically In hypothyroidism of pituitary origin, the administration of TSH will greatly stimulate uptake Thyroxin or T_3 will suppress uptake by its inhibitory effect on TSH release In the hyperthyroidism of Graves' disease however uptake is not suppressable with T_3 and this test has been widely employed to differentiate borderline cases of hyperthyroidism of this kind from otherwise normal individuals with overly active thyroids

HYPERTHYROIDISM

This clinical condition results from excessive levels of thyroid hormone in plasma The term is a physiological designation and, hence, does not denote the source of the hormone Generally, the cause is hypersecretion by the thyroid, but an excessive oral intake of thyroxin will give the same result Hypersecretion by the thyroid commonly arises either from a diffuse hyperplasia of the thyroid or from hyperplastic nodules Rarely, it is associated with thyroid malignancy The first of these afflictions classically occurs in young women and is known in this country by the eponym, Graves' disease The cause of the diffuse hyperplasia has not been clearly established, but there is abundant evidence that it is not the result of an overproduction of TSH since plasma levels are usually within normal limits or even reduced somewhat More recent findings indicate the presence of a long-acting thyroid stimulator (LATS) in the plasma of many patients with this disorder LATS is a protein recovered from γ globulins which is thought to arise as part of an autoimmune response to tissue antigens It exhibits many of the properties of TSH but is clearly not of pituitary origin and would appear to be able to exert its effects independently of the normal thyroid control mechanisms Nodular hyperplasia is more common in older individuals and when associated with hyperthyroidism only portions of the gland may be overly active

Regardless of the cause of the excessive hormone secretion, the effects are about the same and consist of intolerance to heat, increased basal oxygen consumption (BMR), cutaneous vasodilatation and sweating, increased appetite despite weight loss, an in-

crease in the basal heart rate, a fine tremor of the hands, emotional irritability, and characteristic eye signs consisting of lid retraction, exophthalmos, and swelling of the circumorbital tissues The eye signs are more commonly seen in hyperthyroidism of diffuse hyperplasia than in cases of so-called "toxic nodule" Many of the signs and symptoms of hyperthyroidism closely simulate effects of epinephrine While there is no evidence that excessive secretion of epinephrine is a primary factor in hyperthyroidism, it is clear that the effects of these agents are strongly potentiated in this disorder Thus, efforts to reduce epinephrine secretion, by the use of ganglionic blocking agents, have been successfully applied in the treatment of severe thyrotoxicosis

The clinical diagnosis is usually confirmed by objective measurements in the laboratory Estimates of the BMR were widely used in the past but have been superseded by more reliable and convenient diagnostic procedures These include estimations of the amount of hormone in plasma by the PBI, the butanol-extractable iodine or the T_3 uptake test The last involves adding radioactive T_3 to the patient's plasma in vitro and measuring the uptake of T_3 by resin after incubation Assuming the level of binding protein to be normal, a high T_4 level results in a low concentration of unoccupied binding sites, little binding of T_3 and a high uptake by the resin As mentioned above, the uptake of ^{131}I by the thyroid is usually increased, but of more importance diagnostically, is its failure to be suppressed by a trial of T_3 The gland behaves as though it were autonomous and free from pituitary control

The treatment of hyperthyroidism consists of reducing the activity of the thyroid gland by removing it surgically, destroying thyroid tissue by radiation with ^{131}I or by the use of antithyroid drugs such as propylthiouracil, methyl mercaptoimidazole, or perchlorate The choice of treatment in any particular case must be carefully weighed after considering the many factors which bear on treatment The reader is referred to standard clinical textbooks for further discussion

HYPOTHYROIDISM

The consequences of thyroid hormone deficiency are greatly influenced by the age of the individual at the onset of the deficiency When it is present in infancy, treatment must be started promptly or dwarfism, retention of infantile body proportions, and mental retardation will invariably result A term that has been applied to this condition is cretinism Congenital hypothyroidism is most commonly caused by environmental iodine deficiency, although many cases of inherited enzyme defects in hormone production associated with goiter have been reported Adult hypothyroidism may be of pituitary origin, but it is usually the consequence of a primary thyroid disorder Loss or greatly reduced thyroid function may result from the administration of thyroid blocking agents, thyroidectomy or destruction of the gland by ^{131}I, or as the terminal stage in a disease process known as Hashimoto's disease or autoimmune thyroiditis The clinical picture of classical hypothyroidism is one of a gradual onset of lethargy, intolerance to cold, voice changes, slowing of mental faculties, and mental confusion There is a characteristic thickening of the skin of the lips, fingers, below the eyes, and of the legs The thickening is the result of the deposition of mucoprotein in the subcutaneous tissues, and when excessive, is called myxedema

The clinical diagnosis of hypothyroidism may be confirmed in the laboratory by the use of the same tests described under hyperthyroidism When hypothyroidism of pituitary origin is suspected, an increase in ^{131}I uptake by the thyroid after a trial of TSH administration may be helpful Hypothyroidism is treated by the oral administration of T_4 or crude thyroid extract The dose is adjusted after careful consideration of the patient's cardiac status since large initial doses may precipitate acute myocardial ischemia in patients with long standing hypothyroidism

5 / CONTROL OF CALCIUM HOMEOSTASIS BY PARATHYROID HORMONE, CALCITONIN, AND VITAMIN D

The parathyroid glands and thyroid C cells provide hormonal control for fine adjustment in extracellular calcium concentrations Many processes require ionic calcium, within narrow limits of concentration, to function properly Functions of calcium fall into two general categories *1*) maintenance of specific membrane permeabilities, and *2*) activation of enzymatic reactions Examples of calcium-requiring processes include acetylcholine release, neuromuscular excitability, membrane adenosine triphosphatase (ATPase) activities and actin-myosin interaction in muscle contraction Reviews of calcium homeostasis can be found in Copp (1969 and 1970)

The major factors involved in regulation of calcium homeostasis are diagrammed in Figure 7 32 Nonhormonal regulation of blood calcium involves changes in calcium influx through the intestine and excretion through the kidney that are brought about in following ways *1*) If calcium content of the diet is low, little is available for intestinal absorption, but the low amount increases the capacity of the intestine to take up calcium The effective amount of calcium in the diet can be lowered by certain foods such as some cereals and spinach These foods contain acids (phytic and oxalic) forming insoluble complexes with calcium and preventing its absorption *2*) Calcium absorption is changed by the amount of inorganic phosphate in the diet A low level of phosphate increases calcium uptake and a high level decreases it Work with experimental rat diets indicates an optimal ratio of 0 05% Ca/0 03% P Calcium and phosphate absorption are also influenced by parathyroid hormone as will be discussed later *3*) Absorption of calcium by the duodenum and upper jejunum is partly active and partly passive Active calcium transport has been known to require vitamin D But as seen in Figure 7 33, a vascularly perfused isolated intestinal system from a vitamin D deficient animal was not responsive to the vitamin itself when added to the perfusate However, in vivo injection of D_3 12 hr prior to the experiment increased calcium transport The preparation was much more responsive to 25-hydroxycholecalciferol (25-(OH)D_3), a metabolite of D_3 It has since been found that (1,25-(OH)$_2D_3$) is the active metabolite of D_3 (Omdahl et al, 1971) This compound is synthesized in the kidney (Fraser and Kodicek, 1970) and acts to induce synthesis of a specific calcium-binding protein in the intestinal mucosa cells (Wasserman and Taylor, 1966) and a Ca^{++}-dependent ATPase in the brush border Deoxyribonucleic acid (DNA) transcription is not required for the increased calcium transport, but is required for conversion of D_3 or 25-(OH)D_3 to 1,25-(OH)$_2D_3$, (Tanaka et al, 1971) It has been suggested that 1,25 (OH)$_2D_3$ be classified as a hormone controlling calcium metabolism *4*) Hypomagnesemia nearly always results in hypercalcemia, although the mechanism involved is not clear Magnesium itself may be regulated by parathyroid hormone In some instances, these divalent cations may substitute for each other, while in others, their effects are opposing In any case, magnesium modifies the effectiveness of calcium ions *5*) In addition to these effects on intestinal absorption, excretion of calcium through the kidneys can play an important role in nonhormonal control of hypercalcemia When plasma calcium increases above normal, urinary excretion increases rapidly

HORMONAL REGULATION

Two hormones are responsible for fine regulation of blood calcium level, parathyroid hormone (parathormone or PTH) from the parathyroid glands and calcitonin from the ultimobranchial tissue whether present as "C"

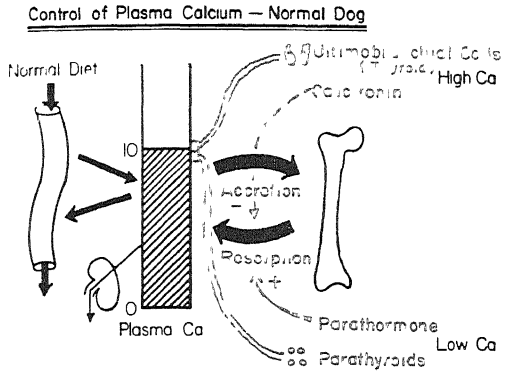

Fig 7 32 Diagram of factors involved in calcium homeostasis Intestinal absorption renal excretion and accretion and resorption of Ca^{++} by bone are the major factors involved Calcitonin produced by the C cells of ultimobranchial origin and parathyroid hormone produced by the chief cells of the parathyroid are major regulatory factors (From Copp 1968)

cells in mammalian thyroid or as a separate gland in other classes of vertebrates The two hormones work in a reciprocal manner to maintain blood calcium concentration near 10 mg/100 ml (5 mEq/liter), with only a small diurnal variation, in spite of large changes in intake Although an adult has a total of 1000 to 1200 g of calcium, more than 99% is unavailable in ionic form since it is crystallized in bone or complexed with protein or other anions in blood (Table 7 4) Quite obviously, blood calcium homeostasis must be regulated by sensitive mechanisms that can be rapidly initiated and terminated

PARATHYROID GLANDS

Parathyroid glands are found in all animals above the fishes In humans, there are usually two pairs, located close to the posterior surface of the thyroid in the neck The number and location may vary significantly, however Total weight for the four glands is about 120 mg Even though the parathyroids were known since 1909 to be associated with blood calcium and with tetany, it was not until 1959 that a fairly pure preparation of PTH was made (Aurbach, 1959) PTH is secreted by the chief cells, especially the dark-staining type of the parathyroid gland PTH is a single chain polypeptide with 83 amino acids and a molecular weight of approximately 9500 (Potts et al, 1968) The amino acid sequence of bovine hormone has been determined (Brewer and Ronan, 1970), and found to have 84 amino acids Only small amounts of human hormone are available for structural studies A portion of the amino terminal end of the molecule (35 amino acids) has significant biological activity and essentially full immunological activity

The overall physiological function of PTH is to maintain blood calcium at 10 mg/100 ml by providing more calcium if the blood level falls For example if an animal is parathyroidectomized, blood calcium will fall from 10 to 6 or 7 mg/100 ml Injection of PTH will re-

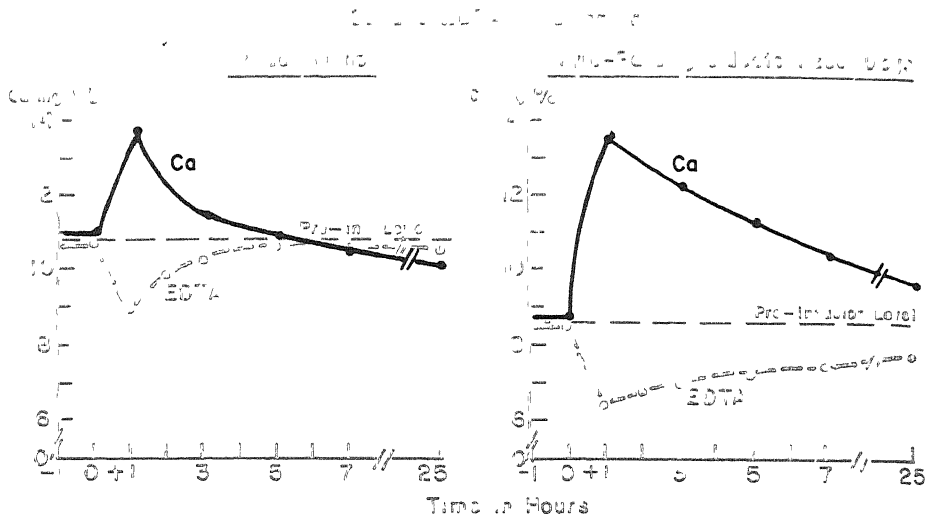

Fig 7 34 Serum calcium levels following calcium and EDTA infusions in normal and parathyroidectomized dogs (From Sanderson et al 1960 as adapted by Copp 1968)

turn the level to normal The parathyroidectomized or thyroparathyroidectomized animal (thyroid and parathyroid glands removed) cannot rapidly compensate for hypercalcemia or hypocalcemia Infusion of calcium or ethylenediaminetetraacetic acid (EDTA) (a calcium-binding agent), systemically, results in a more prolonged period of hyper- or hypocalcemia (Fig 7 34) The only known stimulus for secretion of PTH is low blood calcium This was demonstrated experimentally by perfusing the thyroid-parathyroid gland complex through the arterial supply with blood containing various levels of calcium or EDTA (Copp and Davidson, 1961) Although venous drainage from the glands remained intact, amounts of calcium or EDTA used in the perfusions were not enough to change systemic calcium levels Thus, any change found peripherally was due to hormonal action Using this technique, systemic calcium levels were found to rise if the glands were perfused by EDTA-containing blood, and to fall if high-calcium blood was used With the aid of a sensitive radioimmunoassay, it is possible to measure blood levels of PTH PTH secretion rate is found to be a linear function of plasma calcium concentration in the range of 6 to 12 mg./100 ml (Fig. 7 35) The half-life in blood is 20 min (Melick et al, 1965)

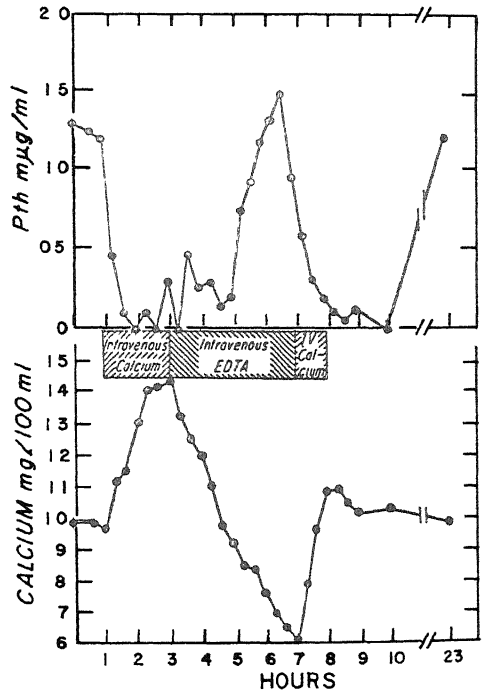

Fig 7 35 The effect of intravenous infusion of calcium and EDTA upon plasma calcium (*lower*) and plasma parathyroid hormone concentrations (*upper*) (From Care et al 1966)

ACTIONS OF PTH

Three sites of action are involved in the ability of PTH to raise plasma calcium concentration The first and probably most important site is bone, where PTH stimulates resorption and release of calcium The mineral in bone is mostly in the form of a complex crystal called hydroxyapatite, $[(Ca_3PO_4)_2]_3$,

$Ca(OH)_2$ Minerals are either part of this crystal or adsorbed to the surface of it A large surface area provided by the crystal arrangement facilitates mineral exchange between bone and blood Some calcium in bone will exchange with plasma calcium rather easily (exchangeable calcium) and some will do so slowly or at an immeasurable rate (stable or nonexchangeable calcium) PTH mobilizes bone calcium from two areas, osteolysis increases around large osteocytes and osteoclast activity increases (Figure 7 36) The result is resorption of bone, and in large part, it is the stable bone that is broken down In this process, the organic matrix of bone is dissolved as well, and hydroxyproline, a product of collagen dissolution, is excreted in the urine This substance forms the basis for assessment of the relative rate of bone dissolution and is used clinically for this purpose Release of calcium appears to occur in two stages *a*) a small amount is liberated in the first several hours, and *b*) a larger amount is liberated more slowly over a longer subsequent period (Rasmussen et al, 1964) Release of the larger amount requires RNA synthesis, since actinomycin D, an inhibitor of this process, will inhibit calcium release PTH has been shown to directly stimulate RNA synthesis in vivo and in vitro in bone (Steinberg and Nichols, 1968)

PTH appears to stimulate adenyl cyclase and to result in the formation of increased amounts of cyclic adenosine monophosphate (cyclic AMP) in bone (Fig 7 37) Calcitonin has only a small effect on cyclic levels and does not antagonize or enhance the effects of PTH

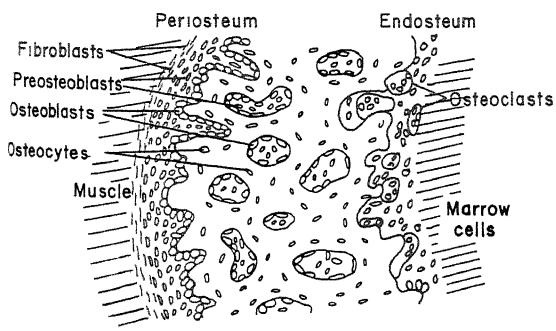

Fig 7 36 Diagrammatic representation of part of the cross section of bone wall from the mid shaft of the femur of a 10-day-old rabbit Layers of cells on the periosteal surface are associated with bone growth while cells on the endosteal surface are associated with bone resorption (From Owen and Bingham 1968)

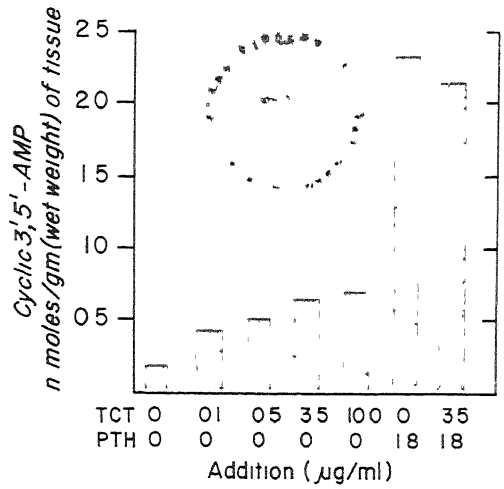

Fig 7 37 Effect of calcitonin (TCT) and parathyroid hormone on 3' 5' AMP in skeletal tissue during 5 min of exposure (From Chase and Aurbach 1970)

Addition of dibutyryl 3'-5'-AMP causes effects in vivo and in vitro similar to those recognized as physiological respones to PTH Parathyroid hormone and dibutyryl 3'-5'-AMP cause increased rates of glycolysis and increased synthesis and release of acid hydrolases, enzymes that are associated with lysosomes (Vaes, 1968a) Increased glycolysis results in production of acid that solubilizes bone mineral Acid hydrolases digest the organic matrix These factors account for release of calcium, phosphate and amino acids into the blood (Fig 7 38) The full effect of PTH on bone requires vitamin D, a substance that can also stimulate bone calcium release Neither compound is completely active in the absence of the other

A second site of PTH action is on the kidney, where it increases reabsorption of calcium and decreases calcium excretion Since PTH also increases serum calcium, the net effect often is an increase in urinary calcium concentration in spite of increased tubular reabsorption Often, a more marked effect of PTH is increased excretion of phosphate Effects of PTH infusion on renal excretion of phosphate and cyclic AMP are shown in Figure 7 39 The phosphaturic effect of parathyroid hormone may be mediated by an effect on the cellular movements of calcium rather than on phosphate itself (Eisenberg, 1968)

Whether vitamin D has a direct effect on kidney or not is still being debated, but like PTH it causes phosphaturia It also increases plasma phosphate and urinary calcium, but

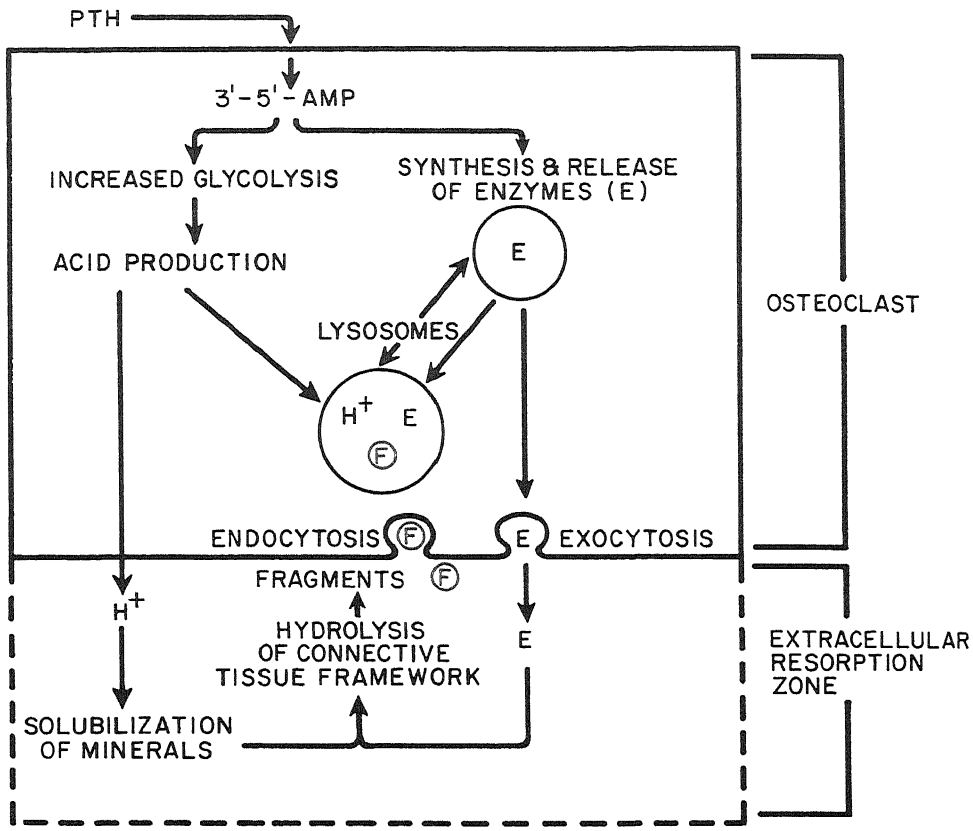

Fig 7 38 Presumed mechanism of PTH-induced bone resorption by osteoclasts (Adapted from Vaes 1968b)

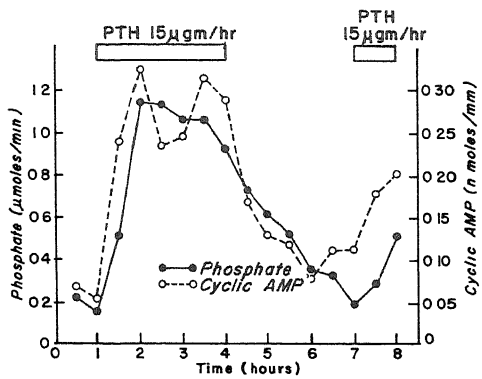

Fig 7 39 Effect of infusion of parathyroid hormone on excretion of phosphate and cyclic-3'-5'-AMP by a parathyroidectomized rat Cyclic AMP appearing in the urine is largely of renal origin and is associated with increased adenyl cyclase activity in cortical tissue In contrast vasopressin increased adenyl cyclase activity in the renal medulla (From Chase and Aurbach 1968)

does not increase calcium reabsorption from the tubule as PTH does

A third site of PTH action is the intestine, where it increases active absorption of calcium, but only in cooperation with vitamin D Some active transport does occur without PTH, but none without the vitamin Phosphate transport by small intestine is also stimulated by PTH and vitamin D

THYROID C CELLS

During the course of studies of parathyroid hormone, several kinds of experiments could not be explained by invoking a calcium-raising hormone alone, but suggested the existence of a calcium-lowering substance as well For example, when thyroparathyroids of dogs were perfused with a high calcium solution, blood calcium fell further and faster than it did in animals that were parathyroidectomized Copp et al (1962) proposed that lowering of serum calcium when the glands were perfused with high calcium was not simply due to shutting off of PTH secretion by negative feedback Munson et al (1968) then found that injection of thyroid extracts decreased serum calcium by 2 mg /100 ml (Fig 7 40)

Since this discovery in the early 1960's, cal-

citonin has been isolated and purified and the structure has been determined Comparative structure of porcine, bovine, salmon, and human calcitonin is shown in Figure 7 41 Mammalian hormones were obtained from extracts of thyroid while salmon calcitonin was extracted from the ultimobranchial body, an outgrowth of the primitive pharynx Each hormone consists of a single chain of 32 amino acids with an intrachain disulfide bridge between positions 1 and 7 and a prolinamide at the carboxyl terminus When tested in mammals, biological activities of porcine, bovine, and human calcitonin are similar, but the salmon hormone is 20 to 40 times more active Only nine positions are occupied by the same amino acid in all 4 molecules Some regularity of structure is apparent, however, since hydrophobic residues occur at almost regular intervals along the molecule Synthesis of the entire molecule and various peptides has shown that all 32 amino acids are necessary for full biological activity (Sieber et al, 1970)

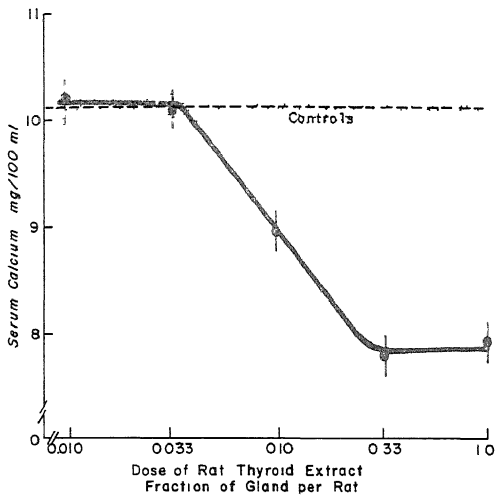

Fig 7 40 Dose response curve illustrating the effect of rat thyroid extract on serum calcium in young male rats 1 hr after subcutaneous infection The horizontal dashed line and shaded band at the top represent the mean and standard error for control rats (From Munson et al 1968)

Calcitonin is synthesized in the parafollicular "C" cells of the thyroid, cells which came originally from embryonic tissue of the ultimobranchial body Immunofluorescence studies have been used to identify calcitonin-producing cells (Fig 7 42) The hormone is stored in the cells in granules measuring 100 to 200 μ When the gland is perfused with hypercalcemic blood, stored hormone is released as indicated by degranulation of the cells Secretion of calcitonin is also stimulated by glucagon and cyclic 3'-5'-AMP, suggesting a role for cyclic-AMP in secretion of this protein (Bell, 1970) Cytological studies indicate that

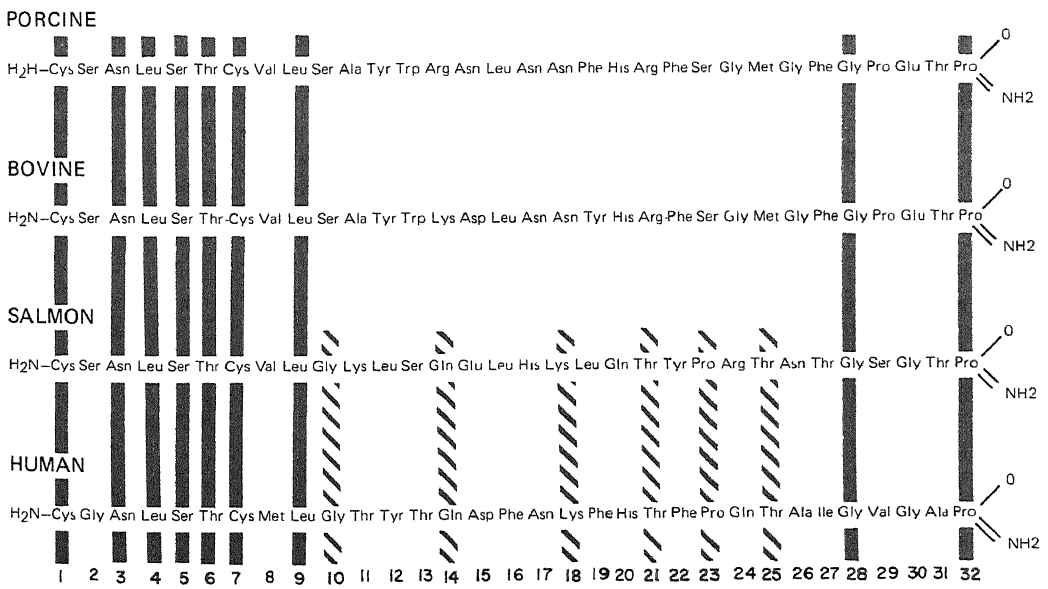

Fig 7 41 Comparison of amino acid sequence of porcine bovine human and salmon calcitonin Solid bars indicate sequence positions homologous between salmon and human hormone stippled bar indicates position where either phenylalanine or tyrosine is found in each of the calcitonins (From Potts et al 1970)

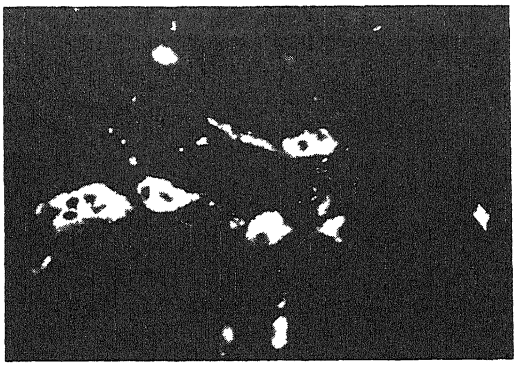

Fig 7 42 Dog thyroid gland The tissue was freeze-dried at −40° C and embedded in paraffin wax Specific immunofluorescence exclusively in C cells was demonstrated using an indirect technique with rabbit antiporcine calcitonin and fluorescence-labelled goat anti-rabbit γ-globulin (From Pearse 1970)

much more calcitonin is stored and ready for release by the "C" cells than PTH by the chief cells of the parathyroid.

Immunoassay of calcitonin has been developed and has shown *1)* that calcitonin is secreted at physiological levels of blood calcium, *2)* that secretion of hormone is raised within a few minutes after blood calcium is raised, and *3)* that the hormone rapidly disappears from the blood The large increase in secretion following perfusion with blood containing high calcium levels confirms the presence of large stores of preformed calcitonin Calcitonin release is proportional to the blood calcium level within 9 to 22 mg /100 ml Inspection of Figure 7 43 shows that PTH and calcitonin are secreted together only within the range of normal plasma calcium levels

ACTIONS OF CALCITONIN

The primary effect of calcitonin is to inhibit bone resorption and calcium release, thereby lowering blood calcium The maximum effect is a decrease of 3 to 4 mg /100 ml of calcium Although not directly competitive to PTH, the effect is opposite. As with PTH, magnitude of the effect on bone is significantly greater in young animals Calcitonin causes a rapid decrease in plasma phosphate as well as calcium The mechanisms of these effects are not understood, but the hormone in some way abolishes the effectiveness of PTH after formation of cyclic AMP. Actually, the bone effects of PTH and calcitonin are somewhat more complicated, since in addition to effects on calcium flux, PTH increases the rate of bone collagen formation, calcitonin inhibits it, and both together will further increase collagen formation (Kalu, et al, 1970) No definite effect of calcitonin has been shown on kidney or gut, and its full effect may be seen even in eviscerated animals

Hypercalcemia is fairly rare under normal circumstances, and this has raised a question about the relative importance of calcitonin The hormone can protect an animal from hypercalcemia after a forced feeding of high amounts of calcium, but recent experiments show that it can also prevent hypercalcemia in a fasted rat eating a normal ion-containing diet (Munson and Gray, 1970) It is likely to counterbalance PTH action in all situations of calcium stress, such as lactation in mammals, starvation, and periods of rapid bone growth

DISORDERS OF CALCIUM HOMEOSTASIS OF C CELL ORIGIN

Calcium imbalances deriving from calcitonin are rare, but it has been proven that medullary carcinomas of the thyroid gland are really tumors of C cells, and these produce large amounts of calcitonin Blood calcium and phosphate may be normal or in some instances low In these cases, PTH levels are elevated Surgery is the only treatment available Calcitonin itself is being tested clinically to correct conditions such as Paget's disease or osteitis deformans and osteoporosis, diseases where bone formation is less than normal Calcitonin extracted from salmon has proven to be many times as effective as that from other species, but use of any protein hormone is complicated

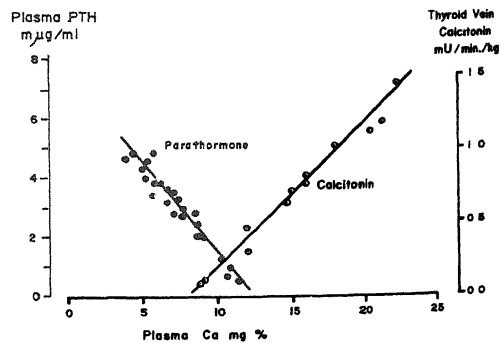

Fig 7 43 Effect of plasma calcium on plasma levels of parathyroid hormone and calcitonin secretion rate (From Copp 1968)

by recipient formation of antibodies to it (Potts, 1970)

DISORDERS OF CALCIUM HOMEOSTASIS OF PARATHYROID ORIGIN

The most common cause of hypoparathyroidism is damage to the glands during thyroid surgery, which is estimated to occur in 1 out of 100 operations However, idiopathic lack of function is found This condition leads to a fall in plasma calcium and a rise in plasma phosphate Urinary calcium increases initially due to lack of reabsorption by the tubules, but falls later as plasma calcium declines Urinary phosphate is low The best known symptom is tetany, which involves muscle spasms and hyperreflexia, general tonicoclonic convulsions, laryngeal spasms, and then death from asphyxia These changes result from a lowering of the threshold for nerve and muscle excitation, so that a nerve may be fired by a slight stimulus anywhere along its length Transmission across synapses is not impaired since the extracellular level of calcium does not get low enough to prevent acetylcholine release

The obvious treatment for hypoparathyroidism would be to raise calcium levels with PTH, but there is little pure hormone available Rather than PTH, very large doses of vitamin D are used along with a high calcium-low phosphate diet

Hyperparathyroidism is usually related to a tumor In this situation, there is no negative feedback and PTH secretion continues even when calcium is high This leads to high blood calcium, low phosphate and increased bone resorption Common findings are bradycardia, ventricular arrhythmias, muscular weakness, urinary stones or soft-tissue calcification, osteoporosis, and ulcers from increased gastric acid secretion Many of the dysfunctions are due to an increased threshold for nerve and muscle depolarization, and precipitation of excess salts in soft tissues Treatment is usually surgery

Secondary hyperparathyroidism can occur from vitamin D deficiency or low calcium intake In these instances, plasma calcium is low, and thus PTH secretion is stimulated Bone resorption will not provide enough ion if absorption continues to be low The continuous stimulus for PTH secretion will lead to hypertrophy of the glands Plasma phosphate may be low, urinary phosphate high, and bone mineralization impaired, leading to ricketts

6 / FUNCTION OF THE ADRENAL GLANDS

The importance of the adrenal glands in maintaining life was first recognized clinically by Addison in 1855 and confirmed experimentally by Brown-Sequard in the following year (Bishop, 1955) The adrenal is, in fact, a compound gland-within-a-gland The outer portion, the cortex, is derived from mesodermal cells which bud from the celomic epithelium It secretes hormonal steroids, as do the ovaries and testes, which are formed from similar mesodermal cells

The developing adrenal cortex is penetrated by chromaffin cells which migrate from the neural crest ectoderm and ultimately form the inner portion of the adrenal gland, the medulla The several endocrine tissues derived from similar neurectodermal cells secrete hormones synthesized from amino acid precursors the polypeptide hormones or, in the case of the adrenal medulla, the catecholamines

The purpose of this chapter is to review very briefly the biosynthesis of the adrenal hormones, the mechanisms controlling their synthesis and release, their general metabolic actions, and the pathophysiology of certain clinical disorders of adrenal function

The Adrenal Cortex

DEVELOPMENT AND HISTOLOGY

The human fetal adrenal is well developed after the first 10 to 12 weeks of gestation The cortex consists of a thin outer rim of small ovoid basophil cells destined to become the definitive adult cortex, and a much wider inner zone of large acidophil cells arranged in anastamosing cords, the fetal cortex The fetal cortex, which comprises 90% of the cortex at term, requires stimulation by fetal pituitary adrenocorticotropic hormone (ACTH) for its development (Benirschke, 1956, Lanman, 1962) The fetal adrenal is larger, in relation to total body weight, than the adult gland and has the ability to synthesize both cortisol and the C_{19} steroids (Bloch and Benirschke, 1959) The fetal cortex begins to involute at about the time of birth and completes this process in 6 to 18 months

The adult human cortex, which differentiates in infancy as the fetal cortex involutes, is divided into three fairly distinct zones the outermost zona glomerulosa, which is concerned primarily with aldosterone synthesis, and the wide middle zona fasciculata and innermost zona reticularis, which together are concerned with cortisol production In some mammals the reticularis is primarily responsible for the synthesis of adrenal androgens It was once thought that the adrenal cortical cells originated in the zona glomerulosa, migrated inward through the fasciculata, and degenerated in the reticularis Although it is true that cell generation appears to be most rapid in the zona glomerulosa (Ford and Young, 1961, Walker and Rennels, 1961), and that a complete adrenal cortex can regenerate from a few cells adherent to the capsule (Penney et al, 1963), there is little evidence that these cells mature and migrate centripetally under normal conditions The ultrastructure of zona glomerulosa cells reveals elongated mitochondria with lamellar cristae, cytoplasm filled with finely vesiculated smooth endoplasmic reticulum, and membrane enclosed lipid droplets The fasciculata cells have round to ovoid mitochondria with vesicular cristae which provide an exceptionally large inner surface area These cells are filled with the abundant smooth endoplasmic reticulum commonly observed in steroid secreting cells, and also contain liposomes The cells of the zona reticularis resemble those of the fasciculata, but have more variable mitochondrial size and appearance (Luse, 1967)

BIOSYNTHESIS OF ADRENAL CORTICOSTEROIDS (Samuels and Uchikawa, 1967 Bransome, 1968)

The adrenal cortex synthesizes three classes of hormones glucocorticoid, mineralocorticoid, and sex hormone The most important steroids secreted by the normal adult human adrenal cortex are the glucocorticoid, cortisol, and the mineralocorticoid, aldosterone In addition, small quantities of estrogens and steroid precursors, including progesterone, are released into the circulation Adrenal androgens, al-

though secreted in large quantities, are of low physiological potency

Glucocorticoid (Cortisol) The hormonal steroids are all synthesized from acetyl coenzyme A with cholesterol as their common intermediate (Caspi et al, 1962) Only a small fraction of the intracellular cholesterol pool is immediately available for steroid synthesis (Hechter et al, 1953, Werbin and Chaikoff, 1961) This small pool appears to be in rapid equilibrium with plasma cholesterol (Borkowski, et al, 1967) The uptake of cholesterol from plasma, furthermore, appears to be stimulated by ACTH (Dexter et al, 1967)

The major reactions in the biosynthesis of adrenal steroids are represented in Figure 7 44 While even this very simplified diagram at first glance appears complex, the biosynthetic process actually represents a series of discrete, rather minor modifications of the cholesterol molecule One needs to understand these pathways in order to understand the pathophysiology of the congenital adrenal hyperplasias The exact sequence in which the reactions occur is not known and may depend upon the relative concentrations of substrates, enzymes, and cofactors The probable major pathways are indicated by the heavy arrows The cleavage of the side chain of cholesterol to form pregnenolone takes place in the mitochondrion Cleavage begins with the formation of 20α-hydroxycholesterol This is the rate-limiting step in steroid synthesis and is accelerated by ACTH in the zona fasciculata and, presumably, by angiotensin II in the zona glomerulosa Conversion to pregnenolone is completed in the mitochondrion by what is referred to as the desmolase reaction (Shimizu et al, 1961) There is an alternate pathway which circumvents pregnenolone by way of 17-hydroxypregnenolone (Shimizu et al, 1965) Pregnenolone now moves out of the mitochondrion The 3β-hydroxyl group of pregnenolone is oxidized to a ketone by 3β-ol dehydrogenase, located on the smooth endoplasmic reticulum This reaction requires nicotinamide adenine dinucleotide (NAD) as the hydrogen acceptor (Beyer and Samuels, 1956) The shift of the double bond is catalyzed by Δ^5-3-ketosteroid isomerase (Ewald et al, 1964), forming progesterone

The remaining reactions in the synthesis of cortisol are all hydroxylations and require as cofactors molecular oxygen, reduced nicotinamide adenine dinucleotide phosphate (NADPH), flavoproteins, the cytochrome system, a nonheme iron protein, and a special cytochrome called cytochrome P-450 because of its sharp absorption peak at 450 mμ after exposure to carbon monoxide An electron is transferred to cytochrome P-450, which in turn reduces molecular oxygen to water and an activated oxygen atom, which is inserted between the steroid ring carbon and its appropriate α or β hydrogen (Harding and Nelson, 1966) Since the zona glomerulosa lacks 17α-hydroxylase, progesterone is converted to 17-hydroxyprogesterone only in the zonae fasciculata and reticularis, where it is then converted to 11-deoxycortisol (Reichstein's "substance S") the final, relatively inactive precursor of cortisol Deoxycortisol then returns from the smooth endoplasmic reticulum to the mitochondrion for the final 11β-hydroxylation to cortisol ("substance F") The normal rate of cortisol synthesis is 15 to 30 mg /day

An intriguing historical facet of the study of glucocorticoid biosynthesis has been the study of the role of adrenal ascorbic acid in this process Ascorbic acid is present in very high concentrations in the normal adrenal gland (Szent-Gyorgyi, 1928) Adrenal ascorbic acid decreases as steroidogenesis is stimulated by ACTH Despite a great deal of interest, speculation, and investigation, the exact relationship of ascorbic acid to steroid synthesis remains a mystery

Mineralocorticoid (Aldosterone). Since 17α-hydroxylase is absent in the zona glomerulosa, progesterone is converted on the smooth endoplasmic reticulum of the glomerulosa first to 11-deoxycorticosterone (DOC) by 21-hydroxylation (Fig 7 44) and then, by 11β-hydroxylation, within the mitochondrion, to corticosterone, "substance B " The mitochondrial enzyme, 18-hydroxylase, catalyzes its conversion to 18-hydroxycorticosterone 18-hydroxycorticosterone is dehydrogenated, by an enzyme found only in the mitochondria of the zona glomerulosa, to aldosterone (Wettstein et al, 1955) It is secreted at a rate of 50 to 200 μg /day

Androgens and Estrogens The side chain of 17α-hydroxypregnenolone is cleaved at the 17-20 carbon bond (Fig 7 44) to form dehydroisoandrosterone (DHA) which, with its sulfate, is the major precursor of urinary 17-ketosteroids Minor quantities of 17-hydroxypro-

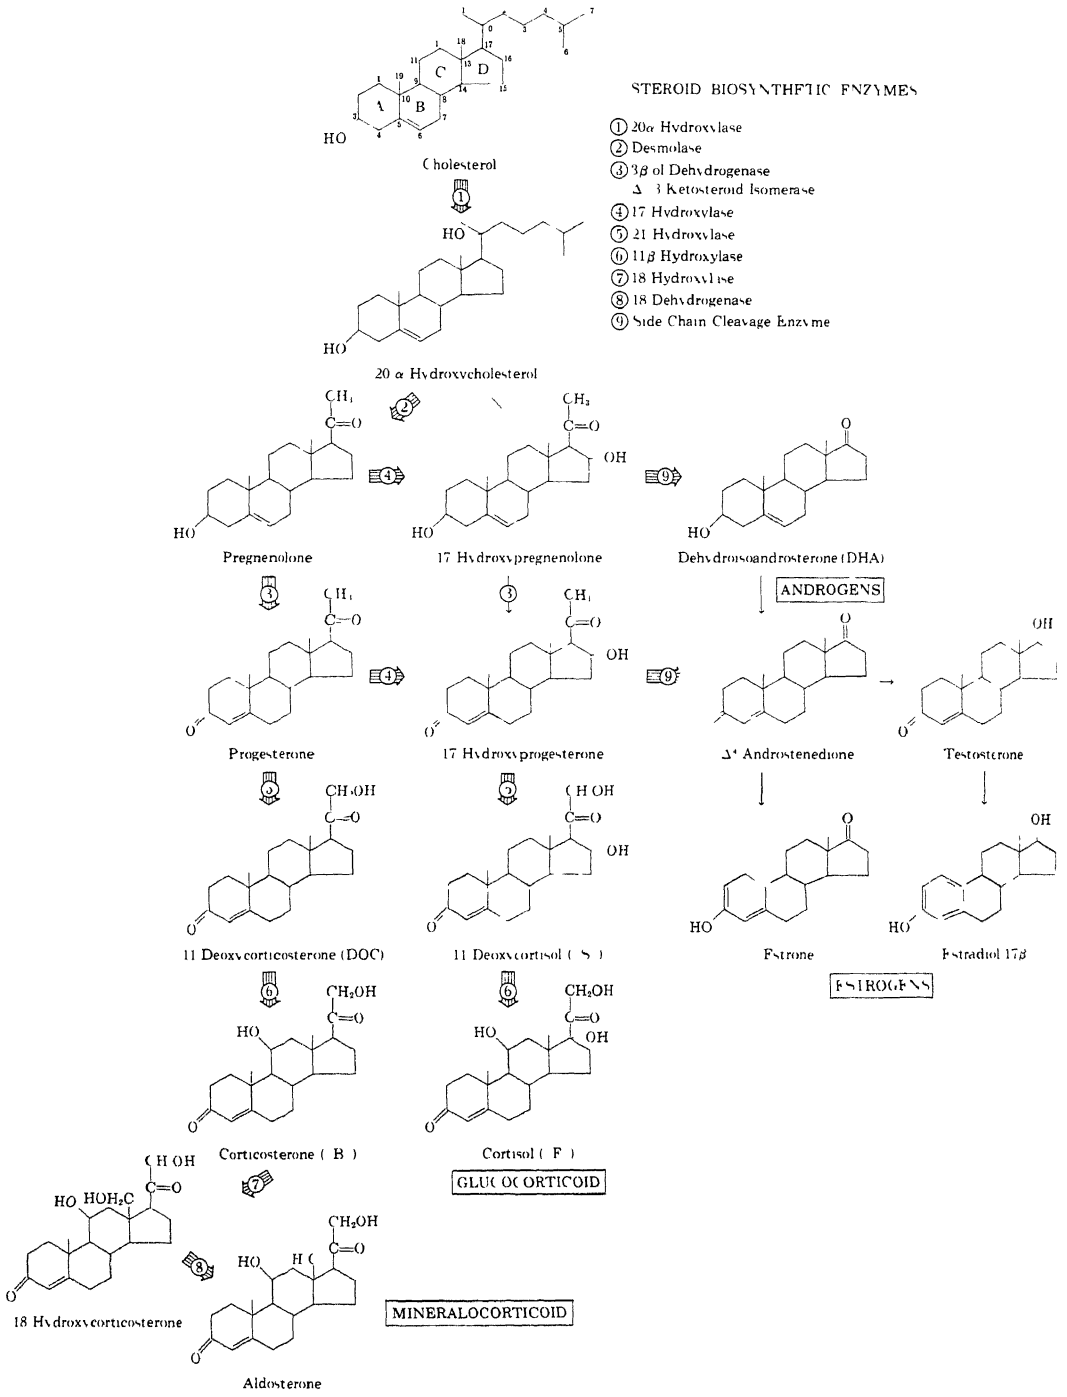

Fig 7 44 A simplified scheme showing the pathways in adrenocortical steroid biosynthesis after formation of cholesterol The probable major reactions are indicated by heavy arrows

gesterone are converted by a similar reaction to another 17-ketosteroid, Δ^4-androstenedione, which can be further converted, by reduction of the 17-ketone, to testosterone Estrogens apparently can be produced by adrenal tissue, as evidenced by estradiol and estrone production, in vitro by feminizing adrenal tumor tissue (Dorfman et al , 1965) The

amounts normally produced, if any, are very small, however, and the biosynthetic pathways are not clear They may involve 19-oxidation of testosterone, followed by 19-demethylation and aromatization of the A ring to yield estradiol-17β A similar series of reactions might produce estrone from Δ^4-androstenedione More important, DHA sulfate, secreted by the adrenal, can be converted to estrogens by the ovaries (MacDonald et al , 1967) Accurate secretory rates for adrenal androgens and estrogens are difficult to establish because of gonadal secretion and peripheral interconversion of these steroids

METABOLISM OF ADRENAL CORTICOSTEROIDS

Glucocorticoid (Cortisol). Cortisol is reversibly oxidized to cortisone ("substance E") in the tissues, predominantly the liver Cortisone is biologically inert and has a half-life in plasma less than half that of cortisol Administered cortisone has about two-thirds the biological potency of cortisol only by virtue of its bioconversion to cortisol

In plasma, about 2% of cortisol normally circulates in the free state, a small fraction is nonspecifically bound to serum albumin, and greater than 90% is specifically bound to corticosteroid-binding α_2-globulin (CBG) (Daughaday, 1967) The normal CBG concentration is about 3 mg /100 ml , but is increased markedly during pregnancy or estrogen administration The normal CBG binding capacity is approximately 20 μg cortisol/100 ml Normal plasma cortisol concentrations are less than 25 μg /100 ml One molecule of steroid is bound by each molecule of CBG, the strength of binding depending upon the molecular configuration of the steroid The cortisol bound to CBG or albumin is metabolically inactive, but is in rapid equilibrium with free cortisol Thus, the binding proteins act as a reservoir for cortisol, releasing it when free cortisol is removed from the circulating plasma After CBG is saturated with cortisol, however, relatively small increases in plasma cortisol result in a disproportionate increase in the free, metabolically active cortisol fraction The high plasma cortisol levels seen during pregnancy or estrogen administration are secondary to increased CBG The metabolically active plasma free cortisol levels are not proportionately elevated

The major pathway of cortisol degradation involves reduction and conjugation reactions Reductases in the liver perform the major irreversible step in the metabolism of cortisol and cortisone reducing the 4-5 double bond of the A ring The reactions require NADPH as cofactor, the predominant products are the 5β, rather than the 5α-metabolites (Fig 7 45) Further reduction of tetrahydrocortisol (THF) and tetrahydrocortisone (THE) at the C_{20} carbonyl yields the cortols and cortolones By far the major portion of the metabolites of cortisol and cortisone are excreted in the urine as conjugates of glucuronic acid Esterification to the glucuronide is catalyzed in the liver by glucuronyl transferase, which transfers glucuronic acid from uridine diphosphate (UDP)-glucuronic acid to a hydroxyl radical, usually the 3β-hydroxyl of tetrahydrocortisol (Fig 7 45) Cortisol is cleared from plasma with a disappearance half-time of 70 to 80 min (Peterson, 1959)

Mineralocorticoid (Aldosterone) Aldosterone is weakly bound to plasma proteins, perhaps to CBG Under normal conditions, aldosterone circulates in the hemiacetal form, which is more stable than the aldehyde configuration (Fig 7 46) The major metabolic pathway for aldosterone degradation is shown Less than 1% of aldosterone is excreted in the urine unaltered The major portion of aldosterone, however, is excreted as tetrahydroaldosterone glucuronide As is the case with the glucocorticoids, the product is formed by the action of hepatic glucuronyl transferase and is conjugated through the 3β-hydroxyl of tetrahydroaldosterone The normal half-life of aldosterone in plasma is approximately 30 min (Coppage et al , 1962)

ASSAY OF ADRENAL CORTICOSTEROIDS

Plasma Corticosteroids. There are four clinically useful methods for measuring corticosteroids in plasma

1) Colorimetric When 17,21-dihydroxy-20-ketosteroids such as cortisol, deoxycortisol, and cortisone react with acid phenylhydrazine, they form yellow phenylhydrazones, the color intensity of which are proportional to the quantities of steroids present, this is the Porter-Silber reaction (Porter and Silber, 1950) Since deoxycortisol and cortisone are normally present only in minor quantities in human plasma, cortisol is the only 17-hydrox-

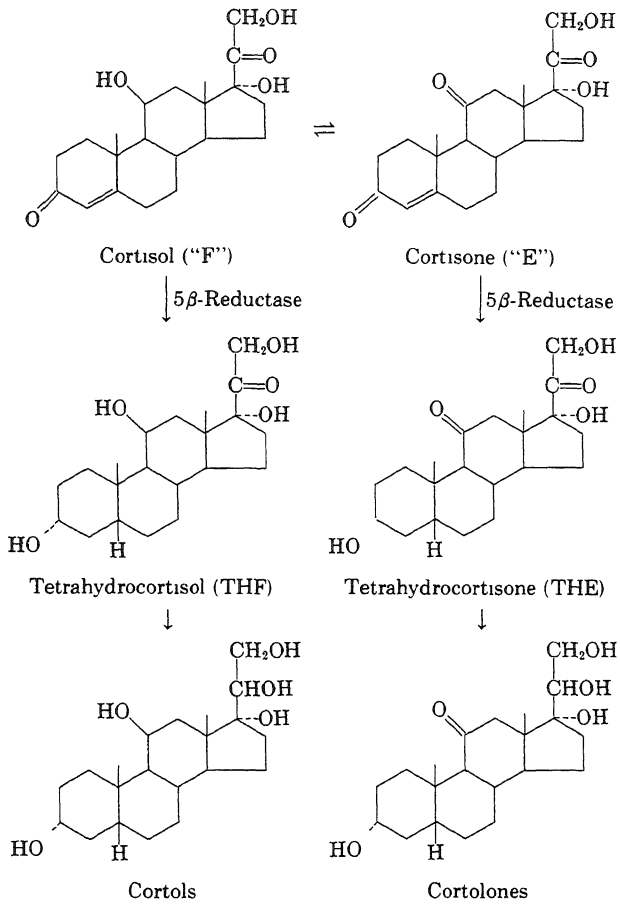

Fig 7 45 The major metabolites of cortisol and cortisone

ycorticosteroid (17-OHCS) of any importance Since many drugs are chromogenic and interfere in this assay, however, they must be excluded by extracting cortisol into lipid solvents, and washing the extract with alkali

2) *Fluorometric* Steroids extracted from plasma first into dichloromethane and then into ethanolic sulfuric acid can be quantitated by their fluorescence (DeMoor et al , 1960, Mattingly, 1962) The structural requirement is the Δ^4-11β,21-dihydroxy-3,20-dione configuration Thus, both cortisol and corticosterone are measured, deoxycortisol is not Since corticosterone is present in only small quantities in human plasma, plasma fluorogenic steroid (11-OHCS) is equivalent to cortisol Very few drugs interfere in this assay An exception is the aldosterone antagonist, spironolactone

3) *Competitive Protein-Binding* (Murphy, 1969) A derivative of the radioimmunoassay technique (Berson and Yalow, 1967, 1968), this assay utilizes CBG, rather than an antibody, to bind the steroid hormone Tracer amounts of labeled steroid are added to a very small concentration of CBG and incubated The percent of labeled steroid bound to CBG is determined As increasing quantities of unlabeled reference standard steroid are added, they compete with the labeled steroid for CBG-binding sites, "displacing" label from the CBG A standard curve can be constructed, plotting the decrease in per cent binding of labeled tracer against increasing concentration of unlabeled standard The concentration of steroid in an unknown can be determined by comparing its ability to displace tracer with that of the reference standard

4) *Radioimmunoassay.* Since aldosterone binds so slightly to CBG or other plasma proteins, it is difficult to measure by the competitive protein-binding method However, steroid

molecules which are not themselves antigenic can be covalently conjugated to larger molecules, such as serum albumin When the conjugate is injected into a recipient animal, antibodies may be formed to the steroid, which acts as a haptenic group These antibodies may bind the free steroid itself, and thus be useful for radioimmunoassay, as has been the case in the assay of plasma aldosterone (Mayes et al , 1970, Bayard et al , 1970) Plasma concentrations in normal subjects on unrestricted sodium diets are between 1 to 16 ng /100 ml of plasma or less

Urinary Corticosteroids. Free cortisol is excreted in the urine in very small quantities —40 to 200 μg /24 hr. Since the great majority of urinary steroids are water-soluble glucuronide conjugates, they must be hydrolyzed with β-glucuronidase in order to extract the free steroids into a lipid solvent

1) 17-Ketosteroids (17-KS) The oldest of the urinary steroid assays, this method utilizes the reaction of the steroid with metadinitrobenzene (Zimmerman's reagent) to form a reddish-purple color, the intensity of which is proprotional to the quantity of steroid present (Zimmerman, 1935, Callow et al , 1938) The major precursor of urinary 17-ketosteroids is dehydroisoandrosterone, the production of which does not always correlate well with cortisol secretion Thus, urinary 17-KS are not a reliable indicator of adrenal glucocorticoid production, but do reflect the secretion of the adrenal androgens except testosterone, which is not a 17-ketosteroid Normal values are usually given as 5 to 15 mg /24 hr in the female, and 10 to 22 mg /24 hr in the male, children less than 9 excrete less than 3 mg /day, but this increases to adult values during puberty

2) 17-Hydroxycorticosteroids (17-OHCS) The Porter-Silber reaction may be used to measure urinary 17,21-dihydroxy-20-ketosteroids Approximately 30 to 40% of secreted cortisol appears in the urine as THF and THE, tetrahydrodeoxycortisol (THS) is normally present in only small quantities While normal values are generally given as 3 to 12 mg /24 hr , cortisol secretion is a function of body size Since urinary creatinine excretion is proportional to lean body mass and generally is very constant from day to day, normal urinary 17-OHCS can better be expressed as 3 to 7 mg /g of creatinine In obese persons, 17-OHCS excretion is greater than one might expect on the basis of lean body mass and normally amounts to less than 0 12 mg /kg /24 hr In children, normal excretion can conveniently be related to body surface area 1 7 to 4 0 mg /M^2/24 hr

3) 17-Ketogenic Steroids (17-KGS) In addition to the 17-OHCS, certain other steroids,

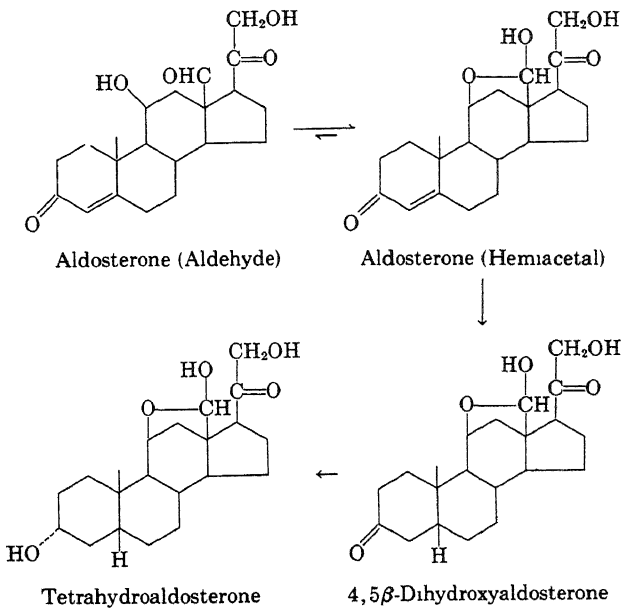

Fig 7 46 The major metabolites of aldosterone Aldosterone is shown both in the aldehyde configuration and the more stable hemiacetal form

such as pregnanetriol, can be oxidized with sodium bismuthate or sodium metaperiodate to 17-KS and measured by the Zimmerman reaction (Norymberski, 1961, Rutherford and Nelson, 1963) They are a less specific indicator of cortisol secretion than the 17-OHCS, but are nevertheless determined in some laboratories The preformed 17-KS must either be determined separately and subtracted from the total 17-KGS, or must first be reduced to a form nonreactive with the Zimmerman reagent Normal values are given as 8 to 20 mg /24 hr

4) Aldosterone Excretion Rate Aldosterone is present in urine mainly as tetrahydroaldosterone glucuronide Thus, it must first be hydrolyzed with β-glucuronidase before extraction into lipid solvents It may then be measured by its fluorescence If the determination is performed on an aliquot of a 24-hr urine collection, the aldosterone excretion rate can be calculated The normal range is 2 to 16 μg /24 hr (Mattox and Lewbart, 1959) For a variety of reasons, however, this method is not a very satisfactory index of aldosterone secretion

5) Aldosterone Secretion Rate A much more definitive procedure is the determination of the aldosterone secretion rate (ASR) by the double isotopic dilution method In this technique, a single tracer dose of tritium-labeled aldosterone is administered to the patient intravenously and the urine is collected for the following 24 hr The administered radioactive aldosterone mixes with that secreted by the adrenal, and both are assumed to be metabolized and excreted by the kidney in an identical manner Approximately 80 to 90% of the administered counts are recovered The aldosterone metabolites are isolated by paper chromatography and are then labeled by acetylation with ^{14}C-acetic anhydride The fraction of the total (^{14}C-labeled) aldosterone accounted for by the administered (^{3}H-labeled) aldosterone will be inversely proportional to the size of the endogenous pool in which it was diluted, the dilution factor is, thus, a measure of the amount of aldosterone secreted, metabolized, and excreted during the 24-hr period Knowing the dilution factor and the exact amount of ^{3}H-labeled aldosterone administered, an accurate estimate of endogenous aldosterone secretion rate can be made Under normal basal conditions on a regular diet, the ASR is 50 to 200 μg /24 hr

PHYSIOLOGICAL EFFECTS OF ADRENAL CORTICOSTEROIDS

There is as yet no unifying concept to explain all of the complex actions of cortisol, which affect virtually every tissue in the body Clinically, cortisol's actions might almost be described as "permissive" (Sayers, 1950), without cortisol secretion, a multitude of seemingly diverse physiological processes fail to function optimally

The term, glucocorticoid, refers to the sum of a wide range of influences on organic metabolism (carbohydrate, fat, and protein) and includes, among others, effects on the immune and inflammatory responses, wound healing, vascular permeability, and muscle integrity Mineralocorticoid effects, on the other hand, are rather well-defined as the sodium-retaining and potassium-wasting effects on the distal renal tubule, the salivary glands, the sweat glands, and the gastrointestinal tract Glucocorticoid and mineralocorticoid are artificial terms, since most natural and synthetic corticosteroids possess at least some of each activity For all practical purposes, however, aldosterone may be considered as a pure mineralocorticoid and dexamethasone, a steroid that is chemically synthetized, as a pure glucocorticoid (Table 7 5) While cortisol has a significant sodium-retaining activity, its effect at normal plasma cortisol concentrations is relatively minor compared to that of aldosterone

General Metabolic Effects of Cortisol (Ashmore and Morgan, 1967) The overall pattern of cortisol action might be viewed as promoting the conversion of protein to carbohydrate and the storage of carbohydrate in the form of glycogen

1) Protein Metabolism Adrenalectomized rats have decreased urea nitrogen excretion, blood glucose concentration, and liver glycogen storage, indicating decreased protein catabolism and decreased gluconeogenesis (Long et al , 1940) These aberrations are corrected with administration of adrenal steroids Glucocorticoids mobilize amino acids from skeletal muscle protein (Bondy et al , 1949, Engel, 1950, Kaplan and Shimizu, 1963) and exert a profound influence on hepatic metabolism Stimulation of the uptake of amino acids from plasma by the liver (Riggs, 1964) and induction of the synthesis of a number of hepatic enzymes, among them the transaminases, pre-

Table 7 5
Relative potencies of various natural and synthetic steroids

Steroid	Glucocorticoid Potency (Cortisol = 1)	Mineralocorticoid Potency (Aldosterone = 1)	Glucocorticoid/ Mineralocorticoid	Daily Secretion Rate or Maintenance Dose
Aldosterone	0 1	1 00	0 005	0 05-0 2 mg
Fludrocortisone	10 0	0 21	2 4	0 1 mg
Deoxycorticosterone	~0	0 05	~0	2 5 mg
Cortisone	0 7	0 0012	27	25-37 5 mg
Cortisol	1 0	0 0015	33	15-30 mg
Prednisone	4 0	0 0020	100	5-7 5 mg
Dexamethasone	30 0	~0	∞	0 5-0 75 mg

pare amino acids for incorporation into carbohydrate (Rosen et al , 1963) Since activities of enzymes in the urea cycle are also increased, conversion of the amino nitrogen to urea is facilitated (McLean and Gurney, 1963) The glucocorticoids, therefore, result in what has been called a "translocation" of protein skeletal muscle protein is depleted, but the synthesis of proteins by the liver and other visceral organs is enhanced by steroid administration (Roberts, 1953, Silber and Porter, 1953) There is an overall negative nitrogen balance

2) *Carbohydrate Metabolism* The action of cortisol is required to maintain normal hepatic production of glucose Cortisol appears to stimulate glycogen synthesis by increasing the conversion of pyruvate to glycogen and by inhibiting the release of glucose from the hepatic cell The net effect of glucocorticoid action on carbohydrate metabolism is increased synthesis and storage and decreased utilization, with a resulting hyperglycemic tendency

3) *Lipid Metabolism* The role of cortisol in lipid metabolism is not well understood Total body fat is increased by glucocorticoid administration (Kyle et al , 1956), but fatty acid synthesis in the liver is inhibited by cortisol (Ashmore et al , 1956) This effect is not observed in adipose tissue, however, where synthesis of fatty acids appears to be regulated primarily by the rate of glucose utilization (Jeanrenaud and Renold, 1960) Cortisol does promote the mobilization of fatty acids from peripheral adipose tissues and plays a permissive role in the lipolytic actions of hormones such as thyroxine and the catecholamines, a minimal amount of cortisol must be present for these hormones to exert their lipolytic effects (Goodman and Knobil, 1961)

4) *Nucleic Acid Metabolism.* Cortisol inhibits the synthesis of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) in lymphoid and connective tissues, thus exerting a catabolic effect, but stimulates RNA synthesis in the liver and other visceral organs The effects of cortisol on the enzyme systems in the liver, like the effects of other steroid hormones on other tissues (O'Malley, 1969), result from stimulation of DNA transcription and the formation of specific messenger RNA species, which in turn regulate the synthesis of specific proteins, including enzymes (Fig 7 47)

Cortisol Effects on Organ Systems. It is easier to define the effects of cortisol deficiency or excess, which are manifested in every organ system, than to define the role of glucocorticoids in normal physiology Some of the effects of cortisol on the various organ systems are listed here

1) *Central Nervous System* Glucocorticoids seem to have a stimulatory effect on brain excitability, independent of electrolyte effects (Woodbury, 1958), and alter electroencephalographic patterns Insomnia, euphoria, irritability and psychotic depression or schizophrenia are associated with hypercortisolemia, inability to concentrate or to perform mathematical calculations and mental fatigue are manifestation of hypocortisolism The mechanisms by which glucocorticoids exert these effects on the central nervous system are unknown

2) *Musculoskeletal System* The catabolic effects of cortisol on skeletal muscle are manifested by muscle atrophy and objective muscle weakness The increased efflux of potassium and amino acids from skeletal muscle in the early morning hours may be a manifestation of the protein catabolic effect of cortisol, which reaches its highest plasma concentration at

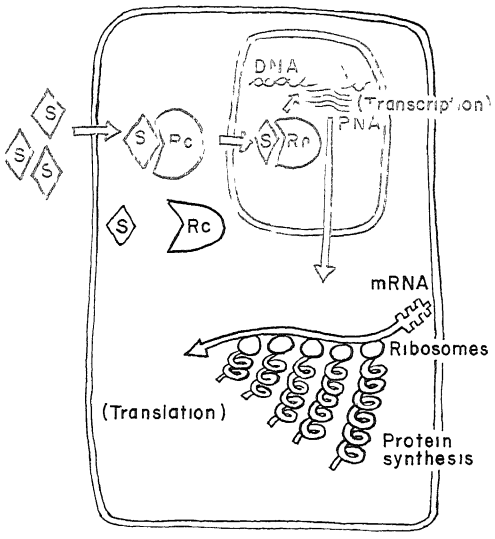

Fig 7 47 A schematic representation of the mechanism of action of a steroid hormone on its target tissue cell The steroid (*S*) diffuses freely into the cell where it is bound by a cytoplasmic receptor protein (*Rc*) The steroid-receptor complex is carried into the nucleus where the receptor may be modified (*Rn*) The complex causes DNA transcription and the synthesis of RNA species Messenger RNA (*mRNA*) directs the synthesis of new proteins on the polyribosomes (translation) (From O Malley 1971)

this time of day (Rabinowitz, 1968) Cortisol has a marked influence on connective tissue integrity In conditions of cortisol excess, peripheral subcutaneous tissue is decreased, the skin becomes thin and friable, and wound healing is delayed Cutaneous striae develop where the skin is stretched These effects may be manifestations of decreased hyaluronic acid and collagen production and inhibition of the growth and function of fibroblasts (Dougherty, 1961, Holden and Adams, 1957) Cortisol inhibits bone formation by decreasing formation of bone osteoid and cartilaginous matrix (Bernick and Ershoff, 1963) Steroids have a hypocalcemic effect, due at least in part to their antagonism to the action of vitamin D in promoting calcium absorption from the gastrointestinal tract

3) Cardiovascular System The maintenance of intravascular volume by sodium retention is mainly the responsibility of aldosterone Cortisol, by virtue of its much greater daily secretory rate, does exert a significant mineralocorticoid effect, however Cortisol appears to potentiate the peripheral arteriolar response to vasoconstrictors It increases cardiac output when given in pharmacologic doses At physiological levels, glucocorticoids decrease the permeability of the vascular endothelium At supraphysiological concentrations, cortisol has a deleterious effect on small vessel integrity

4) Respiratory System Cortisol has no apparent physiological effect on the lungs, although there is evidence that glucocorticoids may be important in the maturation of the fetal lung and its ability to secrete surfactant

5) Gastrointestinal System The antagonism of vitamin D action by cortisol, and cortisol induction of hepatic enzymes have been mentioned While supraphysiological doses of steroid inhibit gastric mucus secretion, there is no conclusive clinical or experimental evidence to support the widely accepted belief that high levels of circulating glucocorticoids can produce ulceration of normal gastric mucosa

6) Genitourinary System Menstrual abnormalities, usually oligomenorrhea, are common in women with hypercortisolism, as is downy hirsutism of the face and trunk More marked hirsutism should suggest the effects of more potent androgens than cortisol

Cortisol acts to increase renal plasma flow, glomerular filtration rate, and free water clearance (Kleeman et al , 1958), which tend to produce a sodium diuresis The mineralocorticoid effect of cortisol, however, increases the reabsorption of sodium in the distal renal tubule In addition, cortisol may decrease the permeability of the distal tubular epithelium to water (Kleeman et al , 1964) Thus, the net effect of cortisol on the kidney is maintenance of the ability to excrete a water load

7) Hematopietic and Lymphoid Systems Glucocorticoids appear to have a permissive role in erythropoiesis, polycythemia is often seen in hypercortisolism, and anemia in adrenal insufficiency Glucocorticoids have a dramatic catabolic effect on lymphoid tissue, manifested by lymphoid and thymic atrophy and lymphopenia in hypercortisolism and by lymphoid hyperplasia in adrenal insufficiency Circulating eosinophils fall rapidly after glucocorticoid administration due to increased destruction, this phenomenon was once used as an index in in vivo adrenocortical activity (Nelson, 1953) As the lymphocytes and eosinophils disappear from the circulating blood, the neutrophil polymorphonuclear leukocytes increase, probably because cortisol impairs

their emigration from the vascular space into the surrounding tissues (Boggs et al , 1965)

8) Effects on Inflammation and Infection The glucocorticoids are involved in almost every phase of the inflammatory response Under conditions of cortisol excess, here is interference with the febrile response, impaired diapedesis of granulocytes into the area of injury, impaired migration of phagocytic cells, decreased ability to localize infection because of impaired connective tissue integrity, impaired bacteriocidal activity of phagocytes, decreased phagocytic activity of the reticuloendothelial system, decreased humoral antibody synthesis, hypogammaglobulinemia, eosinopenia, lymphopenia, thymic atrophy, and stabilization of lysosomal membranes, thereby preventing the release of proteolytic enzymes and kinins which may be important in the inflammatory response (Grant, 1967) In the hypoadrenal patient, on the other hand, infection may elicit an exaggerated febrile and inflammatory response, but the patient suffers from an ill-defined inability to respond to "stress " In normal individuals, plasma cortisol concentrations increase under "stressful" conditions, inability to mount this response may result in adrenal crisis and vascular collapse

General Metabolic Effects of Aldosterone (Mulrow, 1969) The most important biological action of aldosterone is regulation of sodium and potassium excretion by the kidney

1) Direct Effects on the Kidney Aldosterone increases distal tubular sodium resorption and potassium excretion It also enhances wasting of hydrogen, magnesium, and ammonium ions The mechanism by which aldosterone exerts these effects is analagous to that already described for cortisol (Fig 7 48) There is again a specific intracellular receptor protein for the steroid (Fanestil and Edelman, 1966) The aldosterone-receptor complex migrates to the nucleus, where it stimulates DNA-dependent RNA synthesis (Castles and Williamson, 1967) and subsequent protein synthesis The exact nature of the protein synthesized is not known It may be an enzyme which results in generation of adenosine triphosphate (ATP) to provide the energy required for the sodium transport pump (Fanestil et al , 1967), which is shown diagrammatically in Figure 7 48, or a permease which directly facilitates sodium transport across the

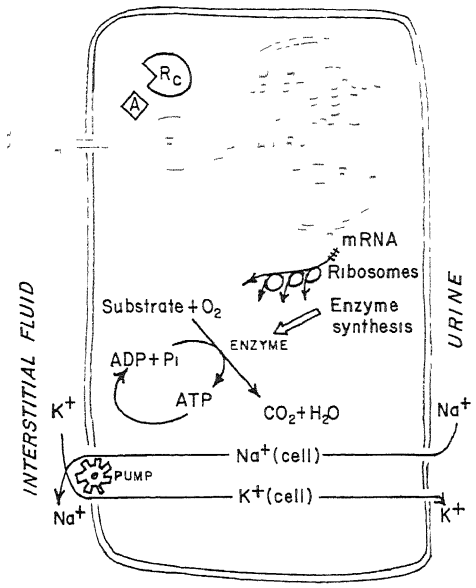

Fig 7 48 A schematic drawing of the mechanism of action of aldosterone (*A*) on the distal renal tubule epithelial cell (From Edelman et al 1964)

cell membrane (Sharp and Leaf, 1966) The effects of aldosterone are facilitated by glucocorticoids but are inhibited by certain cortisol precursors, such as progesterone and 17-hydroxyprogesterone This inhibition is thought to be on the basis of competition for intracellular-binding sites The excretion of potassium normally is coupled directly to sodium resorption Reduced sodium intake or enhanced proximal tubular resorption of sodium, either of which results in less sodium being presented to the distal tubule, prevents the kaliuresis caused by aldosterone (Finn and Welt, 1963) Aldosterone does not affect the excretion of free water by the kidney

2) Indirect Effects on the Kidney The direct sodium-retaining action of aldosterone causes expansion of the plasma volume As a result, renal plasma flow and glomerular filtration increase, renin production decreases After prolonged plasma volume expansion due to sodium retention, the distal tubule exhibits an "escape" phenomenon, it no longer retains sodium in response to aldosterone stimulation, yet it continues to waste potassium (August et al , 1958)

3) Other Metabolic Effects of Aldosterone The sodium-retaining, potassium-wasting effects of aldosterone are expressed in the gastrointestinal tract, salivary glands, and sweat

glands as well as in the renal tubule The difference is that the latent period between administration and observed effect is much longer than the 30 to 120 min delay observed in the kidney and requires de novo protein synthesis Furthermore, these tissues do not "escape" after prolonged administration of mineralocorticoid Aldosterone excess causes hypertension in man, salt deprivation will prevent the hypertension The exact mechanism by which the hypertension is caused is not known It has been suggested that the lumen of the peripheral arteriole is partially occluded by swelling of the arteriolar lining cells, which have retained sodium and water (Tobian, 1960) This partial occlusion would increase peripheral vascular resistance, causing hypertension

REGULATION OF GLUCOCORTICOID SYNTHESIS

The synthesis and secretion of adrenal glucocorticoids are dependent upon stimulation by adrenocorticotropic hormone (ACTH) (Fig 7 49)

Biological Activity. ACTH stimulates the synthesis of cortisol and 17-ketosteroids by the adrenal cortex At physiological concentrations, it has little or no effect on aldosterone secretion ACTH is also necessary to maintain adrenocortical size, structure, and vascularity, growth hormone also plays a minor role in maintaining size In the hypophysectomized animal, the adrenals very rapidly become unresponsive to the acute steroidogenic stimulus of ACTH and eventually become atrophic While secretion of cortisol and adrenal 17-ketosteroids falls to subnormal levels, the secretion of aldosterone remains nearly normal This is because the structure and function of the zona glomerulosa depends, not upon ACTH, but upon the renin-angiotensin system

Actions of ACTH are mediated by cyclic adenosine monophosphate (cyclic AMP) ACTH binds to specific receptor sites on the surface of the adrenocortical cell and activates the associated, membrane-bound adenyl cyclase This promotes the conversion of ATP to cyclic AMP The formation of cyclic AMP is proportional to the amount of ACTH bound and precedes detectable steroidogenesis (Grahame-Smith et al , 1967) There is an intracellular receptor or binding protein for adrenal cyclic AMP, the function of which is not yet known (Gill and Garren, 1969) It is known, however, that ACTH and cyclic AMP stimulate new protein synthesis and that this new protein is required for increased steroidogenesis

This labile protein apparently stimulates the conversion of cholesterol to 20α-hydroxycholesterol in the mitochondrion, either by enhancing the transport of cholesterol from the

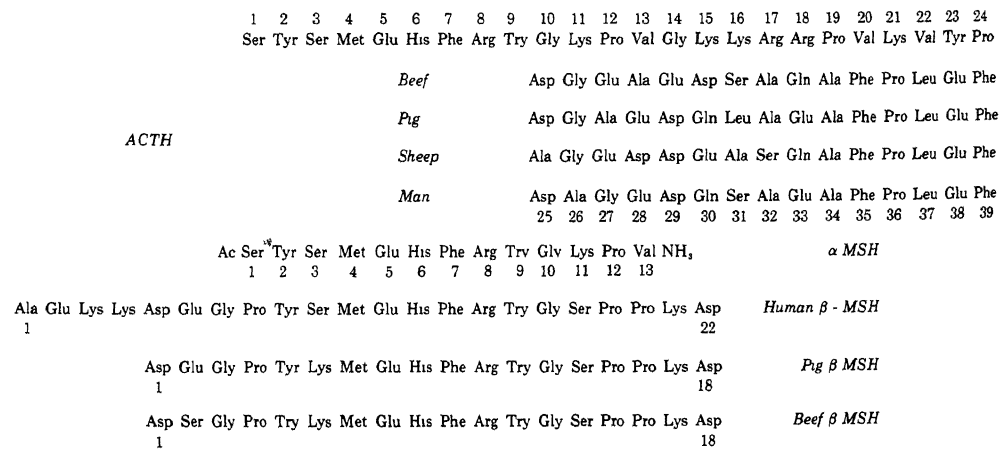

Fig 7 49 The amino acid sequences of representative ACTH s and MSH s The sequence of amino acids 1–24 in ACTH is identical in all four species and possesses full steroidogenic activity (Ney et al , 1965) Species specificity resides in amino acids 25–33 of the ACTH molecule The structure of α-MSH is identical to the first 13 amino acids of ACTH with acetylation of the N-terminal serine and amidation of the C-terminal valine The β-MSH s of three species are shown The dotted lines enclose the sequence of seven amino acids shared by α-MSH the β-MSH s and the ACTH s

liposomes to the mitochondria or by direct stimulation of the hydroxylation reaction

ACTH and the melanocyte-stimulating hormones (MSH's) share certain features They are secreted by the pituitary, they have a common core of seven amino acids (Fig 7 49), and they each have both steroidogenic and melanocyte-stimulating activities One of the extra-adrenal effects of ACTH is the dispersion of melanin pigment in melanocytes, which causes darkening of the skin ACTH has about $^1/_{100}$th the MSH potency of α-MSH The MSH's on the other hand, all have weak intrinsic steroidogenic activity Furthermore, it appears that in man, in whom β-MSH is the principal pigmentary hormone, that ACTH and β-MSH secretion parallel each other, suggesting that they may be synthesized and secreted by a common mechanism within a single cell (Abe et al , 1969a)

Regulation of ACTH Secretion (Liddle et al , 1962) Three factors are of major importance in regulating ACTH secretion First, there is homeostatic negative feedback inhibition of ACTH secretion by circulating cortisol (Fig 7 50) Decreased plasma cortisol concentrations lead to increased pituitary ACTH release, increased plasma cortisol levels inhibit further ACTH secretion This inhibition may act at the hypothalamic level by inhibiting the release of corticotropin-releasing factor (CRF) into the hypothalamic-hypophyseal portal blood vessels, it certainly appears to act at the level of the pituitary, blocking the actions of releasing factors (Fleischer and Vale, 1968) Second, plasma cortisol concentrations show a circadian (circa, about, dies, a day) rhythm, with high levels (15 to 25 μg /100 ml) in the early morning and low levels (less than 7 μg /100 ml) late in the evening (Fig 7 51) This rhythm is the result of a circadian rhythm in ACTH secretion (Ney et al , 1968) and appears to be synchronized by the daily environmental shift from darkness to light (Orth and Island, 1969) There is a constantly changing "set-point" for the concentration of plasma cortisol required to inhibit ACTH secretion during the course of the day, high levels being required in the early morning hours and low levels in the late afternoon and evening Whether or not this is mediated by CRF secretion is not known The third important factor governing ACTH secretion is "stress " Thus, plasma ACTH levels are increased during fever, laparotomy, or acute severe depression, resulting in increased secretion of cortisol While some of the influence of stress may be mediated via hypothalamic CRF release, it is of interest that section of the pituitary stalk not always, and seldom permanently, abolishes stress-induced ACTH release

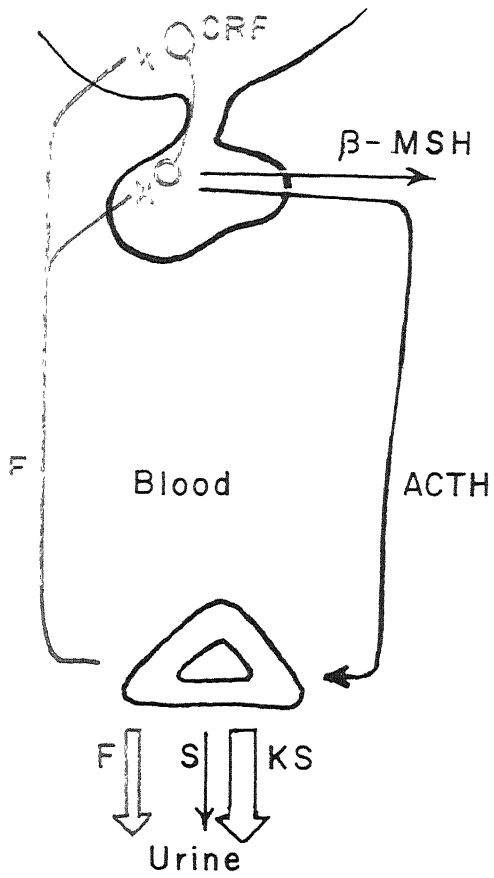

Fig 7 50 A diagram of the normal hypothalamic-pituitary-adrenal axis Corticotropin releasing factor (*CRF*) is released by the hypothalamus into the portal circulation and causes ACTH and *β MSH* release ACTH stimulates adrenal synthesis of cortisol (*F*) Cortisol deoxycortisol (*S*) and 17-ketosteroid (*KS*) metabolites appear in the urine Cortisol exerts a negative feedback inhibition on ACTH secretion and perhaps on CRF secretion Thus decreasing plasma cortisol leads to increasing plasma ACTH Increased plasma ACTH stimulates increased adrenal cortisol production and increased plasma cortisol inhibits further ACTH secretion

Measurement of ACTH. There are currently three basic methods by which ACTH may be assayed The oldest, and in many ways the most reliable, is the bioassay (Lipscomb and Nelson, 1962) Its greatest advantage is specificity for the biologically active ACTH

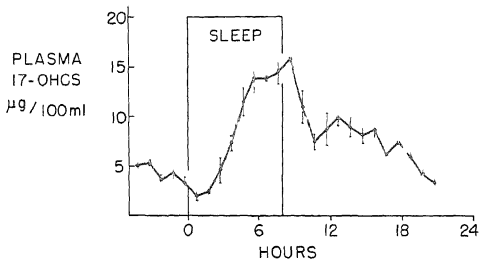

Fig 7 51 Plasma cortisol (17-OHCS) concentrations in eight normal subjects confined to a metabolic ward They slept regularly from 10 PM until 6 AM for several days before and during the period when blood was sampled hourly via indwelling venous catheters The mean 17-OHCS and the standard error of the means are shown

molecule Its greatest disadvantages are relative insensitivity and difficulty of performance In essence, it measures the adrenal production of corticosterone ("substance B") by the hypophysectomized rat in response to intravenous injection of an unknown sample, and compares this with the response caused by injection of known quantities of reference standard ACTH The corticosterone can be measured in extracts of the adrenal gland, in adrenal vein blood, or in peripheral blood, using the fluorometric technique The second method is the ACTH radioimmunoassay (Yalow et al , 1964, Orth et al , 1968, Berson and Yalow, 1968), which has the great advantage of sensitivity and therefore requires much less plasma for assay While the radioimmunoassay is an extremely useful technique, it has the intrinsic disadvantage that it does not necessarily measure biologically active ACTH, it may also detect inactive ACTH fragments (Besser et al , 1971) Recently, a new assay method has been reported that appears to have many of the advantages of both previous methods In the radioreceptor assay (Lefkowitz et al , 1970), the ACTH receptor site from the cell membrane of an ACTH-responsive adrenocortical tumor cell is used to bind labeled ACTH, rather than using an antibody If the biological activity of an adrenocorticotropin is proportional to its energy of binding to the receptor site, then the competition for binding by unknown samples should give an accurate estimate of the biological ACTH activity of the sample Furthermore, this very sensitive technique should be applicable to any hormone for which a target tissue receptor can be isolated

REGULATION OF MINERALOCORTICOID SYNTHESIS

Renin-Angiotensin System. The synthesis and secretion of adrenal mineralocorticoid are dependent primarily upon the renin-angiotensin system This system is discussed in detail elsewhere in this volume Renin is an enzyme produced by the juxtaglomerular cells which surround the afferent arteriole just before it reaches the glomerular capillary tuft These cells may function as baroreceptors and release renin when renal perfusion falls due to decreased blood pressure or blood volume (Tobian, 1960) Several other factors, including urine sodium concentration at the level of the macula densa in the distal renal tubule and renal sympathetic nervous tone may modify renin release (Vander and Miller, 1964, Gordon et al , 1967, Brubacher and Vander, 1968) Renin converts circulating renin substrate to the decapeptide, angiotensin I A converting enzyme that is produced in the lung removes the two C-terminal amino acids of angiotensin I to form the biologically active octapeptide, angiotensin II Angiotensin II has two major effects *1)* it has an immediate effect on the peripheral arterioles to cause vasoconstriction and increased systemic blood pressure, *2)* it stimulates secretion of aldosterone by the adrenal cortex Aldosterone secretion results, secondarily, in sodium retention, expansion of the intravascular volume, and increased blood pressure Thus, both the acute and chronic effects of angiotensin II tend to correct the original stimulus to renin release, decreased renal perfusion This is another example of a negative feedback regulatory system Angiotensin II is rapidly inactivated by proteolytic enzymes in the plasma and tissues The exact mechanism by which angiotensin II exerts its effect on the adrenal zona glomerulosa cell is unknown It is presumed that it accelerates the conversion of cholesterol to 20α-hydroxycholesterol, the rate-limiting step in aldosterone biosynthesis It is known at least that its site of action precedes the synthesis of DOC (Brown et al , 1971)

Plasma renin activity can be bioassayed in the nephrectomized rat (Boucher et al , 1964) The plasma of the patient is first incubated so as to convert the renin substrate to angiotensin I This is then injected into the rat, where it is converted to angiotensin II The

amount of plasma renin activity is measured by the degree of rise in blood pressure which it causes in the assay animal Plasma renin activity can also be measured by radioimmunoassaying the angiotensin I generated during the incubation of the patient's plasma (Catt et al , 1967, Boyd et al , 1967, Vallotton et al , 1967)

Electrolytes. Increased serum potassium and decreased serum sodium concentrations stimulate aldosterone secretion in the absence of changes in plasma volume in vivo, similar stimulation is observed in vitro Both of these monovalent cations exert their effects early in the aldosterone biosynthetic pathway, prior to the formation of deoxycorticosterone (DOC) (Brown et al , 1971) Aldosterone secretion is sensitive to changes in serum potassium concentration of less than 1 mEq /liter, while a very considerable change in serum sodium is required to effect a similar response

ACTH. The role of ACTH in aldosterone synthesis and secretion is relatively unimportant After chronic hypophysectomy, aldosterone does not rise normally during sodium deprivation It has not been shown that this is due specifically to ACTH deficiency, however In the hypophysectomized rat, ACTH injections do not restore the aldosterone response to hyponatremia (Palmore and Mulrow, 1967) Aldosterone secretion is temporarily increased by very large doses of ACTH, but falls to normal levels despite continued ACTH administration (Liddle et al , 1956)

DISORDERS OF ADRENOCORTICAL FUNCTION

Primary Adrenocortical Insufficiency Addison's disease (Addison, 1855) is usually caused by destruction of the adrenal glands by infection with tuberculosis or histoplasmosis or by idiopathic atrophy associated with circulating antibodies to adrenal tissue (Blizzard and Kyle, 1963) It may also be caused by other granulomatous diseases, infiltration by carcinoma, involvement with amyloid, or by hemorrhage into the adrenals which occurs very rarely in association with severe systemic infections (Waterhouse-Friderichsen syndrome)

The manifestations of primary adrenocortical insufficiency are primarily those of deficient aldosterone secretion, complicated by the loss of cortisol secretion They are quite different, therefore, from the manifestations of secondary adrenocortical insufficiency caused by decreased pituitary ACTH secretion, in which aldosterone production is adequate and only glucocorticoid is deficient Mineralocorticoid insufficiency leads to sodium wasting and potassium retention, causing hyponatremia, hyperkalemia, and a metabolic alkalosis The salt depletion leads to fluid loss and dehydration The effects of glucocorticoid insufficiency are less well-defined They include weakness, irritability, drowsiness and easy fatigability Without the hyperglycemic effects of cortisol to dampen the insulin response to a glucose load, reactive hypoglycemia is frequently observed

The loss of negative feedback inhibition of pituitary ACTH secretion leads to hypersecretion of both ACTH and β-MSH (Fig 7 52)

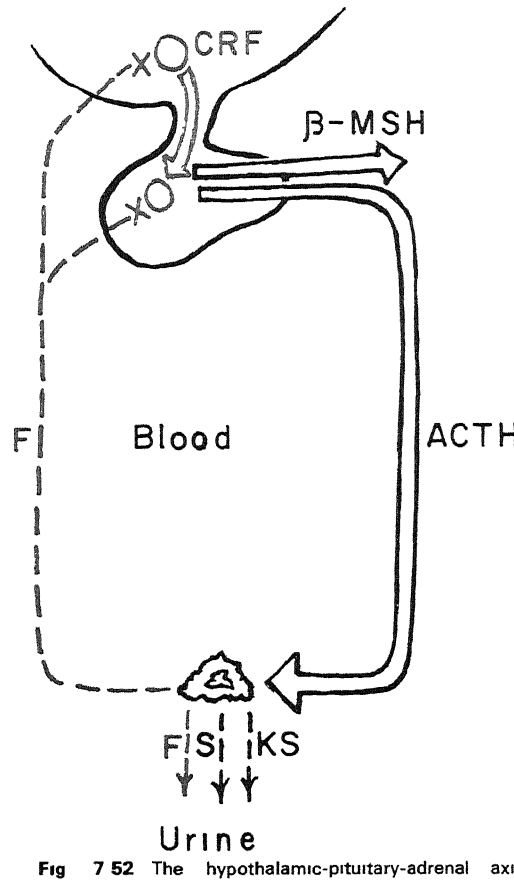

Fig 7 52 The hypothalamic-pituitary-adrenal axis in primary adrenal insufficiency or Addison s disease The atrophic adrenal secretes little or no corticosteroids plasma and urinary steroids are low The loss of cortisol negative feedback inhibition leads to increased secretion of both ACTH and β-MSH by the pituitary

The latter results in "addisonian" hyperpigmentation of the skin, particularly marked in exposed areas and in recent scars, over pressure points such as the elbows, in the buccal mucosa, the areolae, genitals, and intertriginous areas In women, the loss of adrenal androgen results in loss of axillary and pubic hair, men are not affected because of testicular androgen production

The diagnosis can be confirmed by finding low plasma cortisol levels early in the morning, when cortisol is normally high, decreased urinary excretion of 17-OHCS and 17-KS, and failure of the plasma or urinary steroids to increase in response to administration of exogenous ACTH In addition, plasma ACTH and β-MSH are markedly elevated, aldosterone secretion rate is low, and, as a result of decreased plasma volume and renal blood flow, plasma renin activity is increased

Treatment is directed immediately toward restoring plasma volume by infusion of physiological saline solution The addisonian patient requires life-long replacement therapy with both glucocorticoid and mineralocorticoid The adrenal medulla is not necessary for life, no replacement of catecholamines is required for maintenance of good health

Adrenocortical Hyperfunction. Harvey Cushing first described (Cushing, 1932) the "constellation of clinical and metabolic abnormalities resulting from a chronic excess of cortisol" (Liddle, 1967) Apart from the administration of excessive amounts of glucocorticoid medications, there are now three well-defined causes of Cushing's syndrome

1) Adrenal Tumors Benign or malignant adrenal tumors may secrete cortisol autonomously, independent of ACTH stimulation (Fig 7.53)

2) Ectopic Production of ACTH by Nonpituitary Tumors A variety of tumors arising in nonpituitary tissues autonomously secrete ACTH and MSH (Liddle et al, 1969) These hormones appear to be similar to, if not identical with, the authentic pituitary hormones (Fig 7 54)

3) Excess Pituitary Production of ACTH The term, "Cushing's disease," is reserved for this variety of Cushing's syndrome, since Cushing's original concept was that the syndrome he described was caused by an abnormality in pituitary function, "pituitary basophilism" In a few cases, pituitary basophil or

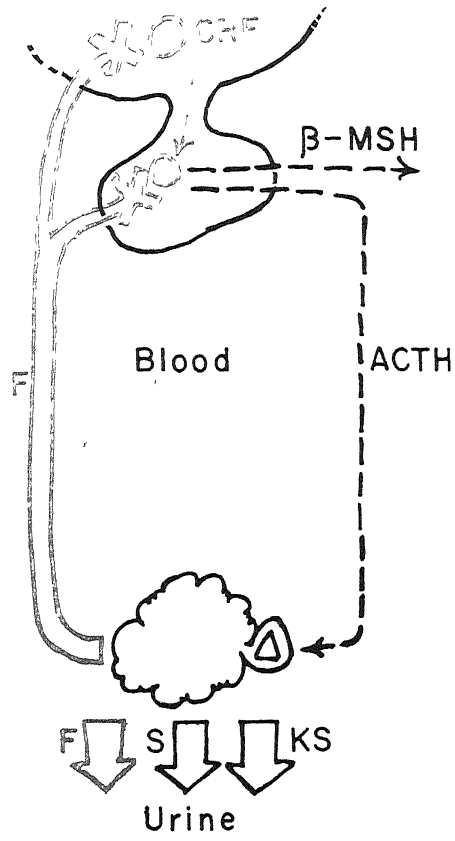

Fig 7 53 Hypothalamic-pituitary-adrenal dynamics in Cushing s syndrome due to adrenocortical tumor The tumor produces increased quantities of cortisol (*F*) deoxycortisol (*S*) and 17-ketosteroids (*KS*) the metabolites of which appear in the urine Plasma cortisol concentrations are increased inhibiting hypothalamic CRF secretion and pituitary ACTH and β-MSH secretion Since ACTH is suppressed the non-tumorous adrenal tissue becomes atrophic

chromophobe tumors may be the source of ACTH In most instances, however, no tumor is found The exact nature of the pituitary aberration is as yet unknown If the defect is at the hypothalamic level, increased secretion of CRF or changes in hypothalamic catecholamine levels might be involved The characteristic feature of Cushing's disease is that ACTH secretion is not autonomous, it is merely "inappropriate" (Liddle, 1967) First, there is relative resistance to glucocorticoid negative feedback, so that it takes a greater than normal plasma cortisol level to suppress ACTH release (Fig 7 55) Second, the normal circadian rhythm in ACTH secretion is lost, whereas, early morning ACTH and cortisol levels may be within the normal range, they do

not fall during the day and are, therefore, clearly elevated above normal values in the evening

The clinical and metabolic abnormalities characteristic of Cushing's syndrome might be predicted from what has already been said about the physiology of cortisol The Cushing's patient is aptly described as "a caricature of the physiologic effects of cortisol" (Rabinowitz, 1968) The patient develops centripetal obesity, wasting of the extremities with increased fat deposition about the trunk, in the supraclavicular areas, the neck and the face There is plethora of the neck and face Wide cutaneous striae are found over the flanks and thighs and, in women, the breasts They represent stretching and thinning of the skin, and

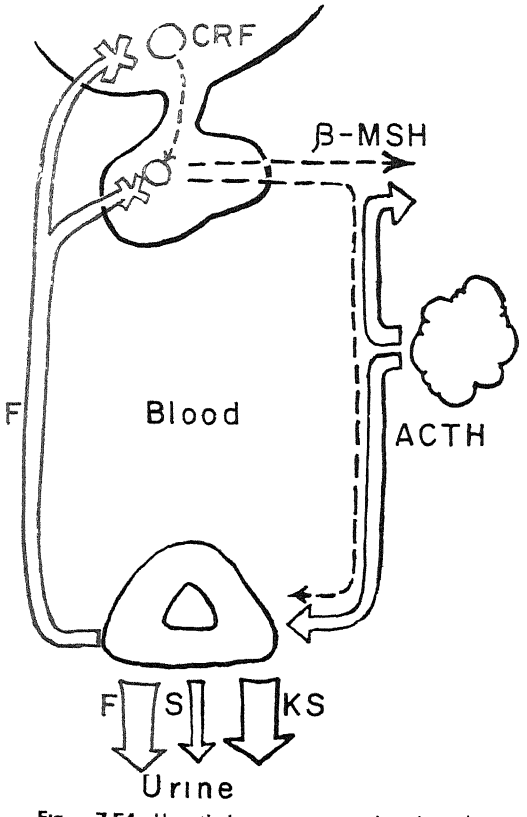

Fig 7 54 Hypothalamic-pituitary-adrenal relationships in the ectopic ACTH syndrome Autonomous hypersecretion of ACTH by a nonpituitary tumor causes bilateral adrenal hyperplasia and increased secretion of corticosteroids Steroid metabolites appear in increased quantities in the urine Plasma cortisol is increased suppressing hypothalamic CRF secretion and pituitary ACTH and β-MSH release Since the tumor itself secretes both ACTH and β-MSH, however, the plasma concentrations of both are increased

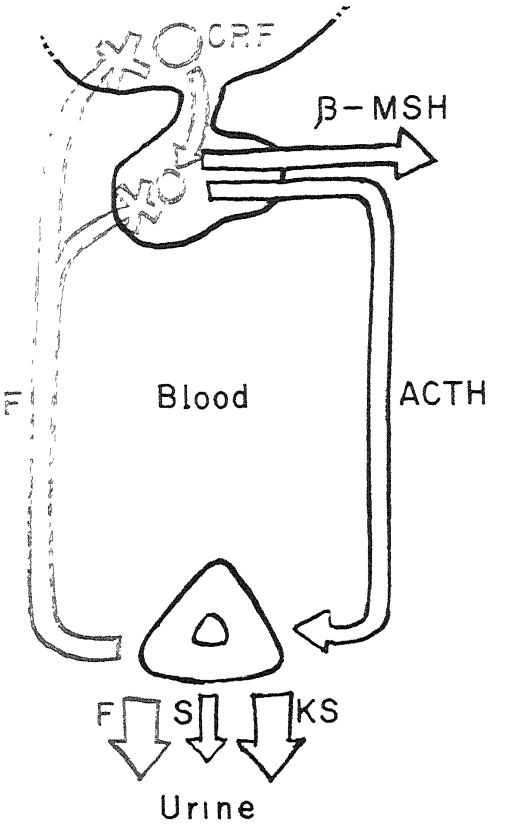

Fig 7 55 Hypothalamic-pituitary-adrenal axis in Cushing s disease The pituitary secretes excessive quantities of ACTH and β-MSH possibly because of increased stimulation by hypothalamic CRF The increased plasma ACTH causes bilateral adrenal hyperplasia and hypersecretion of corticosteroids Urinary corticosteroid levels are increased The hypothalamic-pituitary axis is relatively resistant to suppression since elevated plasma cortisol concentrations fail to suppress pituitary ACTH and β-MSH secretion into the normal range

appear purple because they reveal the underlying vascular dermia Wounds heal poorly The patient's muscles become atrophic, and he cannot rise from a squatting position without assistance Carbohydrate intolerance is the rule, and frank diabetes mellitus may be seen in patients with a familial predisposition to this disorder The patient may have mental aberrations ranging from euphoria to frank schizophrenia In children, a dramatic arrest of linear growth is observed In adults, osteoporosis may be severe, resulting in compression fractures of the vertebrae The sodium-retaining effects of high cortisol levels result in hypertension, which may be aggravated by the potentiation of the vasoconstrictor effects of

endogenous catecholamines The Cushing's patient is abnormally susceptible to infections Menstrual aberrations and downy hirsutism are frequent findings in women, as is acne over the face and shoulders in both sexes Hyperpigmentation may be seen in Cushing's disease or the ectopic ACTH syndrome because of the effects of β-MSH

The diagnosis of Cushing's syndrome can be confirmed and its cause determined by applying physiology to clinical medicine (Fig 7 56) In the patient with suspected Cushing's syndrome, the physician tests his clinical impression by determining if hypercortisolism is actually present If plasma concentrations and urinary excretion of 17-OHCS are elevated, if there is no diurnal rhythm in plasma cortisol concentration, and if ACTH (and, secondarily, cortisol) secretion cannot be suppressed by low doses of the potent glucocorticoid, dexamethasone, the patient has Cushing's syndrome The cause of the hypercortisolism can then be determined by two further procedures We have already seen that ACTH secretion in Cushing's disease is only relatively resistant to feedback inhibition Thus, pituitary ACTH secretion will be suppressed with high doses of dexamethasone If it is not, the patient has either autonomous production of ACTH by a nonpituitary tumor or autonomous production of cortisol by a benign or malignant adrenal tumor These two can be differentiated by measuring plasma ACTH In the ectopic ACTH syndrome, plasma ACTH is obviously elevated In the patient with Cushing's syndrome due to adrenal tumor, on the other hand, autonomous hypersecretion of cortisol suppresses ACTH secretion by the normal pituitary, and plasma ACTH is low

Treatment of Cushing's syndrome depends on the cause If there is a tumor, the only satisfactory treatment is surgical removal In Cushing's disease, one can either direct one's attack at the pituitary, to reduce ACTH secretion, or at the adrenals, to remove the source of the excess cortisol Pituitary irradiation is successful in reducing ACTH secretion to normal in many patients Surgical hypophysectomy has also been used Bilateral surgical adrenalectomy is successful in curing Cushing's disease, but the patient then requires steroid replacement therapy for the rest of his life Adrenolytic drugs and drugs which interfere with corticosteroid biosynthesis are also sometimes used (Temple and Liddle, 1970)

Congenital Adrenal Hyperplasia. The first detailed description of this syndrome (Baulieu et al, 1967) was published by DeCrecchio (1865) It is caused by inborn errors of metabolism involving deficiency of specific enzymes which participate in adrenal steroid biosynthesis The common feature of the congenital adrenal hyperplasias is that cortisol synthesis is impaired (Fig 7 57), resulting in increased

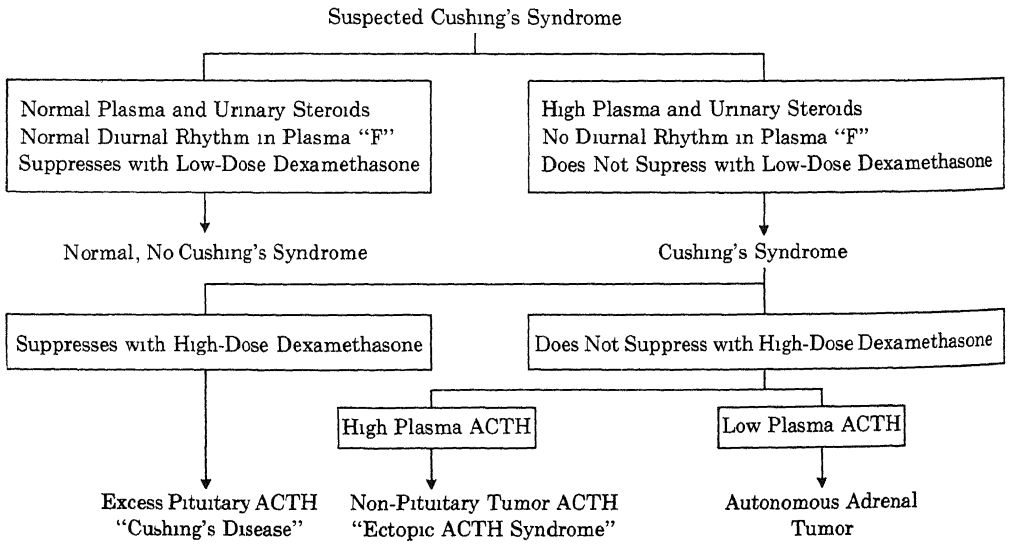

Fig 7 56 A flow diagram for establishing the diagnosis of Cushing s syndrome and determining its etiology by means of physiologic manipulations See text for discussion

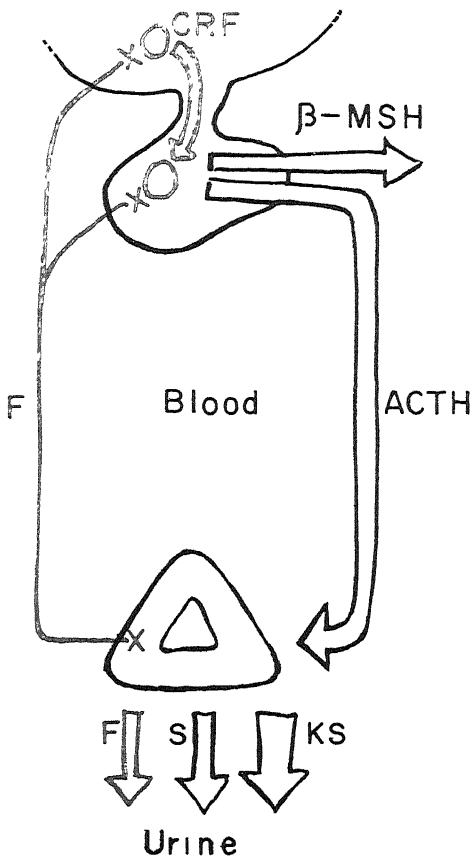

Fig 7 57 Hypothalamic-pituitary-adrenal dynamics in the congenital adrenal hyperplasias The adrenal cannot synthesize normal amounts of cortisol because of an inborn enzymatic defect Low plasma cortisol concentrations result in increased secretion of ACTH and β-MSH by the pituitary Under the influence of chronic ACTH stimulation the adrenals become increasingly hyperplastic and cortisol precursors are produced in increasing quantities until normal or near-normal plasma cortisol levels are achieved The cortisol is produced at the expense of increased secretion of androgenic 17-ketosteroid precursors the metabolites of which appear in the urine

ACTH secretion by the pituitary Increased ACTH stimulation results in bilateral adrenal hyperplasia, increasing the total adrenal mass and providing sufficient precursor steroids that cortisol production reaches normal or near-normal levels Normal cortisol production is achieved at the expense of excessive production of adrenal androgens, however, which cause the characteristic virilization seen in this disorder There are four major types of congenital adrenal hyperplasia *1)* simple virilizing, *2)* salt-losing, *3)* hypertensive, and *4)* 3β-ol dehydrogenase defect, in order of decreasing incidence There are, in addition, other very rare forms that will not be discussed here

Simple Virilizing Type A partial deficiency of the 21-hydroxylase enzyme is responsible for this type of congenital adrenal hyperplasia, more complete deficiency causes the salt-losing variety

The defect in steroid biosynthesis is shown in a simplified schematic diagram in Figure 7 58 Synthesis of both cortisol and aldosterone are affected Subnormal cortisol production results in increased plasma ACTH levels, which cause accelerated production of 20α-hydroxycholesterol and, since this is the rate-limiting step in steroidogenesis, increased production of the other cortisol precursors Cortisol levels are normal or subnormal in both plasma and urine, depending upon the degree of enzyme deficiency Urinary excretion of 17-ketosteroids (DHA and its sulfate, Δ^4-androstenedione, androsterone, and etiocholanolone) is increased Metabolites of cortisol precursors also appear in increased quantities in the urine Pregnanediol is a metabolite of pregnenolone and progesterone, and pregnanetriol is derived from 17-hydroxypregnenolone and 17-hydroxyprogesterone Pregnanediol and pregnanetriol are easily measured in urine (Bongiovanni and Clayton, 1954) Testosterone is also increased in the urine It is not measured in the 17-KS, but must be quantitated by other methods (Camacho and Migeon, 1966) Since the adrenals are already maximally stimulated by endogenous ACTH, plasma and urinary steroids are usually not increased by administration of ACTH

The clinical picture depends upon the severity of the enzyme defect, which dictates the degree of excess androgen production, and the time at which excessive androgen secretion begins during fetal life In the female, pseudohermaphroditism results, with varying degrees of genitourinary anomaly Increased pigmentation, particularly of the areolae and the genitals, may be observed, and is the result of increased β-MSH secretion If the patient is not treated, progressive virilization will occur, with increasing clitoral hypertrophy and development of a male pattern of pubic hair, usually be the age of 3 years Early growth acceleration is accompanied by early closure of the epiphyseal growth centers Although these patients are tall as young children, they do not reach normal adult height if untreated The

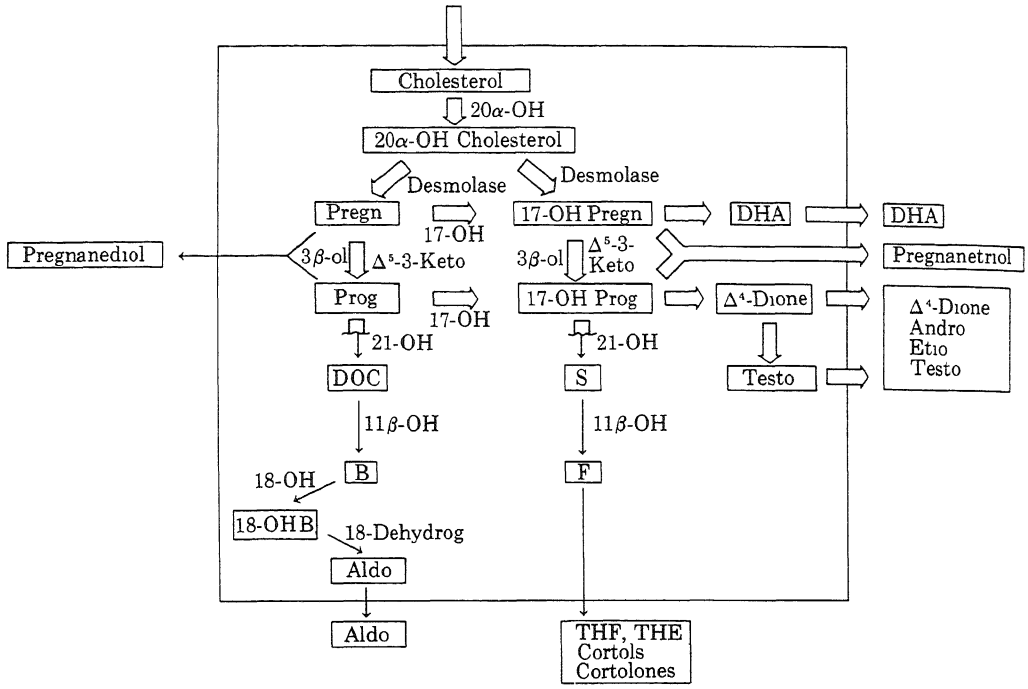

Fig 7 58 A diagram of the biosynthetic defect in simple virilizing congenital adrenal hyperplasia and salt losing congenital adrenal hyperplasia both of which are the result of a deficiency in 21-hydroxylase Refer to Figure 7 44 and to the text for discussion

child may be raised as a boy and will develop a masculine body habitus, deep voice, body hair, and beard The breasts fail to develop, the uterus remains infantile, and the patient fails to menstruate

The syndrome in the male is much more difficult to recognize Except for increased pigmentation, no abnormalities are obvious at birth Precocious puberty and rapid growth—macrogenitosomia praecos—usually are noted within the first few years While the child may appear to be a "young Hercules," his epiphyses, too, will close at age 8 or 10 if he is not treated, and normal adult stature will not be achieved In contrast to enlargement of the penis and prostate, due to stimulation by adrenal androgens, the testes usually remain small and immature, since they require stimulation by pituitary gonadotropic hormones

The diagnosis depends upon the early recognition of the syndrome and is verified by finding normal or subnormal 17 OHCS levels in plasma and urine and markedly elevated 17-KS and pregnanetriol The markedly elevated urinary levels of pregnanetriol and other metabolites of 21-deoxy steroids causes the 17-KGS to be increased Thus, they do not reflect the rate of cortisol secretion in this condition The 17-KS (and the 17-KGS) rapidly suppress to normal with replacement doses of glucocorticoids, since pituitary ACTH is normally responsive to feedback inhibition

Treatment consists only of replacement corticosteroid therapy The diagnosis must be made at an early age in order to prevent growth arrest and, in the female, in order to prevent progressive virilization and male psychosexual fixation

Salt-Losing Type. This represents a more severe form of the simple virilizing type of congenital adrenal hyperplasia The signs and symptoms are the same, with the additional very serious complication of the syndrome of primary adrenal insufficiency This usually manifests itself in dehydration and shock within the first 2 weeks of life, but may occur later in childhood, precipitated by some stress such as infection Death may occur because of hypovolemic shock or cardiac arrest caused by extreme hyperkalemia

There are at least three factors involved in the salt wasting (Baulieu et al , 1967) First, aldosterone secretion does not rise normally with salt deprivation, there is loss of aldoster-

one secretory "reserve" (Blizzard et al., 1959) Second, cortisol normally exerts a permissive effect on the renal tubular actions of aldosterone (Eberlein and Bongiovanni, 1958), and cortisol secretion is impaired Third, progesterone and 17-hydroxyprogesterone, which are secreted in very large quantities in this syndrome, antagonize the actions of aldosterone, perhaps by competing for intracellular receptor-binding sites (Crigler et al 1952, Jailer, 1953) These patients usually require mineralocorticoid replacement therapy

Hypertensive Type. Much less common than the 21-hydroxylase deficiency types, this variety is caused by a deficiency in 11β-hydroxylase (Fig 7 59) The pathogenesis and clinical syndrome are essentially the same, except for the associated moderate to severe high blood pressure The urinary 17-OHCS are actually elevated in this syndrome because of increased excretion of tetrahydrodeoxycortisol (THS), the last steroid precursor before the enzymatic defect Plasma and urinary cortisol and cortisol metabolites are normal or low, depending upon the completeness of the enzyme deficiency The hypertension is caused by hypersecretion of deoxycorticosterone (DOC), a moderately potent mineralocorticoid (Table 7 5) The hypertension is corrected and the virilization arrested by simple glucocorticoid replacement therapy

Another variety of hypertensive congenital adrenal hyperplasia has recently been described in which the activity of the 17-hydroxylase enzyme is deficient (Biglieri 1966) Since this deficiency is present not only in the adrenal but in the ovary, neither adrenal androgens nor ovarian estrogens are synthesized Increased synthesis of corticosterone and deoxycorticosterone causes hypertension and hypokalemic alkalosis, aldosterone secretion is actually suppressed by the salt-retaining effects of deoxycorticosterone The patient is phenotypically female, but fails to menstruate or sexually mature because of lack of estrogen The diagnosis is confirmed by finding absent 17-OHCS, 17-KGS, and 17-KS in the urine in the presence of excessive quantities of tetrahydrocorticosterone and tetrahydrodeoxycorticosterone Treatment consists of replacement both with glucocorticoid and with estrogen and progesterone

3β-ol Deficiency Type This rare form of congenital adrenal hyperplasia is usually fatal early in infancy because of severe sodium loss and resulting dehydration and hypovolemic

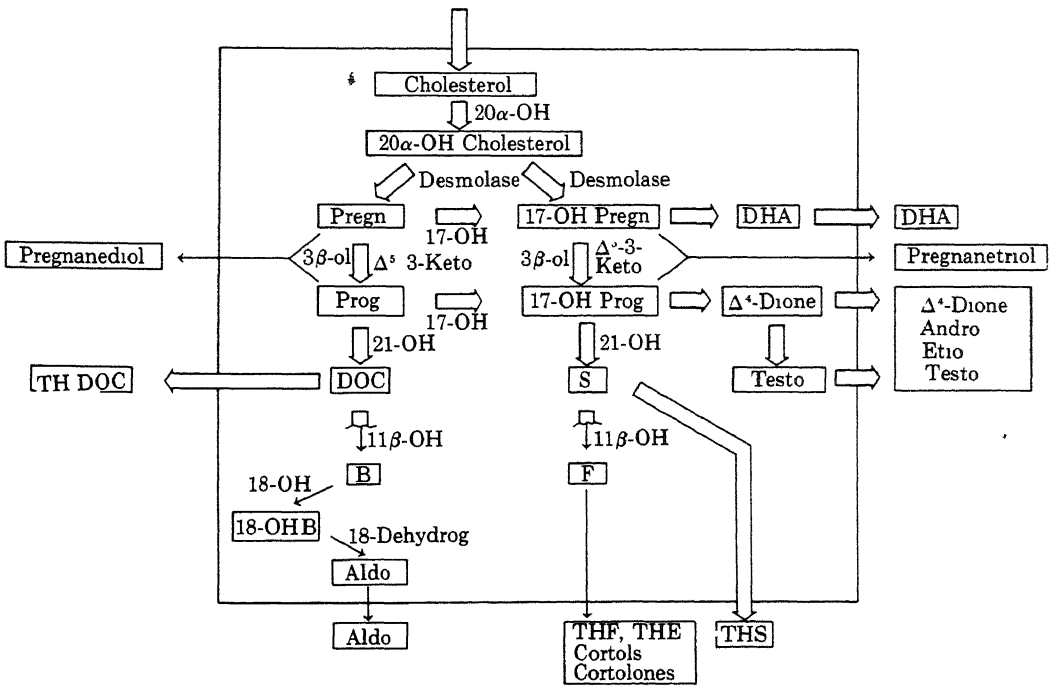

Fig 7 59 The biosynthetic defect in the hypertensive form of congenital adrenal hyperplasia caused by 11β-hydroxylase deficiency Refer to Figure 7 44 and to the text for discussion

shock Essentially no physiologically useful adrenal corticosteroids are synthesized Virilization of females is less marked than in the other congenital adrenal hyperplasias because no androgen more potent than DHA is secreted In addition, males very often have incomplete fetal genital development, with severe hypospadias Since fetal testicular androgen is required for normal male genital development, it appears that the testes share the 3β-ol dehydrogenase deficiency (Bongiovanni, 1962) These patients, if diagnosed in time, require complete steroid replacement Even then, few survive more than a month or two It is not known why these infants fail to respond to apparent adequate replacement of their missing steroid hormones

Primary Hyperaldosteronism. Autonomous hypersecretion of aldosterone by an adrenocortical tumor arising from the zona glomerulosa causes a syndrome due to pure mineralocorticoid excess (Conn, 1955) The major features of the syndrome are hypertension and hypokalemic alkalosis The hypertension is secondary to sodium retention and, possibly, to partial obliteration of the lumina of peripheral arterioles by swollen arteriolar cells These patients do not develop edema, despite the fluid retention, unless congestive heart failure occurs Hypokalemia is often mild, but may be worsened by diuretic therapy Severe hypokalemia may result in weakness, paresthesias, decreased deep tendon reflexes, cardiac arrhythmias, and even paralysis The hypokalemia interferes both with insulin secretion and with the peripheral action of insulin Carbohydrate intolerance is seen in half the patients with this syndrome The low serum potassium also interferes with renal concentrating ability, polyuria and polydipsia are the result The urine is dilute and neutral

The diagnosis is confirmed by finding of *1)* an elevated aldosterone secretion rate on a liberal salt diet (100 mEq sodium per day) which tends to suppress aldosterone secretion by increasing renal perfusion, and *2)* a suppressed plasma renin activity, even after sodium depletion (10 mEq sodium diet and sodium-wasting diuretic therapy) and during upright posture Furthermore, if balance studies are performed, it will be found that the patient is in negative potassium balance and positive sodium balance Treatment is removal of the aldosterone-secreting adrenal tumor Aldosterone antagonists, such as the spironolactones are often useful in correcting the electrolyte abnormalities and hypertension prior to surgery

Secondary Hyperaldosteronism. Hyperaldosteronism secondary to increased stimulation by the renin-angiotensin system occurs when perfusion of the kidneys, or a portion of one of them, is decreased This is a normal, homeostatic defense mechanism when effective arterial plasma volume is decreased This occurs in dehydration, hemorrhage, or shock It may also occur when intravascular fluid is lost to another compartment in the body the interstitial spaces filled with edema fluid in congestive heart failure, or the intraperitoneal space filled with ascitic fluid in hepatic cirrhosis In these situations, the renin-angiotensin-aldosterone system is functioning normally to maintain effective arterial plasma volume There is a condition, however, in which secondary aldosteronism is pathological In unilateral renal artery stenosis, the main renal artery or one of its segmental branches may become partially occluded so that the renal cortex supplied by it becomes ischemic The juxtaglomerular cells in this portion of the kidney then behave as though arterial volume were decreased, they release renin The renin-angiotensin system stimulates aldosterone secretion, and a syndrome that mimics primary aldosteronism develops It can be differentiated from primary hyperaldosteronism, however, by demonstrating both an elevated aldosterone secretion rate and an elevated plasma renin activity Assay of plasma renin activity in blood obtained by catheterizing each renal vein will reveal greatly elevated levels on the side of the stenotic artery (Michelakis et al , 1967)

Treatment is directed at relieving the stenosis by vascular surgery or, if that is not possible, removal of the ischemic kidney

The Adrenal Medulla

DEVELOPMENT AND ANATOMY

Early in fetal life, sympathetic cell precursors migrate from the neural tube which eventually differentiate into either sympathetic ganglion cells or chromaffin cells The latter cells remain closely associated with the sympathetic nervous system and form the paraganglia, the preaortic plexuses of Kuhn and

Zuckerkandl, the carotid and glomus bodies, and the adrenal medulla Similar chromaffin cells are associated with the sympathetic and parasympathetic nerves in many organs and viscera of the body While most of these cells atrophy during infancy, some survive and can be the origin of "ectopic" functional hormone-secreting tumors in later life

The medulla is composed at birth of primitive sympathetic cells which fully differentiate into chromaffin cells (pheochromocytes) during the first 3 years of life Most of the blood supply to the adrenal medulla arrives via a portal system draining the cortex Thus, the afferent blood has very high concentrations of adrenal corticosteroids In contrast to the cortex, the adrenal medulla is not essential to life, although it normally functions to release catecholamines in the "fight or flight" response to emotion or stress

BIOSYNTHESIS OF CATECHOLAMINES

The synthesis of epinephrine, the important catecholamine secreted by the adrenal medulla, is outlined in Figure 7 60 Tyrosine is derived primarily from dietary sources (Levine and Conn, 1967) The first step in the biosynthetic pathway, conversion of tyrosine to dopa, is the rate-limiting reaction (Levitt et al , 1965, Kaufman and Friedman, 1965) The reaction is catalyzed by tyrosine hydroxylase, an enzyme found only in neurectodermal tissues Tyrosine hydroxylase is inhibited by a variety of catecholamines, which thereby function as an intracellular negative feedback regulatory control on their own synthesis (Undenfriend, 1968) Dopa is converted to dopamine by L-aromatic amino acid decarboxylase, and thence to norepinephrine by dopamine β-oxidase Phenylethanolamine-N-methyl trans-

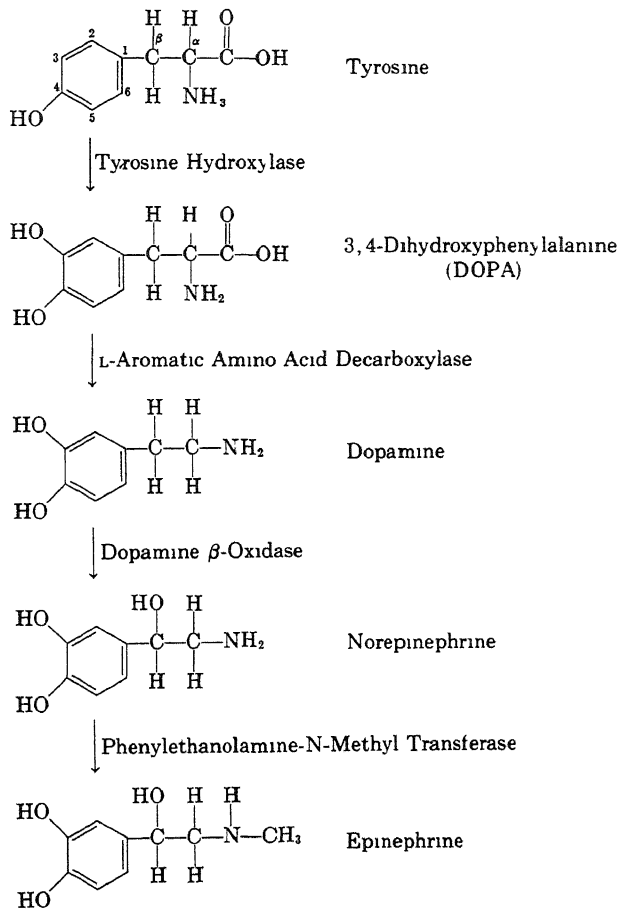

Fig 7 60 The biosynthetic pathway for conversion of tyrosine to norepinephrine and epinephrine

ferase (PNMT), the enzyme that catalyzes the conversion of norepinephrine to epinephrine, is found in significant concentrations only in the adrenal medulla This is of interest because phenylethanolamine-N-methyl transferase is induced by high concentrations of cortisol, which are found only in the portal blood draining the adrenal cortex and supplying the medulla (Wurtman and Axelrod, 1966) Thus, while other catecholamines are synthesized widely in the central nervous system and in sympathetic nerve endings, epinephrine is synthesized almost exclusively by the adrenal medulla

STORAGE AND RELEASE OF CATECHOLAMINES

Unlike the adrenocortical steroids, which are released almost as soon as they are synthesized, catecholamines are stored in the adrenal medullary cells They are held in membrane-enclosed secretory vesicles similar to those seen in the synaptic nerve endings of the sympathetic nerves They are complexed with adenosine triphosphate (1 mole of ATP for 4 moles of catecholamine) and a specific protein (MW 40,000) The vesicles also contain a Ca^{++} and Mg^{++} dependent ATPase (Kopin, 1967) The binding of the amine to the complex is moderately structure-specific and requires both the catechol configuation (Fig 7 61) and the β-hydroxyl group for maximum binding These subcellular vesicles take up epinephrine and norepinephrine by a transport process requiring energy The free catecholamine which is not taken up immediately by the vesicles is metabolized by monamine oxidase (MAO) located within the mitochondria The hormone contained within the secretory vesicle can be released in response to an appropriate stimulus which, in the case of the adrenal pheochromocyte, is acetylcholine secreted by the preganglionic nerve fibers that terminate in the medulla Other agents, such as histamine and glucagon, can stimulate epinephrine release, their physiologic importance is not clear Calcium ions enter the cell in response to acetylcholine stimulation and mediate the excitation-secretion coupling phenomenon by which a unit stimulus causes the release of a "quantum" of catecholamine The quantal release of epinephrine is due to the fact that the contents of a single secretory vesicle are extruded into the extracellular space The catecholamine, vesicle-binding protein and ATP products are released in the same ratio in which they are found in the secretory vesicle (Douglas, 1966a, 1966b, Kirschner et al , 1966) In the synapses of the sympathetic nerve cells, most of the norepinephrine released is taken up immediately by the cell and incorporated into secretory vesicles There is little evidence to suggest that this is true of the adrenal medullary pheochromocyte Presumably, most of the epinephrine is carried away either to act upon distant target tissues or to be metabolized by catechol-O-methyl transferase (Fig 7 62)

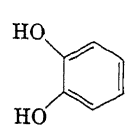

Fig 7 61 Catechol (pyrocatechin)

METABOLISM OF CATECHOLAMINES

Norepinephrine and epinephrine are metabolized by two enzymes, primarily Monamine oxidase (MAO), which is found in the mitochondria of chromaffin cells (DeLores Arnaiz and DeRobertis, 1962), deaminates the α-carbon of norepinephrine, epinephrine, and other catecholamines, such as serotonin and dopamine The free epinephrine not contained within the secretory vesicles is metabolized in situ by this enzyme Catechol-O-methyl transferase (COMT) catalyzes the transfer of the methyl group from S-adenosyl methionine to the catechol 3-hydroxyl radical and requires Mg^{++} as a cofactor (Axelrod, 1957, Wurtman, 1965) Catechol-O-methyl transferase is present in many tissues and metabolizes the circulating free catecholamines The major metabolites of epinephrine and norepinephrine are shown in Figure 7 63

ASSAY OF CATECHOLAMINES

The technique for assaying catecholamines requires that they first be extracted from the specimen either by adsorption onto aluminum hydroxide at alkaline pH, followed by elution with weak acid, or by ion exchange chromatography on acid resins They are then converted to fluorescent derivatives which can be quantitated The most commonly used method involves oxidation in weak acid to form the qui-

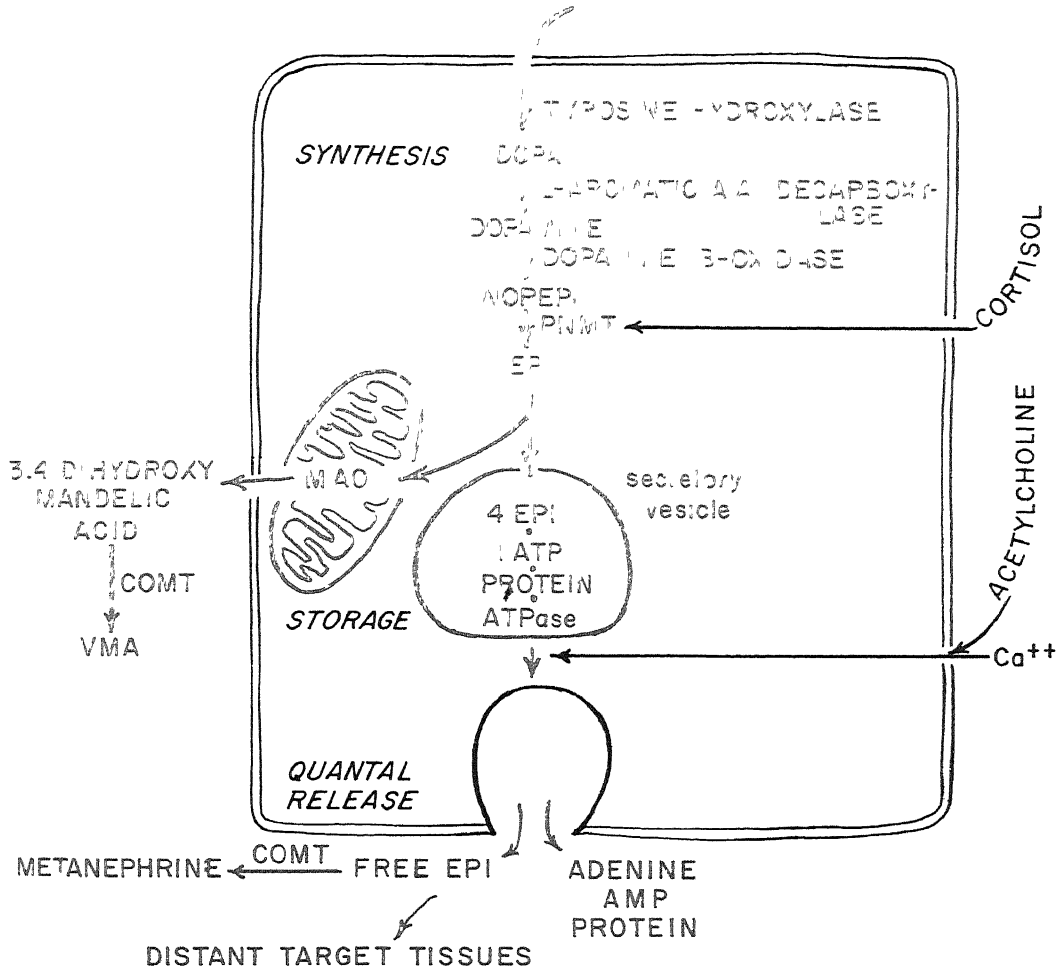

Fig 7 62 A diagrammatic representation of epinephrine synthesis storage release and metabolism by the adrenal medullary pheochromocyte See text for discussion

none derivatives (adrenochrome, noradrenochrome) with subsequent conversion, by exposure to alkaline solution, to their fluorescent trihydroxyindole derivatives (Fig 7 64) (Anton and Sayre, 1962, Haggendal, 1963) The method is quite specific, dopa and dopamine interfere somewhat, but they are usually present in only small quantities. The antihypertensive agent, α-methyl dopa, on the other hand, interferes grossly in this assay

Free or conjugated catecholamines, vanillyl mandelic acid (VMA), or total metanephrines (normetanephrine plus metanephrine) can be assayed in the urine (Page and Copeland, 1968) Free epinephrine is excreted in the amount of 20 μg or less per day The excretion of free norepinephrine, the great majority of which is released by the sympathetic nerve endings, is 80 μg or less per day The upper limits of normal for total metanephrines and VMA are 1 3 mg and 6 5 mg /day, respectively

PHYSIOLOGICAL EFFECTS OF CATECHOLAMINES

The catecholamines exert their effects on target tissues by binding to a receptor site on the cell membrane, influencing the activity of the associated enzyme, adenyl cyclase (Sutherland and Rall, 1960) Adenyl cyclase regulates the synthesis of cyclic 3′,5′-AMP Cyclic AMP is the intracellular mediator of catecholamine action The receptors have been divided into two categories by pharmacologists on the basis

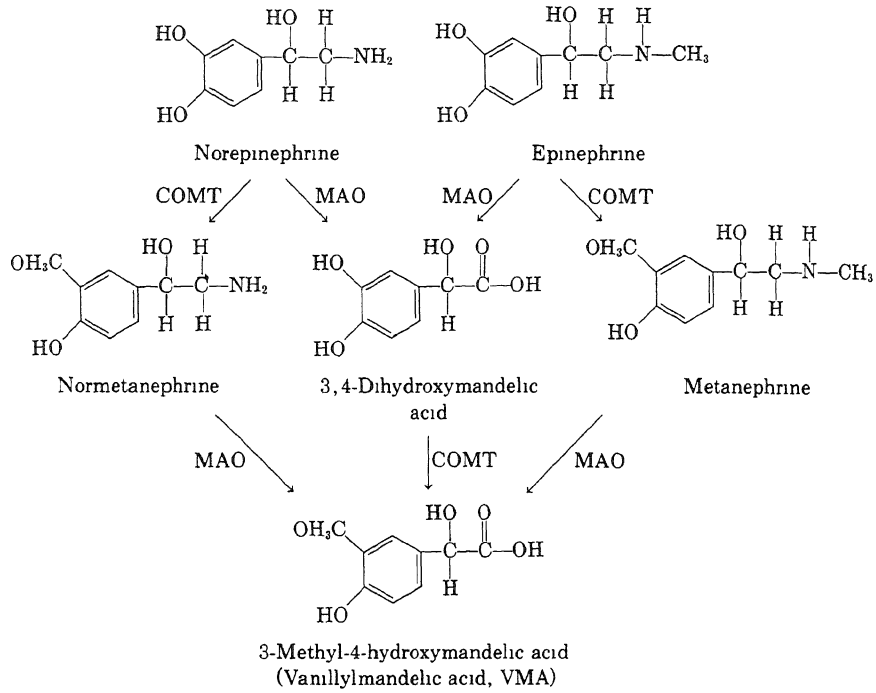

Fig 7 63 The major pathways of metabolism of norepinephrine and epinephrine Two enzymes are involved Catechol-O-methyl transferase (COMT) and monamine oxidase (MAO)

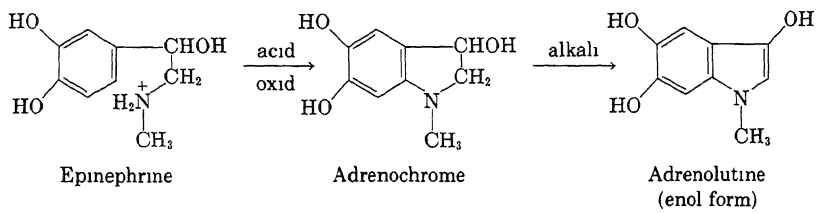

Fig 7 64 Conversion of epinephrine to adrenolutine a fluorescent trihydroxyindole in the assay of catecholamines

of the compounds that bind to the receptor sites (Ahlquist, 1948). Although there is no compelling evidence for the existence of two structurally distinct receptors, an α (vasoconstrictor) and β (vasodilator) receptors have been identified Since synthetic agents have been developed that stimulate or block only one of these types of activities, however, it has remained a useful working concept (Sutherland and Rall, 1960) There is some evidence that β-adrenergic agents increase intracellular cyclic AMP levels and that α-adrenergic agents decrease it (Abe et al, 1969b), but the exact mechanism of α-adrenergic agents is still in doubt Both norepinephrine and epinephrine have both α- and β-adrenergic activities

A list of some of the metabolic effects of catecholamines is given in Table 7 6 Catecholamines stimulate glycogenolysis and therefore have an anti-insulin effect The catecholamines stimulate the mobilization of free fatty acids from adipose tissue, skeletal muscle and myocardium in the presence of minimal concentrations of glucocorticoids, which exert a permissive effect These actions, which involve activation of adenyl cyclase, might be expected to be β-receptor activities This appears to be the case Epinephrine is more po-

Table 7 6
Some effects of catecholamines

Effector Organ	Receptor Type	Response
Eye		
Radial muscle, iris	α	Contraction (mydriasis)
Ciliary muscle	β	Relaxation for far vision
Heart		
Sinoatrial node	β	Increase in heart rate
Atrioventricular node	β	Increase in conduction velocity and shortening of functional refractory period
Atria	β	Increase in contractility
Ventricles	β	Increase in contractility and irritability
Blood vessels	α	Constriction
	β	Dilatation (predominates in skeletal muscle)
Bronchial muscle	β	Relaxation (bronchodilatation)
Gastrointestinal tract		
Motility		
Stomach	β	Decrease
Intestine	α, β	Decrease

tent than norepinephrine in producing these effects

DISORDERS OF ADRENOMEDULLARY FUNCTION PHEOCHROMOCYTOMA

Pheochromocytomas are functioning tumors, usually benign, that arise from pheochromocytes They occur most commonly in the adrenal medulla, but may arise wherever these chromaffin cells are found in the body They occasionally are familial (Page and Copeland, 1968) and may be associated with benign tumors of other endocrine glands, malignant tumors of the thyroid, and certain other conditions (von Recklinghausen's neurofibromatosis, von Hippel-Lindau's hemangioblastomatosis)

The clinical manifestations of pheochromocytoma are due to catecholamine hypersecretion and depend upon whether the tumor tends to release the catecholamines constantly or paroxysmally, and whether it secretes mostly epinephrine or norepinephrine Hypertension, usually constant but sometimes paroxysmal and associated with excessive perspiration, flushing, palpitations, and tremor, is the hallmark of the disease The patient may also have headaches, pallor, nausea, nervousness, and weakness

The diagnosis is confirmed by documenting increased excretion of catecholamines, VMA or total metanephrines in the urine If epinephrine is elevated without a parallel increase in norepinephrine, the tumor is virtually always found in the adrenal medulla of the organ of Zuckerkandl Treatment is removal of the tumor

7 / HORMONAL CONTROL OF THE PANCREATIC ISLETS

Insulin and Glucagon

Insulin and glucagon are peptide hormones which are secreted by pancreatic islet cells and exert important regulatory effects on carbohydrate, fat, and protein metabolism The discovery of insulin is closely linked with attempts to understand the nature of diabetes mellitus, a disorder which results from a relative or absolute deficiency of this hormone Studies of von Mehring and Minkowski in the late 1800's, clearly established the pancreatic origin of diabetes mellitus by showing that the disorder appeared in dogs following pancreatectomy In 1922, Banting and Best reported the isolation of an active hormonal principal, insulin, from the pancreas and were able to reverse the metabolic changes of diabetes In the early 1950's, Sanger and co-workers (Sanger, 1959) established the complete amino acid sequence of insulin This pioneering accomplishment ushered in a new era in protein chemistry and led to the equally exciting achievement of the total chemical synthesis of a biologically active protein Vasopressin and oxytocin were the first peptide hormones to be synthesized, and the list now includes insulin (Katsoyannis et al , 1964) and glucagon (Wunsch, 1967)

CHEMICAL NATURE OF INSULIN

Insulin has a molecular weight of about 6000 and consists of two polypeptide chains, A and B, which are joined at two places by disulfide bridges (—S—S—) of cystine (Fig 7 65) A third disulfide bridge within the A-chain forms an intrachain disulfide ring Similar cyclic disulfide structures are found in vasopressin and oxytocin but, as far as is known, these two posterior lobe hormones do not share any important physiological property of insulin

Insulin activity is thought to be related closely to its natural conformation or three-dimensional shape, which in turn is determined largely by its primary or amino acid structure The three-dimensional shape of insulin is stabilized by hydrogen bonding and loss of biological activity occurs when these bonds are broken (denaturation) as by excessive heat or exposure to alkali, even though there has been no alteration in amino acid structure The disulfide bridges are also important biologically and their disruption by reducing agents will result in nearly complete loss of insulin potency On the other hand, many chemical modifications of the amino acid structure of insulin have been made without significant alteration in biological activity Some of these alterations have proved to be useful in labeling insulin with radioactive markers One of the most widely used modifications at the present time is ^{125}I- or ^{131}I-labeled iodoinsulin By its use, it has been possible to measure very small concentrations of insulin in metabolic experiments either directly or by the use of radioimmunoassay procedures In addition to these man-made modifications, many natural variations in amino acid composition of native insulin have been found In a comparison of amino acid sequences among 16 or so species, variations have been found in about 60% of the amino acid residues (Smith, 1966) One unchanging feature, however, is the relative position of the disulfide bridges, and in all species of insulin thus far identified, identical numbers of amino acids are contained within the cyclic peptide in the A-chain and between the points of attachment of the disulfide bridges joining the A- and B-chains The only differences noted among the five species of mammalian insulin —beef, pork, sheep, horse, and whale—reside in the sequence of three amino acids within the A-chain ring (Smith, 1966) With the exception of guinea pig insulin which exhibits reduced biological potency in other mammals, none of these natural variations in amino acid structure is associated with alteration in biological activity. These variations do confer differences in immunologic activity, however, and it is sometimes necessary in the management

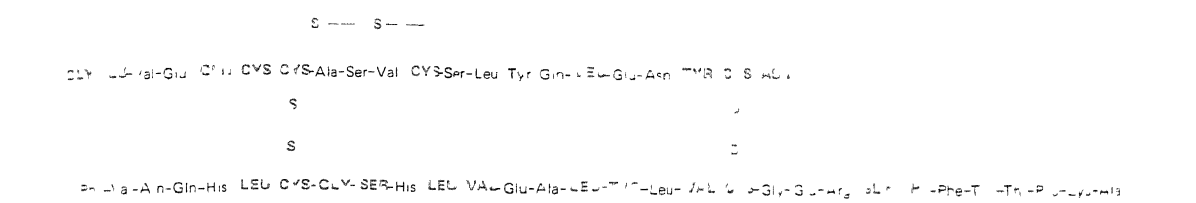

Fig 7 65 Structure of bovine insulin redrawn to illustrate the invariant amino acids (brown type) among vertebrates (Ryle et al 1955 Smith 1966)

of patients with diabetes to change the source of mammalian insulin when insulin resistance from antibodies complicates treatment

INSULIN BIOSYNTHESIS

Pancreatic Islets (Lacy, 1970) Insulin biosynthesis is the exclusive property of the β-cell of pancreatic islet tissue (Fig 7 66) In some lower vertebrates, notably certain teleosts, islet tissue is formed as a separate organ from the exocrine pancreas, but in higher forms, including all mammals, the islet cells are scattered throughout the pancreas Human pancreatic islets are characterized by the presence of four distinct cell types, each with its own unique type of secretory granules Analysis of the insulin granules indicate that the insulin molecules are packed as a structural unit giving rise to a distinct crystalline periodicity Zinc appears to be bound with this complex but its importance is still not understood The secretory mechanism of β-cells is a matter of debate While many investigators feel that the granule is released by reverse pinocytosis, a process referred to as emiocytosis, other investigators have found no evidence for fusion of the limiting membrane of secretory granules with the plasma membrane of the cell The latter would imply an intracytoplasmic dissolution of the granule and subsequent transport of insulin across the plasma membrane to the interstitial space α-cells are characterized by the presence of extremely electron opaque granules and are thoroughly documented as a site of glucagon secretion in the islet The secretory mechanism of these cells is not known Δ-cells are present in the pancreatic islets of all species studied to date and are characterized by the presence of a secretory granule that has moderate electron opacity and is extremely uniform in its ultrastructural appearance The hormones secreted by Δ-cells are not clearly established although there is some data from immunofluorescence studies suggesting that gastrin is secreted by these cells The ubiquitous fourth cell type which has been described in monkey, human, and rabbit pancreatic islets as well as the islets of some reptiles, appears to resemble some of the enterochromaffin cells of the intestinal tract

Proinsulin The amino acids in insulin are presumed to be assembled in peptide linkage on ribosomes in the same way that other peptides are formed and the reader is referred to Chapter 13 for a description of this process While our knowledge of protein synthesis is able to explain the formation of single chain peptides, the question as to how the separate A- and B-chains are combined was a mystery until recently It is known from laboratory experiments that the recombination of separated A- and B-chains is often extremely inefficient, since chains often join together in a haphazard fashion producing biologically inactive material The problem was solved by the discovery of proinsulin (Steiner et al, 1969) As shown in Figure 7 67, proinsulin is a single-chain polypeptide comprising both the A- and B-chains of active insulin with a connecting peptide of 30 amino acids residues The connecting or C-peptide apparently serves to place the A- and B-chains in proper position for the establishment of the disulfide bridges When the bridges are deliberately broken in samples of proinsulin, they may be united efficiently without any resultant loss of biological activity The C-peptide is removed intracellularly by the action of a trypsin-like enzyme shortly after the synthesis of proinsulin Insulin is then stored within membrane-bound granules prior to secretion as described above This method of activation by enzymatic digestion of a portion of the parent peptide chain is analogous to trypsin activation of a number of pancreatic digestive enzymes which are secreted as inactive forms

Although most insulin is activated within the β-cell before secretion, about 5% of the

insulin in blood exists as proinsulin Proinsulin has very little biologic activity and there is no evidence that it can be converted to insulin outside the pancreas The discovery of this new step in the biosynthesis of insulin raises the possibility that some forms of diabetes can generate from either genetic alterations in the synthesis of the C-peptide or in the mechanism of activation of insulin

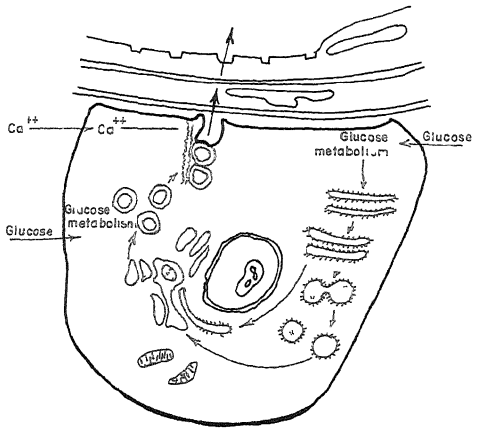

Fig 7 66 Proposed model of β cell secretion Glucose metabolism signals the initiation of proinsulin synthesis in the endoplasmic reticulum Proinsulin is either transferred directly to the Golgi complex or via saccular forms of the endoplasmic reticulum The site of transformation of proinsulin to insulin probably occurs in the Golgi complex and intermediate granules may be present in the sacs of the Golgi apparatus The mature β granules are encased in smooth membranous sacs and discharged into the cytoplasm The granules become associated with the microtubular-microfilamentous system of the β cell calcium influx is produced by glucose metabolism and the calcium ions produce contraction or a change in physical conformation of the microtubular-microfilamentous system with resultant displacement of the granules to the surface of the cell where they are liberated by emiocytosis (From Lacy 1970)

CHEMICAL NATURE AND BIOSYNTHESIS OF GLUCAGON

Glucagon is a single-chain peptide with a molecular weight of about 3500 (Fig 7 68) It is difficult to separate from insulin and is a common contaminant of many commercial preparations of insulin The discovery of glucagon was the result of attempts to understand the nature of a transient hyperglycemia which was noted with many early preparations of insulin Subsequent isolation and characterization of a material, which was known as hyperglycemic factor, revealed a discrete small protein which promoted hepatic glycogenolysis in extremely small concentrations The peptide has 29 amino acid residues and its structure has been confirmed by total chemical synthesis (Wunsch, 1967)

Glucagon is synthesized and secreted by the α-cells of the pancreatic islets Small amounts have also been extracted from gastric and intestinal mucosa of a number of animal species (Marks and Samols, 1970) The nature and properties of gut or enteroglucagon are not well understood, but there is considerable evidence that this latter factor or factors may be of importance in the regulation of insulin se-

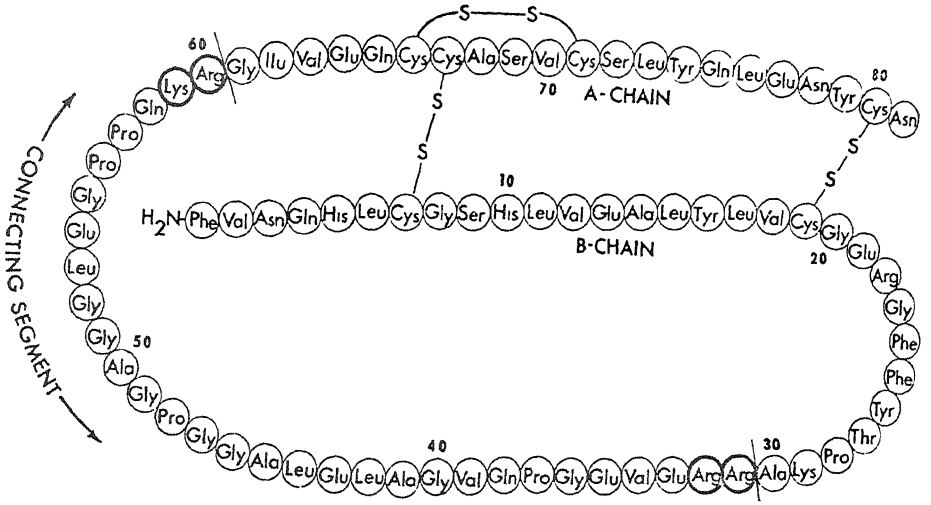

Fig 7 67 Primary structure of beef proinsulin Numbers above sequence indicate position with respect to amino-terminus of the B-chain segment which is amino-terminal in proinsulin (From Nolan et al 1971)

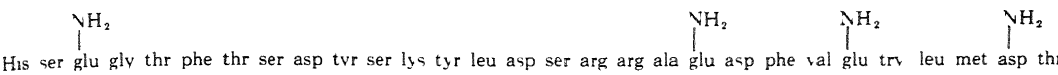

Fig 7 68 Structure of glucagon (From Bromer et al 1957)

cretion Present evidence indicates that there are at least two fractions of immunoreactive glucagon in the gut one has a molecular weight twice that of pancreatic glucagon, another, comprising nearly half of the immunoreactivity, has a molecular size comparable to pancreatic glucagon

MECHANISM OF INSULIN AND GLUCAGON SECRETION (Meyhew et al, 1969)

Insulin (Table 7 7) In a classic study with the perfused rat pancreas, Anderson and Long (1948) clearly demonstrated the primary role of glucose in stimulating insulin secretion Since the response was obtained with the isolated pancreas, it was apparent that an intact nerve supply was not absolutely required Development of improved electron microscopic methods and sensitive immunoassay techniques for the measurement of insulin have greatly stimulated research in this area As a result, a number of additional factors have been shown to be of importance in modulating insulin secretion

As was mentioned in an earlier discussion of islet cells, some investigators have observed striking morphologic changes in β-cell granules following the stimulation of insulin secretion The picture that is presented is one in which insulin granules which are scattered throughout the cytoplasm move toward the outer membrane of the cell The membrane surrounding the granules fuses with the cell membrane, and, at the point of fusion, a hole appears through which the granule is extruded This process, known as emiocytosis, so distorts the cell membrane as to give the appearance of microvilli which are also characteristic of membranes from absorptive cells

With the isolated pancreas, stimulation of insulin secretion by glucose occurs in two distinct phases (Grodsky et al, 1970, Levine, 1970) Immediately after the addition of glucose, insulin is rapidly released in a burst of secretory activity, the rate of secretion then falls With maximal stimulation, only about 2% of the total quantity of insulin present in the pancreas is released With continued application of the glucose stimulus, a lower rate of secretion (Phase II) is maintained for longer periods of time Inhibitors of protein synthesis, such as puromycin, will reduce the second phase and for this reason this phase is thought to be dependent in part, at least, on the release of newly synthesized insulin

Table 7 7
Factors stimulating or inhibiting insulin secretion

Stimulants	Inhibitors
Glucose	2-Deoxyglucose
Mannose	Mannoheptulose
Arginine	Epinephrine
Leucine	
β ketoacids	
Secretin	
Pancreozymin	
Glucagon	
Cyclic AMP	
Theophylline	
Sulfonylureas	

Modified from Levine, 1970

The mechanism of the stimulation of insulin secretion by glucose is not known, but it appears to be closely related, in some way to the utilization of glucose (Randle et al, 1968) Mannose, which can be utilized by the β-cell, will substitute for glucose, but nonmetabolizable sugars such as galactose or D-xylose fail to stimulate secretion Furthermore, interference with glucose metabolism by the addition of mannoheptulose, a seven-carbon sugar, or 2-deoxyglucose, will also block the stimulatory effects of added glucose or mannose From present information, it would appear that the signal generated by glucose for the release of insulin is derived from some intermediate in the pathway of glucose metabolism beyond glucose-6-phosphate

In addition to glucose, amino acids have also been shown to evoke insulin release Ingestion of protein or the infusion of a mixture of amino acids in vivo will cause a substantial increase in levels of plasma insulin which are seemingly unrelated to the slight elevation in glucose that accompanies the infusion The most potent effects are produced by arginine and lysine, although other amino acids, in-

cluding leucine, are effective Christensen (1971) has recently shown that certain amino acid analogues which are transported but not metabolized by the B-cell will also evoke a secretory response The mechanism of the amino acid effect is not understood The ketone bodies, β-OH-butyric and acetoacetic acids, have also been reported to stimulate insulin secretion (Madison et al , 1964)

Cyclic Adenosine Monophosphate (Cyclic AMP). Several lines of evidence strongly implicate cyclic AMP in some fundamental way in the mechanism of secretion Glucagon has been shown to increase cyclic AMP levels in islet tissue and to stimulate insulin synthesis and release from the β-cell (Table 7 8) The stimulatory effect is augmented by agents such as theophylline which inhibit phosphodiesterase, the enzyme responsible for cyclic AMP degradation Moreover, the administration of the cyclic nucleotide itself evokes secretion Analogous effects of cyclic AMP have been noted in the thyroid and the anterior pituitary As in many other secretory cells, the stimulus to secretion appears to be strongly dependent on Ca^{++}, K^{+} is also required At first, investigators were puzzled by the fact that epinephrine either failed to stimulate secretion or exerted an inhibitory effect in the presence of glucose It is now known that epinephrine attaches itself to an α-adrenergic receptor site, which inhibits cyclic AMP formation When an α-adrenergic blocking agent, such as phentolamine, is added, epinephrine exerts its effects via the β-adrenergic site which is stimulatory to cyclic AMP formation and insulin secretion (Table 7 8)

In addition to the effects of glucagon and epinephrine, the intestinal hormones, secretin and pancreozymin, are known to stimulate insulin secretion (Marks and Samols, 1970) The role of these hormones in modulating the insulinotropic effects of glucose and glucagon will be discussed below Tolbutamide, a sulfonylurea, which has been used in the treatment of maturity-onset diabetes, is an effective stimulus of insulin secretion This agent apparently works independent of the stimulation by glucose since mannoheptulose, which blocks the effect of glucose on insulin release, fails to inhibit the tolbutamide effect

Glucagon Secretion (Marks and Samols, 1970) Owing to the presence of interfering and cross-reacting materials in plasma, glucagon has been more difficult to measure by immunologic techniques than has insulin For this reason, comparatively little information is available either on the mechanism of secretion or the nature of agents that stimulate or inhibit release Severe hypoglycemia that is induced by phloridzin in dogs has been shown to promote glucagon secretion However, glucagon secretion is either unaffected or decreased somewhat with prolonged fasting While high glucose concentrations in the blood perfusing the pancreas will apparently suppress glucagon secretion, moderate degrees of hypoglycemia are seemingly not a stimulus to glucagon secretion Fasting may indirectly promote secretion by other mechanisms Both pancreozymin and amino acids have been shown to exert potent stimulatory effects in vitro

Secretion under Physiological Conditions. There is general agreement that glucose is the

From Turtle and Kipnis, 1967

primary agent which regulates insulin secretion Plasma insulin levels increase promptly in response to hyperglycemia, and secretion is diminished during hypoglycemia and fasting It would appear that epinephrine, which may be released in response to hypoglycemia, is able to exert a restraining effect on insulin secretion

It has long been observed that the magnitude of the hyperglycemia following oral glucose is appreciably smaller than that resulting from a comparable quantity of glucose administered intravenously (Fig 7 69) This difference has been attributed to an augmentation of insulin secretion by intestinal factors which are mobilized during the absorption of glucose in the gut These factors have not been identified but intestinal glucagon is a possibility Both secretin and pancreozymin are known to stimulate insulin secretion, but it is unlikely that the elaboration of these intestinal hormones is significantly increased by the absorption of glucose Other foodstuffs, such as amino acids and fat, will evoke pancreozymin secretion, which in turn may stimulate the release of insulin Although this sequence would not explain the increased release of insulin in response to the absorption of glucose, it does suggest a possible mechanism whereby the process of digestion can promote insulin secretion in anticipation of increased blood levels of substrates

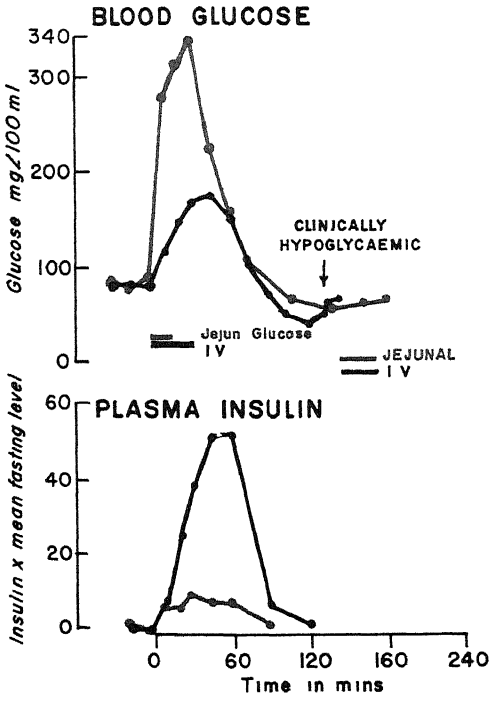

Fig 7 69 Blood glucose and plasma insulin response to rapid infusion of 60 g of glucose either intravenously or intrajejunally to a normal subject (From McIntyre et al, 1965)

FATE OF INSULIN AND GLUCAGON AND REACTION WITH SYSTEMIC TISSUES

Measurements of plasma insulin turnover by disappearance of ^{131}I insulin or immunoreactive insulin has shown that insulin is rapidly removed from plasma by the body tissues (Williams, 1968) The half-life of plasma insulin is 10 min or less which makes it necessary for the pancreas to secrete insulin steadily in order to maintain levels that are sufficient for optimal metabolic performance Little or no insulin is taken up by the brain or red cells, but the liver, kidneys, and skeletal muscle remove almost all of the insulin that is secreted Very little is excreted in the urine The relative affinity of the tissues for insulin appears to bear no relationship to the biological effects of the hormone on the tissues, instead, the very large uptape of circulating insulin by the liver and kidneys is thought to be primarily related to the need of the body to degrade insulin This function facilitates regulation of plasma insulin by providing a means to decrease insulin concentrations when insulin secretion is cut off Although skeletal muscle is one of the important sites of insulin action, the removal of plasma insulin per unit mass of tissue is relatively small as compared with either the kidney or the liver However, owing to the large mass of muscle, the total quantity of insulin removed is similar to that degraded by the kidneys or the liver

Knowledge of the nature and location of insulin-binding sites on cells is of great importance to further understanding of the mechanism of insulin action In general, the binding of insulin appears to serve at least two functions The first involves the attachment of the hormone to receptor sites which directly or indirectly alter the rates of metabolic functions The nature of the metabolic effect depends on the particular tissue involved, as well as its metabolic state. It is clear from recent studies by Cuatrecasas (1969) with isolated fat cells that most of the well-known effects of insulin in that tissue can be mediated from

receptor sites on the cell surface In these particular experiments, the insulin that was used was chemically attached by the N-terminal amino acid of the B-chain to a very large agarose polymer particle The modified insulin was reacted with isolated fat cells and found to retain all of the biological activity of native insulin Since the large size of the agarose prevented penetration of insulin into the interior of the cell, it appeared to act through a receptor site that was on or close to the outer membrane of the cell While this experiment does not eliminate the possibility that there are other receptor sites within cells, it is in keeping with a large body of evidence indicating that many of the metabolic effects, including those concerned with membrane transport, are mediated at sites on the cell membrane

The second function served by insulin binding is the destruction of insulin As mentioned above, the necessity for such a mechanism becomes clear when one considers that metabolic regulation is a bidirectional process requiring downward as well as upward adjustments in hormone levels The continuous secretion of insulin by the pancreas, which in the human averages 1 to 2 mg /day, is determined in part by the rate of destruction of insulin in peripheral tissues All tissues that respond to insulin appear to be capable of degrading insulin to some extent The converse is not true, however, since the kidney, which is apparently unaffected by insulin, does bind and degrade insulin to a considerable extent The process of insulin degradation has been studied extensively in liver, and studies employing the isolated perfused liver have shown that the capacity for destroying insulin far exceeds the limits of the tissue to respond to the metabolic effects of the hormone This indicates that sites of insulin inactivation may differ from those concerned with metabolic regulation Little is known of the insulin-inactivating mechanism except that the hormone is known to be completely broken down to its constituent amino acids An enzyme, insulin-glutathione transhydrogenase, in liver has been found to catalyze the reductive cleavage of the disulfide bridges in insulin (Tomizawa, 1962, Katzen et al., 1963) For a time it was thought that this enzyme played an important role in insulin inactivation Results of more recent studies, however, make it doubtful that this enzyme plays a specific role in insulin destruction

The question whether binding of insulin involves a covalent bonding between the hormone and reactive groups on the receptor site has been raised One possibility would be the breaking of the disulfide bridges and reattachment of insulin to free SH-groups on the receptor sites Preliminary attempts to study this possibility have indicated that bonding of this type may occur but the evidence is far from conclusive The well-known fact that the metabolic effects of insulin can be promptly stopped by the addition of insulin-binding antibody indicates that the attachment mechanism is readily reversible

Systemic Effects of Insulin and Glucagon

INSULIN

Insulin exerts a variety of metabolic effects on many tissues of the body but its fundamental mode of action or actions at the cellular level is unknown Hormonally-responsive tissues include muscle (skeletal and heart), adipose tissue, liver, white cells, mammary glands, bone, skin, lens, pituitary, peripheral nerve, and aorta Brain, gonads, and red cells are notable for their lack of responsiveness to insulin, the question as to whether the kidney is responsive is a matter of debate The failure of insulin to cross the blood-brain barrier may explain the lack of responsiveness by the brain, but there is no explanation for the other insulin-insensitive tissues except for the apparent absence of specific receptor sites Since metabolic responses to insulin differ among the various tissues according to the functional differentiation of the cells, the role of insulin in regulating specific metabolic processes will be discussed in chapters dealing with these processes

One of the primary roles of insulin in the overall economy of the body is to regulate uptake, storage, and release of important circulating substrates—glucose, amino acids, and fatty acids The levels of these constituents in plasma reflect the sum of their individual rates of production and utilization by the body tissues Many of these processes are strongly influenced by insulin and glucagon (see chapt 10 through 13) Inasmuch as the secretion of in-

sulin and glucagon is in turn affected by the level of circulating glucose and amino acids (and possibly ketone bodies), the dominant pattern of regulation appears to be of the feedback type This is now well-documented in the case of regulation of plasma levels of glucose and a similar pattern for regulation of plasma amino acid levels is now beginning to emerge

Glucose Regulation. Blood glucose is maintained within reasonably narrow limits under a wide variety of metabolic conditions and, even with prolonged fasting, values seldom fall below 60 mg /100 ml of blood This regulation requires the coordinated control of metabolic processes in many tissues in order to balance glucose utilization against glucose production Many tissues, such as skeletal muscle, brain, heart, and adipose tissue consume sizeable quantities of glucose, but only the liver is capable of releasing sufficient amounts into the circulation during the postabsorptive period to balance the rates of utilization The vital role of the liver as a source of glucose was shown several years ago by Mann and Magath (1924) who studied the effects of hepatectomy in dog Removal of the liver resulted in hypoglycemia which invariably proves fatal unless glucose is administered Although glucose is stored in the form of glycogen in muscle, absence of glucose-6-phosphatase prevents its release as free glucose into blood The solution to this impasse is conversion of glucose to lactate by glycolysis in muscle, but in the absence of liver, there is little reconversion of the lactate to glucose, a process known as gluconeogenesis While the kidney possesses the enzymes that are required for gluconeogenesis, the quantitative capacity is not sufficient to maintain normal glucose levels in the absence of liver

The two major pathways of glucose formation in liver, viz , glycogenolysis and gluconeogenesis, are regulated by insulin When rates of glucose formation are increased by agents such as glucagon or epinephrine, which increase tissue levels of cyclic AMP, the addition of insulin exerts a strong inhibitory effect on glucose formation and release from the liver, presumably by its effect to reduce tissue levels of cyclic AMP (chap 12) In addition to these hormonal factors, blood glucose itself strongly inhibits hepatic glucose release and stimulates its uptake by effects which are exerted predominantly on glycogen metabolism Attempts to demonstrate effects of insulin on hepatic glucose production in vivo have been only partially successful due to the fact that an effect of insulin to reduce glucose output may be masked by an opposite effect of the hypoglycemia to increase glucose output (deBodo et al , 1963) Since the effect of insulin to lower blood glucose can be attributed to stimulation of glucose uptake by muscle and adipose tissue, the role of the liver in glucose regulation was not readily recognized Direct measurements of hepatic glucose output during insulin hypoglycemia generally have shown that output remains unchanged If, however, glucose is administered with insulin in amounts sufficient to prevent the hypoglycemia, hepatic glucose output is significantly reduced One may deduce from these findings that the failure of the liver to alter glucose release during insulin-induced hypoglycemia represents a very strong effect of insulin to restrain glucose output By contrast, the effect of agents such as phloridzin, which can reduce blood glucose by blocking the reabsorption of glucose in the renal tubule, evokes a large increase in hepatic glucose output An acute deficiency of insulin produced in the rat by administration of anti-insulin serum or mannoheptulose is associated with an immediate increase in hepatic glucose release and a rise in blood glucose which reaches a new steady state In this situation, reduction in circulating insulin will not reduce the actual uptake of glucose by muscle and other peripheral tissues since the level of glucose also increases Thus, the upward or downward adjustment in the level of insulin results in significant changes in the steady-state levels of blood glucose with only temporary alterations in glucose utilization and production

In the human, as opposed to the rat liver, glycogen is comparatively stable and is not depleted readily for glucose production during the postabsorptive period Most of the glucose that is produced by liver under these conditions is derived by gluconeogenesis (see chap 12) Approximately 20% of the glucose which is produced in this way is synthesized from lactate derived by glycolysis in the red cell, skeletal muscle, and other tissues This fraction may be thought of as a pool of carbon which is continuously recycled through the glycolytic and gluconeogenic pathways However, a major fraction of the glucose that is released is oxidized to CO_2 or utilized for lipogenesis and

other synthetic reactions Since this carbon cannot reappear as glucose, it must be replaced by carbon from other sources Amino acids from the breakdown of tissue protein contributes the largest fraction of carbon for gluconeogenesis, glycerol derived from the hydrolysis of esterified fatty acids also makes a significant contribution During the immediate postabsorptive period and during short periods of fasting, the brain is known to subsist entirely on glucose as a source of fuel By contrast, such tissues as muscle oxidize fatty acids and ketone bodies in preference to glucose Thus, there appears to be an absolute requirement for new glucose synthesis based on the metabolic needs of the central nervous system During prolonged fasting, the brain can oxidize ketone bodies that are derived from the breakdown of fatty acids (Cahill et al , 1970) This slower adaptive response provides an additional safeguard against the ultimate depletion of gluconeogenic reserve

The necessity for restocking carbon stores presents itself at intervals and is signaled by the awareness of hunger The metabolic events leading to the repletion of stores are initiated by the ingestion of food Insulin secretion increases in response to the rise in blood glucose and possibly also to the increased elaboration of intestinal hormones, such as enteroglucagon and pancreozymin With increased rates of insulin secretion and absorption of glucose and amino acids, levels of glycogen and protein increase to replace deficits that were incurred during the previous postabsorptive period The largest changes in carbon stores per unit of organ weight occur in liver, corresponding changes in skeletal muscle are far smaller by comparison At the same time, fat stores in adipose tissue are repleted The extent to which the glycogen deposition is the result of diminished rates of glycogenolysis as opposed to the stimulation of glycogen synthesis is not established with certainty, but it is likely that both mechanisms operate Insulin has been shown to stimulate glycogen synthesis in liver of alloxan diabetic rats (Steiner and King, 1964) Recent studies indicate that acetylcholine or electrical stimulation of the vagus nerve may also potentiate glycogen synthesis in rat liver and that this cholinergic effect may be of importance in the regeneration of fuel stores during feeding

Amino Acids. The role of insulin in the regulation of blood levels of amino acids is not as well-documented as in the case of glucose Certain features, however, are now emerging which suggest that a similar type of control exists It has long been known that the injection of insulin will promptly decrease blood amino acid levels in vivo Such an effect could be mediated by one or more of the following possible responses to insulin which have been demonstrated experimentally in isolated tissues *1*) increased membrane transport of certain amino acids in muscle, 2) increased incorporation of amino acids into muscle, and possibly liver protein, and *3*) decreased proteolysis in liver and muscle Amino acids as well as insulin appear to exert any inhibitory effect on proteolysis in the liver and muscle, in addition to potentiating protein synthesis In studies with the isolated perfused liver, net changes in liver protein breakdown can be followed by the release of valine since the latter is not metabolized significantly by liver Some inhibitory effects of infused insulin and amino acids on net valine release under these conditions are shown in Figure 7 70 Since amino acids have been shown to stimulate insulin secretion in the isolated pancreas or in vivo

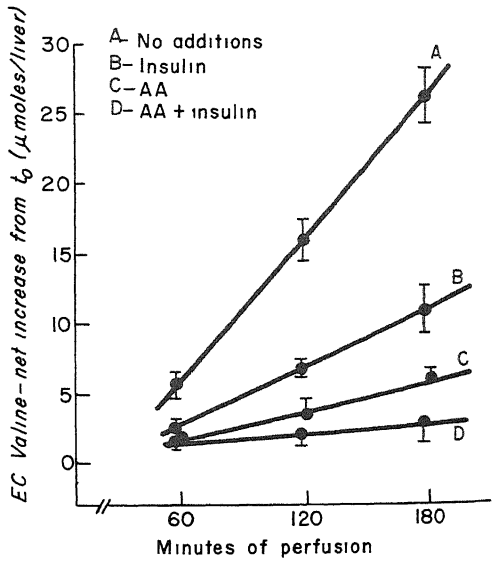

Fig 7 70 Effects of insulin and amino acid infusions on the accumulation of extracellular valine during perfusion of livers from nonfasted rats weighing about 125 g Insulin and an amino acid mixture containing glutamic acid lysine histidine arginine aspartic acid glycine proline, alanine serine cysteine methionine threonine phenylalanine and tryptophan were infused as indicated (From Mortimore 1971)

when administered either orally or intravenously, there is a strong possibility that blood amino acid levels are regulated by a feedback mechanism analogous to that previously described for glucose Much work remains to be done before such a possibility is established, but the need for amino acid regulation is clearly evident from the point of view of providing steady-state concentrations of free amino acids for protein synthesis and gluconeogenesis during the postabsorptive state

GLUCAGON

The action of glucagon on the regulation of circulating substrates is limited mainly to the liver where it is known to exert strong effects to promote glycogenolysis (and to inhibit glycogen synthesis), gluconeogenesis, lipolysis, and ureogenesis We have mentioned earlier its potentiating effect on insulin secretion by the β-cell Glucagon is known to stimulate lipolysis in adipose tissue, but the physiological importance of this effect is still a matter of debate (see chap 11) As far as it is known, glucagon exerts no effects in skeletal muscle, although it is capable of promoting glycogenolysis in the heart where it also exerts a strong inotropic effect

In liver all of the known effects of glucagon can be attributed to its primary action in stimulating the biosynthesis of cyclic AMP Under the influence of glucagon, processes concerned with glucose formation are accelerated, thus increasing rates of glucose output by the liver In some avian and amphibian species, glucagon appears to be a dominant factor in glucose regulation and pancreatectomy in these animals results in hypoglycemia rather than hyperglycemia In mammals, however, the stimulatory effects of glucagon (and catecholamines) are normally suppressed by insulin Studies employing the isolated perfused rat liver, a preparation which is devoid of most extrinsic influences, indicate that some continuous stimulation of glucose release by glucagon or catecholamines is required for insulin to exert its inhibitory effects (Fig 7 71) The present view is consistent with the notion that insulin (and glucose) are responsible for much of the moment-to-moment regulation of glucose output by the liver, the magnitude of this regulation, however, is set by a more "tonic" influence of glucagon or other agents to maintain adequate levels of tissue cyclic AMP This

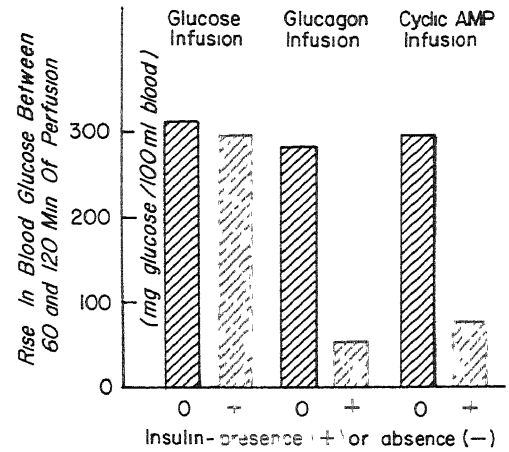

Fig 7 71 Effect of insulin on hepatic glucose production Livers were obtained from nonfasted rats All additions were made by infusion into the medium after a 60-min period of equilibration (Modified from Glinsmann and Mortimore 1968)

notion is also compatible with what is presently known of the regulation of insulin and glucagon secretion Thus, while insulin secretion is sensitive to small fluctuations in blood glucose, glucagon levels are comparatively stable and are affected only by more extensive deviations in glucose concentration

Glucagon is also a potent stimulator of ureogenesis, an effect which has been demonstrated both in vivo and in vitro The effect is closely linked with the stimulation of gluconeogenesis and increased amino acid oxidation (chap 12) Net protein breakdown in liver is also increased by glucagon but it is not known whether the effect is primarily to stimulate proteolysis or to inhibit protein synthesis With regard to the interaction between insulin and glucagon on regulation of amino acid metabolism, it is clear that, in contrast to the regulation of glucose, insulin is able to inhibit the release of amino acids from liver in vitro in the absence of any added glucagon

Physiological Aspects of Insulin Deficiency

INSULIN ANTAGONISTS

There are a number of factors of physiological importance whose actions, in general, are opposite to those of insulin One of these, glucagon, has been discussed, the others, epinephrine, glucocorticoids, growth hormone, and

fatty acids, are discussed below Normally, the effects of these agents are well-integrated with those of insulin However, when one or more of these antagonists is greatly increased or decreased in amount, then the effectiveness of insulin will be decreased or increased accordingly, giving rise to significant alterations in metabolic regulation

Epinephrine. Epinephrine, by its action to increase cyclic AMP, is similar to glucagon Its effects are more widespread, however, and in addition to liver, tissues such as muscle and adipose tissue are highly responsive Of all the known physiological antagonists, it is perhaps the most rapidly acting In fight-or-flight responses, the release of epinephrine or related catecholamines into plasma or at nerve-endings promotes rapid glycogenolysis in liver and muscle and stimulates lipolysis in adipose tissue and gluconeogenesis in liver Owing to the increased levels of fatty acids in plasma, glucose utilization in muscle and other peripheral tissues will be reduced Blood glucose increases rapidly, presumably to ensure adequate energy-yielding substrate for use by the central nervous system, the rise in free fatty acids provides an abundant source of fuel for oxidative processes in muscle

Glucocorticoids. Adrenal cortical steroids, such as cortisol, are potent catabolic agents which exert widespread effects in nearly all tissues of the body They play important roles in promoting lipolysis and gluconeogenesis and in the latter process, for example, steroids are responsible for the maintenance of much of the enzyme machinery in the liver In fact, the stimulating effect of glucagon on gluconeogenesis cannot be expressed in the absence of glucocorticoids (chap 12) In adrenal cortical insufficiency, the ability of the liver to mobilize glucose during fasting is limited, a situation which may lead to fatal hypoglycemia The opposite extreme is seen in instances of chronic glucocorticoid excess, where excessive rates of proteolysis and gluconeogenesis lead to nitrogen depletion Since insulin is relatively ineffective in restraining these alterations, overproduction of glucose coupled with its decreased utilization in systemic tissues gives rise to moderate hyperglycemia The pancreatic islets will be stimulated to secrete insulin in excessive amounts In patients with early diabetes the secretory capacity of the islets is limited and severe clinical diabetes may result

Growth Hormone In addition to anabolic activity, growth hormone has long been known to be diabetogenic (chap 13) The acute metabolic effects of growth hormone simulate those of insulin, but they are transient and the continued administration of this agent, experimentally, has been shown to produce hyperglycemia, degenerative changes in the β-cells of the pancreatic islets, and eventually permanent diabetes in some mammalian species The initial hyperglycemia is associated with striking increases in plasma insulin, a fact which suggests that part of the diabetogenic mechanism of growth hormone may involve the antagonism of insulin at effector sites in peripheral tissues, a situation which could bring about a chronic overproduction of insulin and eventual exhaustion of the β-cell There is also evidence that growth hormone may stimulate hypersecretion of the β-cell directly The marked amelioration of diabetes produced by hypophysectomy that was first described by Houssay and Biasotti (1931) can be attributed in part to the loss of this growth hormone effect The loss of adrenocorticotrophic hormone (ACTH) and diminished secretion of glucocorticoids also contribute to the amelioration

Effect of Fatty Acids. Fatty acids and ketone bodies are known to be utilized by skeletal muscle and heart in preference to glucose as an oxidizable substrate (chap 10) In situations where lipolysis is accelerated, fatty acid levels in plasma are increased and rates of glucose phosphorylation in muscle will decrease Thus, the effectiveness of insulin in regulating glucose utilization will be diminished This fatty acid effect is thought to account in part for the glucose intolerance and insulin resistance seen in fasting and certain forms of diabetes where the breakdown of fat stores is a dominant feature Whether or not it accounts for the insulin resistance seen in obesity has not been established

Antagonism by Insulin-Binding Antibodies. Insulin resistance from the development of insulin-binding antibodies is not infrequently encountered in diabetic patients taking insulin Antibodies develop in response to the injection of foreign protein, in this case from another mammalian species, and the effect is to inactive large quantities of the in-

jected insulin Treatment involves changing to an insulin preparation from an animal source which does not cross-react immunologically

DIABETES MELLITUS
(Camerini-Davalos and Cole 1970)

In the majority of instances the cause of this disorder is a genetic defect in insulin secretion by the β-cell The expression of this defect ranges from minimal in the case of pre- or early diabetes to an absolute insulin deficiency seen in severe juvenile diabetes In most cases of clinically recognized diabetes, the defect falls somewhere between the two extremes and the metabolic consequences are of moderate severity Since under normal conditions the amount of insulin secreted by the β-cell represents only a small fraction of its maximal secretory capacity, diabetes is not ordinarily manifested until most of the secretory reserve is lost It should be emphasized, however, that when insulin antagonists are present, as with stress-induced glucocorticoid secretion, the need for insulin may exceed the existing secretory capacity and the metabolic consequences of severe insulin lack will often appear

The question has been raised as to whether certain forms of maturity-onset diabetes, often associated with obesity, are primarily the result of an acquired resistance to insulin since in some instances plasma insulin values have been found to be increased and the insulin response to oral glucose exaggerated More recent studies, however, indicate that the increase in insulin resistance associated with obesity is not directly linked with an inherent defect in the ability of the B-cell to secrete insulin Thus, while the insulin resistance associated with obesity may act like growth hormone or fatty acids in antagonizing the effects of insulin, the phenomenon may or may not be associated with a genetic defect in insulin secretion

EFFECTS OF ABSOLUTE INSULIN DEFICIENCY— KETOACIDOSIS

With the complete loss of insulin effectiveness, a series of metabolic derangements takes place which eventually lead to ketoacidosis Since the forces which stimulate lipolysis and gluconeogenesis are unrestrained in the absence of insulin, the rates of these processes will rapidly increase, resulting in high levels of glucose and free fatty acids in plasma The breakdown of protein in liver and muscle will increase, thus providing a steady source of carbon for gluconeogenesis Since the quantity of free fatty acids presented to the liver will greatly exceed and capacity of liver to oxidize these substrates to CO_2, fatty acid oxidation will proceed only through β-oxidation and the partially oxidized products will accumulate as ketone bodies, β-OH-butyric acid, acetoacetic acid, and acetone These will spill into the blood where the concentrations may reach values as high as 90 mg /100 ml of plasma Since β-OH-butyric and acetoacetic acids are moderately strong, blood pH will drop and a state of metabolic acidosis will ensue Owing to the extreme hyperglycemia which may reach values as high as 400 to 800 mg /100 ml of blood, glycosuria is pronounced and will continue as long as there is sufficient gluconeogenic reserve If the metabolic defect is not corrected by the administration of insulin, further complications, largely of renal origin, will appear Owing to the excretion of large volumes of water which accompanies the glucose, dehydration develops and with the loss of fixed base in the form of Na^+ and K^+, the acidosis becomes even more severe In an attempt to compensate for the acidosis, respiration becomes rapid and deep (Kussmaul breathing) and the kidney, in an effort to conserve the fixed base, will excrete ammonia With further dehydration, decreased plasma volume, peripheral circulatory failure, and coma terminated by death are the usual sequence of events

Members of our society are taught from early years to distinguish men from women, however, sex identification is a comprehensive concept implying more than gender recognition Sexual differentiation begins at the time of fertilization and continues into early adult life This is a complex process which is influenced independently by genetic, hormonal, and behavioral determinants When we speak of the sex of an individual we mean the composite of the chromosomal sex, gonadal sex, genital sex, and psychological sex In this chapter the development and interrelation of each of these parameters are discussed

GENETIC CHROMOSOMAL, OR NUCLEAR SEX

Genetic sex is determined at the time of fertilization when the spermatozoon and ovum unite and depends upon which sex chromosome is present in the sperm cell All extragonadal cells in the human contain 23 pairs of chromosomes (22 pairs of autosomes and 1 pair of sex chromosomes) In the male the sex chromosomes are X and Y, whereas in the female there are two X chromosomes During the process of ova and sperm development germ cells divide by a process called myosis so that pairs of chromosomes are split between two daughter cells As a result each gamete contains 22 autosomes and 1 sex chromosome In the testis myosis produces sperm which contain X and others containing Y chromosomes Ova, however, contain only X chromosomes At the time of fertilization the sex of the resulting zygote will be determined by the sex chromosome carried by the fertilizing sperm If an ovum is fertilized by a sperm bearing an X chromosome, then the combination XX results and a female develops On the other hand, if the fertilizing sperm bears a Y chromosome, then the XY combination produces a male

In recent years techniques have been developed for examining human chromosomes Cells in metaphase are spread and the chromosomes are stained for counting or photography and mounting A systematized array of chromosomes from a single cell is called a karyotype (Figs 7 72 and 7 73) The meaning of this term is usually extended to imply that the chromosomal pattern of the cells examined are typical of all the cells of the individual To accurately determine the karyotype, however, one must characterize the chromosomes from several tissues and at least 100 metaphase cells from each tissue should be counted The karyotype of a normal woman designated 46, XX (Fig 7 72) and that of a normal male 46, XY (Fig 7 73)

Biologic function of the sex chromosomes has been inferred from the examination of patients with an abnormal number of sex chromosomes In individuals with an XXY (Ford et al , 1959), or an XXXXY (Barr et al , 1963) complement of sex chromosomes, testes develop indicating that the Y chromosome carries strong male-determining genes which can induce fetal testicular development even in the presence of two or more X chromosomes Without a Y chromosome testicular development does not usually occur Only a few genes which influence extragonadal structures have been identified on the Y chromosome

The biologic functions of the X chromosomes are more diverse (Moore, 1966) The requirement for a pair of X chromosomes for ovarian differentiation is suggested by the fact that ovaries do not develop in women with an unpaired X chromosome (Turner's Syndrome, 45, XO) In contrast to the Y chromosome, which is mainly concerned with sex differentiation, the X chromosome contains genes which influence the differentiation of a wide variety of extragonadal characteristics

Sex Chromatin (Nuclear Sex). Since the chromosomal composition of the male differs from that of the female, it was not surprising that Barr and Bertram (1949) observed a mor-

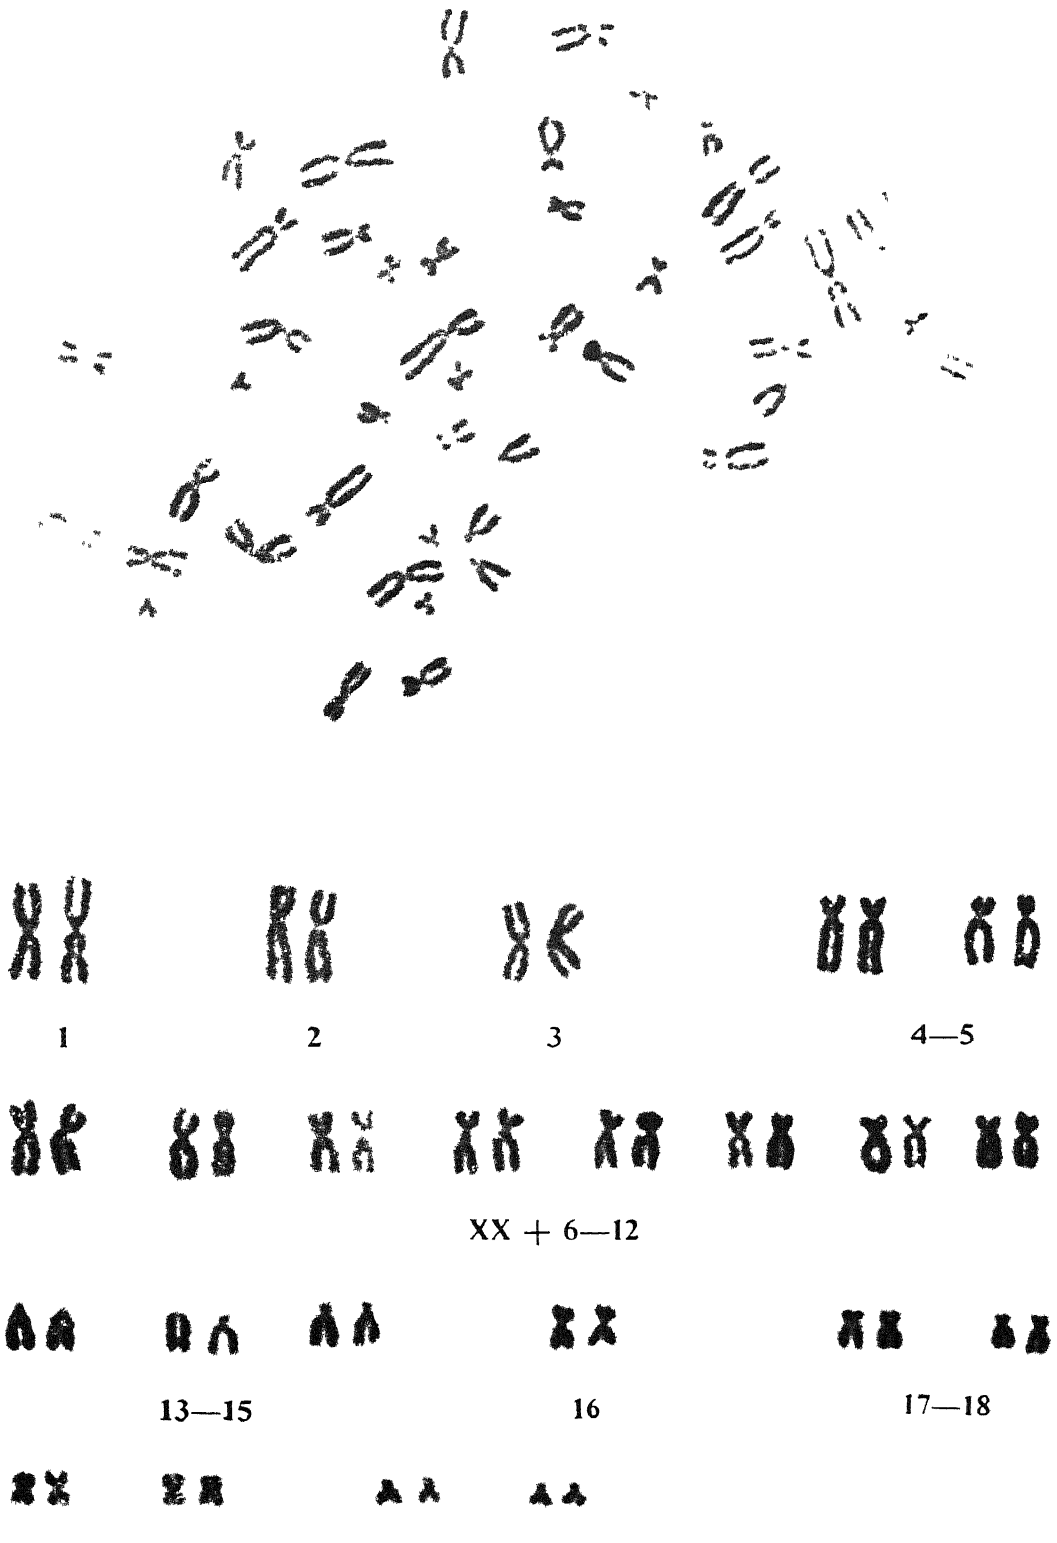

Fig 7 72 Karyotype of blood lymphocytes from a woman The pair of X chromostmes is placed at the left hand of the second row

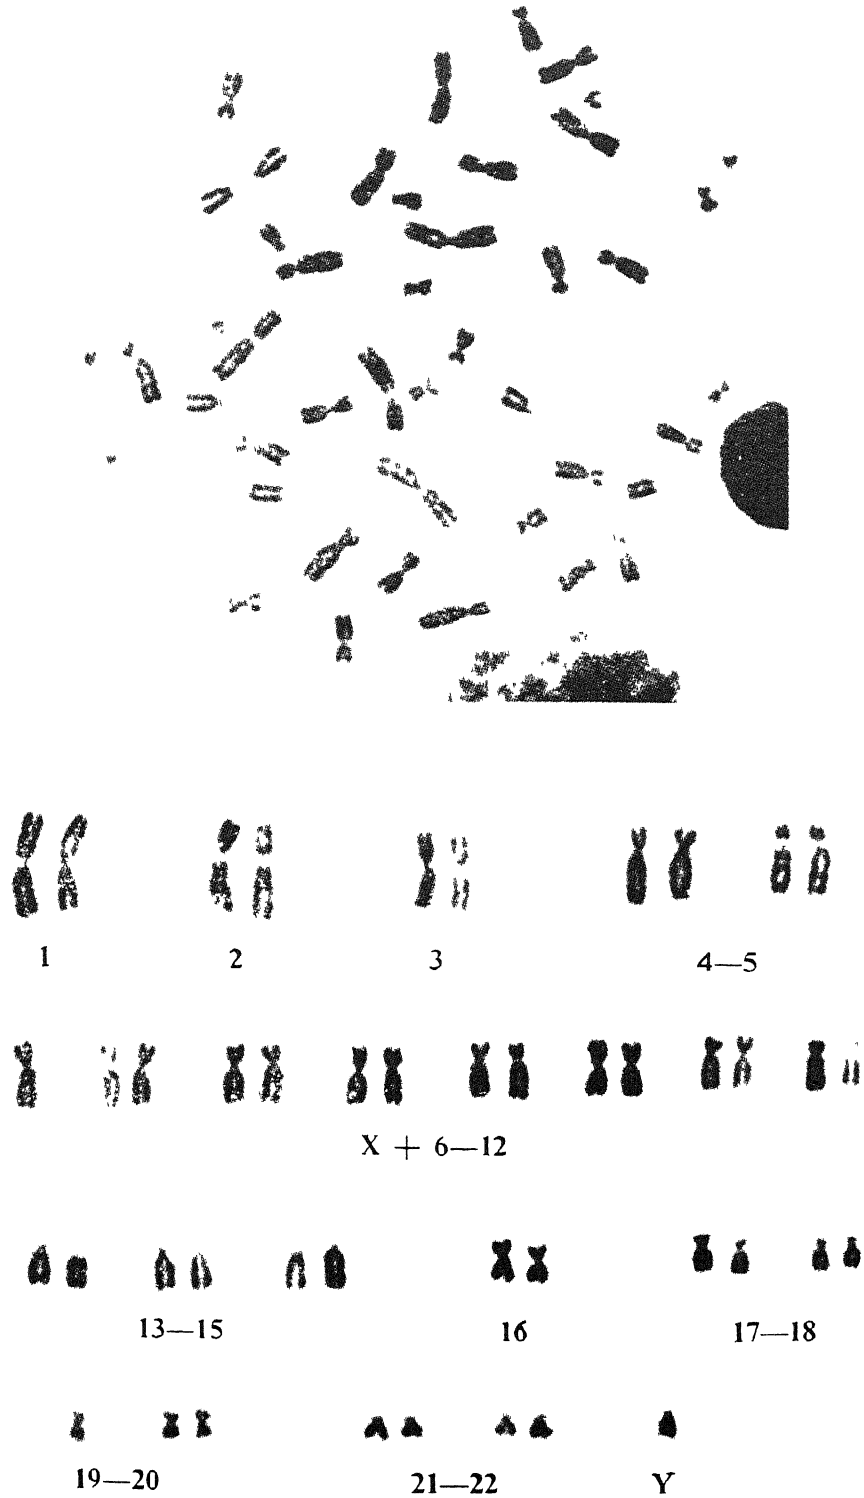

Fig 7 73 Karyotype of blood lymphocytes for a man The X chromosome is at the left of the second row and the Y chromosome is at the bottom right

phologic difference in nuclei from male and female animals The difference between the male and the female lies in a special mass of chromatin (sex chromatin or Barr body) in the female The sex chromatin is typically a plano-convex mass about 1 μ in diameter which stains positively for deoxyribonucleic acid (DNA) and which lies close or in contact with the nuclear membrane (Fig 7 74) It is now generally accepted that the sex chromatin is comprised of one of the X chromosomes which remains genetically inactive during interphase Chromatin positive cells which contain two X chromosomes (46, XX, 47, XXY) have a single Barr body, whereas those with more than two X chromosomes may have two chromatin bodies It follows, therefore, that the number of chromatin bodies in any diploid nucleus is one less than the total number of X chromosomes (Mittwoch, 1964)

GONADAL SEX

Until the 5th or 6th week of embryonic life the gonad in both sexes develops in an identical fashion with the potential to develop into either a testis or an ovary (Grumbach and Barr, 1958) At the 6th week the embryonic gonads appear as ridges on either side of the dorsal mesentery immediately adjacent to the developing adrenal gland The outer layer or cortex is comprised of coelomic epithelial cells into which the primary germ cells migrate from the endoderm of the yoke sac The inner or medullary portion of the indifferent gonad is comprised of stromal mesenchyme which surrounds cords of epithelial cells (primary sex cords) which are derived from the overlying coelomic endothelium If the indifferent gonad is to become a testis due to the presence of Y chromosomes a marked proliferation of the primary sex cords occurs in the medulla about the 7th week of fetal life Primary germ cells migrate from the cortical area and are incorporated into the developing seminiferous tubules About the 8th week Leydig cells appear in the medullary mesenchyme and their function assures subsequent male differentiation of the genital ducts and external genitalia As testicular differentiation proceeds the medulla of the testis progressively enlarges and the cortex regresses In the mature testis the only remnant of the embryonic cortex is the tunica vaginalis

Differentiation of the indifferent gonad into an ovary occurs at about 9 weeks of fetal life It is of interest to note that primary germ cells of a fetus with a 46, XX karyotype have a sex chromatin body (inactive X chromosome) prior to their migration into a genital ridge Once inside the embryonic gonad, however, the sex chromatin body is lost, suggesting that both X chromosomes in the primordial germ cell are active (Witschi, 1957) As noted above, *two* active X chromosomes are believed to be necessary for differentiation of an ovary In the developing ovary the embryonic cortex proliferates to form the major portion of this gonad The medulla regresses and forms the hilum of the mature ovary

From these observations it is apparent that the gonadal sex is to a large extent determined by the chromosomal sex and in most instances both are the same By contrast, genital sex and secondary sexual characteristics are hormonally determined and can easily be made inconsistent with the genetic sex by treatment with sex steroids

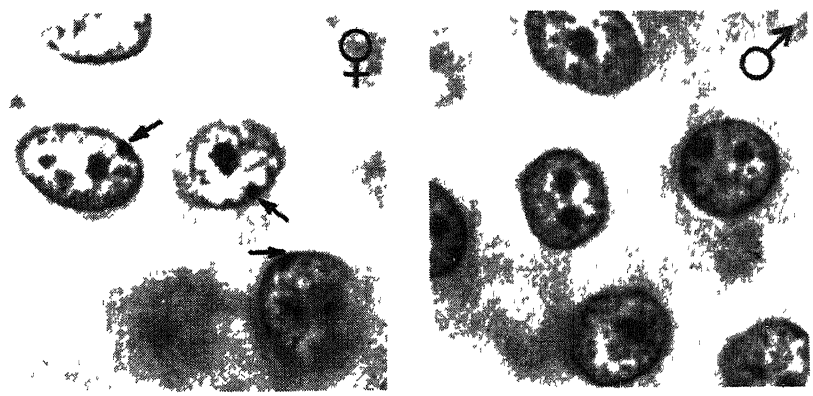

Fig 7 74 Nuclei of cells in the epidermal spinus layer of a genetic female (left) and a genetic male (right) The sex chromatin bodies are indicated by arrows in the female (From Grumbach and Barr 1958)

GENITAL SEX

Differentiation of the Genital Ducts. At the 7th week of embryonic life the fetus contains primordia of the genital duct systems for both the male (Wolffian ducts) and the female (Mullerian ducts) If a male develops, the Wolffian duct system will give rise to the epididymis, vas deferens, seminal vesicles, and the ejaculatory duct, whereas, in the female the Mullerian ducts serve as the anlage of the Fallopian tubes and uterus During the 3rd month of fetal life either the Mullerian or the Wolffian ducts complete their differentiation while the others regress

The mechanism whereby one set of ducts dominates over the other to form the internal genitalia of the developing embryo was demonstrated in a series of experiments by Jost (1953) In these studies embryonic rabbits were either gonadectomized or treated with steroids in utero and the subsequent effect upon Mullerian and Wolffian development observed The results of these studies are schematically summarized in Figure 7 75 In the presence of a testes Wolffian structures develop and Mullerian structures regress (Fig 7 75*A*, *B*, *C*) The development of normal Mullerian structures is not dependent upon the ovary since this ductal system differentiates in both the castrate female and male even if the castration is unilateral (Fig 7 75*D*, *E*) Transplantation of a testis into the female adjacent to the ovary results in unilateral Wolffian differentiation associated with Mullerian regression on the side of the trans-

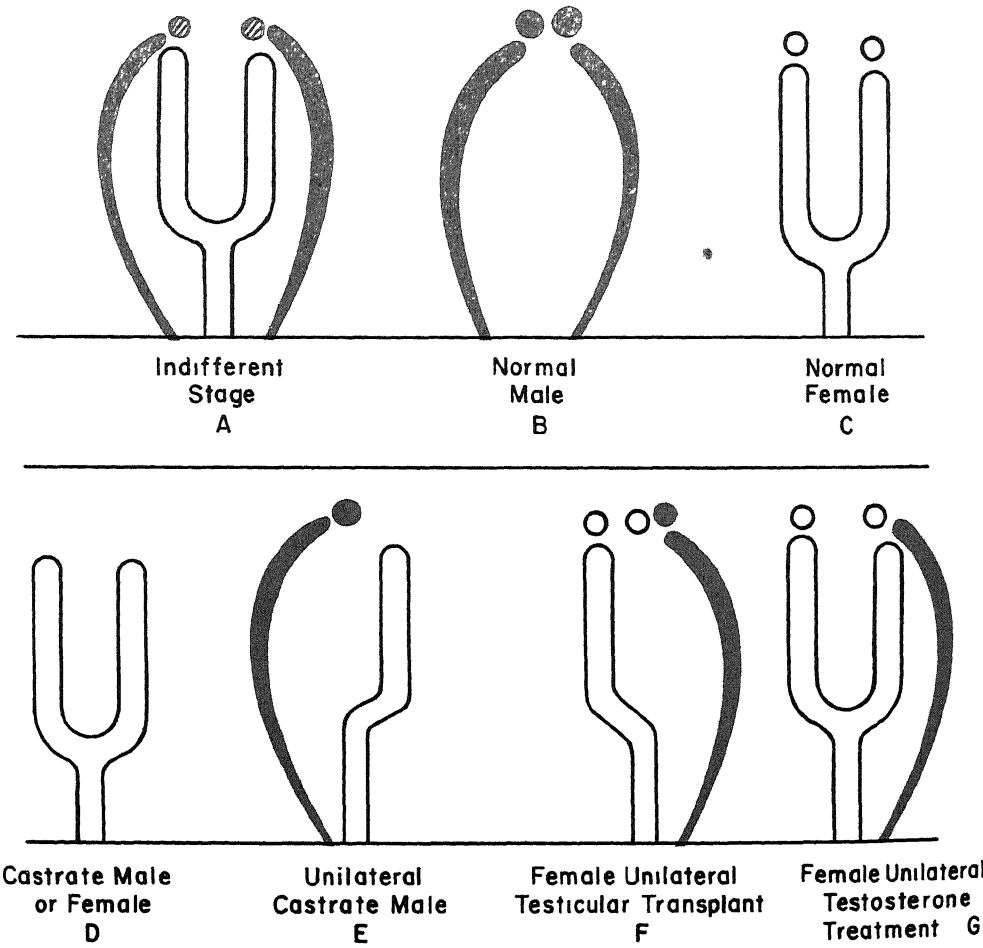

Fig 7 75 Schematic summary of Wolffian and Müllerian development in rabbit embryos (Jost, 1953) Ovaries and Müllerian structures are indicated by open figures and the Wolffian structures by the shaded areas

plant (Fig 7 75*F*) By contrast testosterone treatment of the female resulted in only Wolffian development (Fig 7 75*G*) From these observations the hormonal control of gonaduct differentiation can be summarized as follows

1) Testosterone stimulates Wolffian development and without the influence of this steroid this ductal system regresses

2) Mullerian duct system develops normally in the absence of a hormonal stimulus from either gonad but regression of this ductal system is due to a nonandrogenic hormonal product from the testis

Differentiation of the External Genitalia The external genitalia of both sexes are identical up until the end of the 8th fetal week and have the potential to differentiate into the organs of either sex At this stage the major components of the external genitalia are the genital tubercle, urethral folds, urogenital slit, and labioscrotal swelling (Fig 7 76) Under the influence of testosterone from the fetal testes (or from exogenous administration) male differentiation of the external genitalia occurs The genital tubercle forms the penis, the urogenital folds, the penile urethra, and the labioscrotal swellings, the scrotum In the absence of androgens female differentiation of the external genitalia proceeds with the development of a clitoris, labia minoria, and labia majora The structures which develop from the indifferent genital primordia in the presence and in the absence of androgens are summarized in Table 7 9 It is significant that the androgen dependent differentiation of the external genitalia can only occur during fetal life Even though the female structures are not hormone dependent, once the vagina and labia have developed they cannot be differentiated into analogous male structures even if exposed to very large quantities of androgens

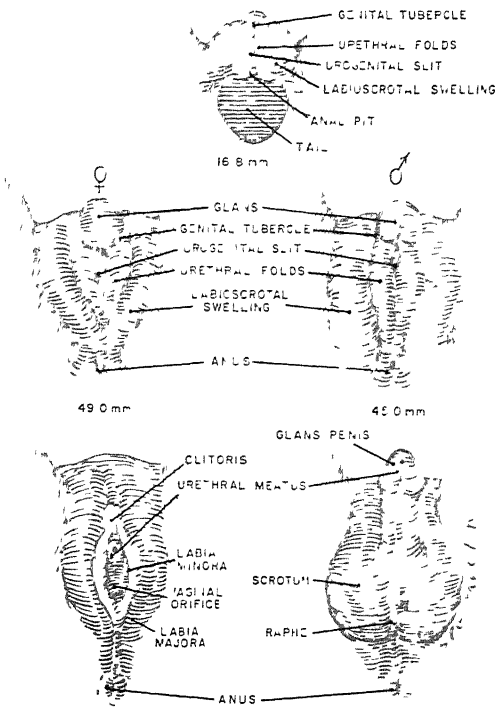

Fig 7 76 Differentiation of male and female external genitalia from indifferent primordia Male differentiation occurs only in the presence of androgenic stimulation during the first 12 weeks of fetal life (From Van Wyk and Grumbach 1968)

Hypothalamic Differentiation Even though the central nervous system is anatomically remote from the external genitalia, the differentiation of both of these structures is similar since both require fetal androgen exposure if a masculine pattern of development is to occur In the adult female, pituitary gonadotropins are released in a cyclic fashion In the mature male, gonadotropins are secreted in relatively constant rates even when an ovary is transplanted into an orchiectomized host

Table 7 9
Differentiation of the external genitalia from indifferent primordia

Primordial Structure	Structures Which Develop *with* Androgen Exposure	Structures Which Develop *without* Androgen Exposure
Genital tubercle	Penis	Clitoris
Urethral folds	Corpus spongiosum (penile urethra)	Labia minora
Labioscrotal swellings	Scrotum	Labia majora
Urogenital sinus	Prostatic utricle	Lower ⅓ of vagina
	Bulbourethral glands	Skene's glands
		Bartholin's glands

Androgen treatment of female rat fetuses either in utero or in the early neonatal period results in a noncyclic pattern of gonadotropin secretion after puberty even in the presence of a functioning ovary. From these observations it is apparent that in the absence of fetal androgens, the hypothalamus develops a cyclic center for gonadotropin release, whereas fetal androgen exposure produces a noncyclic center (Barraclough, 1966). Another way that the development of the hypothalamus is similar to that of external genitalia is that only a brief androgen exposure is required to effect an irreversible change.

Psychological Sex or Gender Role. Gender is selected at birth in accord with the apparent genital sex. This becomes the legal sex and also sets the behavioral patterns which stimulate psychosexual identification of the individual with others in society. Prior to the age of 2 years a child can identify either as a male or a female. Psychosexual differentiation or gender role is established by sex orientation through dress, hair style, toilet habits, and by constant comparison with other children and adults. Through this exposure a child is continually reminded of his gender and comes to identify with one of the sexes. From psychological studies of girls who were mistakenly raised as boys, and vice versa, it is now clear that gender role is established early in life and maintained even in the face of abnormal external genitalia and subsequent development of secondary sexual characteristics which are opposite to those of the identified sex (Hampson and Hampson, 1961). There is little evidence to suggest that gender role is an inherent characteristic of the fetus or that it is established by a direct hormone action on the central nervous system similar to that responsible for differentiation of the gonadotropin release centers.

Secondary Sexual Characteristics. The secondary sexual characteristics are the last sexual features to develop in both sexes as they occur as a result of gonadal hormonal secretion at the time of puberty. In the female, estrogens produce breast development and deposition of subcutaneous adipose tissue. By contrast, in the male testicular testosterone secretion is responsible for increase in muscle mass, deepening of the voice, male hair pattern, and growth of internal and external genitalia.

9 / HORMONAL CONTROL OF GONADAL FUNCTION

The Testis

The testis, like the ovary, has endocrine as well as reproductive functions The two major activities of the testis are segregated anatomically with androgen biosynthesis occurring in the Leydig cells and spermatogenesis in the seminiferous tubules The anterior pituitary participates in the control of both of these functions through its secretion of gonadotropins (LH and FSH) The essential features of testicular function and its control by the anterior pituitary and hypothalamus are shown schematically in Figure 7 77 Although testosterone secretion and spermatogenesis are intimately related, for convenience they are discussed independently as a hypothalamo-pituitary-Leydig cell axis and a hypothalamo-pituitary tubular axis

HYPOTHALAMO-PITUITARY-LEYDIG CELL AXIS

Luteinizing Hormone (LH) Luteinizing hormone derives its name from its function in the female where it facilitates ovulation and converts the ovulated follicle into a functional corpus luteum When this hormone was discovered in the male it was called interstitial cell-stimulating hormone (ICSH) because of its effect on testicular Leydig cells It is now recognized that these two hormones are the same, and so the term "LH" is used in both sexes As noted in Chapter 2, LH is secreted from periodic acid Schiff (PAS) positive basophils in the anterior pituitary in response to increased secretion of LH-releasing factor (LRF) from the central nervous system LH is a glycoprotein with an approximate molecular weight of 30,000 This molecule contains mannose, hexosamine, and sialic acid Both the biologic activity and the structure of LH are similar to those of human chorionic gonadotropin (HCG) which is a product of the trophoblasts of the human placenta

Leydig Cells. The interstitial cells of Leydig are located in the connective tissue stroma of the testis between the seminiferous tubules These cells differentiate in the testis of the 7-week fetus Since Leydig cells regress soon after birth it has been assumed that their initial development resulted from gonadotropin stimulation HCG is probably the hormone responsible for fetal differentiation since functional Leydig cells occur in ancephalic infants born without a pituitary (Villee, 1969) During the 1st month of neonatal life, Leydig cells revert to undifferentiated mesenchyme cells but appear once again at the time of puberty as plasma LH levels increase The morphologic differentiation of Leydig cells in the fetus, in the puberal boy, or following stimulation with either exogenous LH or HCG correlates with androgen secretion (Lipsett et al , 1966) Distinguishing morphologic characteristics of the functional Leydig cell in the human testis are abundant, smooth, endoplasmic reticulum which contains many of the enzymes necessary for steroid synthesis, lipochrome pigment, and crystalloids of Reinecke

Testicular Androgens. An androgen is a substance which stimulates growth of the prostate and seminal vesicles It is important to recognize that this is a biologic and not a chemical definition Most potent androgens are steroids and several of these are shown in Figure 7 78 Extensive studies have demonstrated that testosterone is the most important androgen both in testicular tissue and in the spermatic venous plasma Androstenedione, a testosterone precursor (Fig 7 79), is also secreted by the testis but it is a weak androgen Its only importance in men is as a plasma precursor for estrogens Other testosterone precur-

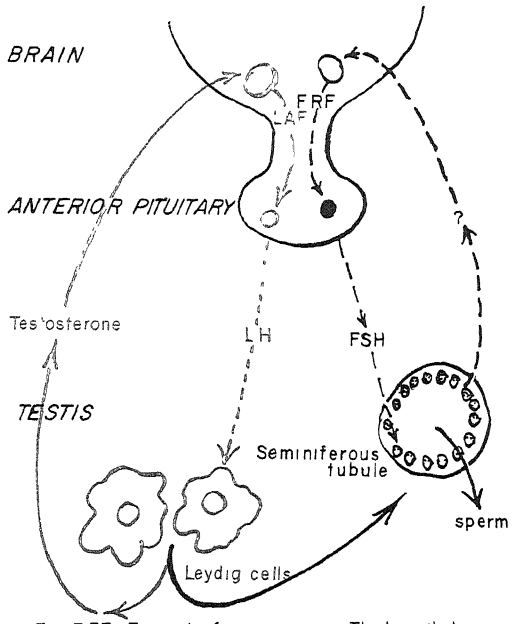

Fig 7 77 Testicular function in man The hypothalamo-pituitary-Leydig cell axis is shown on the left with pituitary LH stimulating testosterone secretion The hypothalamo-pituitary tubular axis is shown on the right with FSH and testosterone stimulating spermatogenesis A factor from the seminiferous tubules (?) is believed to regulate FSH secretion

sors such as 17-OH-progesterone (Fig 7 79) are secreted by the testis but their biologic function, if any, is not known Mean blood levels urinary levels, and production rates of testosterone and androstenedione in man are shown in Table 7 10

The Leydig cells are the primary sites of testosterone synthesis and the testes secrete 95% of the testosterone in the blood of men (Lipsett et al, 1968) In the Leydig cells, cholesterol is synthesized from acetate as in other tissues of the body In addition, mitochondrial enzymes of these cells, like those of the adrenal, ovary, and placenta, have the unique ability to cleave the cholesterol side chain to produce pregnenolone This C-21 steroid is subsequently converted to testosterone by several microsomal enzymes Some of the important steps of testicular androgen biosynthesis are shown in Figure 7 79 and are compared to steroid synthesis in the ovary

Control of Testosterone Secretion. The rate of testosterone synthesis and secretion by the Leydig cells is dependent upon LH levels in the blood (Fig 7 77) Increased LH levels produce Leydig cell hyperplasia and increased testosterone secretion, whereas lowered LH

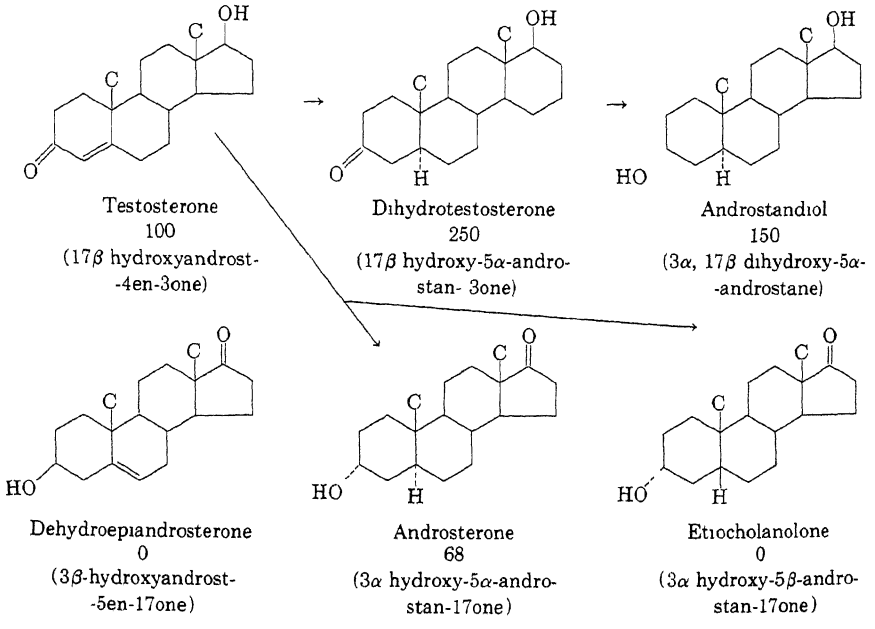

Fig. 7 78 Androgens and ketosteroids On the top line are the most important naturally occurring androgens The relative biologic potency of each is shown with testosterone having a potency of 100 Testosterone is metabolized in tracellularly to dihydrotestosterone and androstanediol On the bottom line are the relatively nonandrogenic 17 keto steroids which are secreted by the adrenal Testosterone is also metabolized to ketosteroids

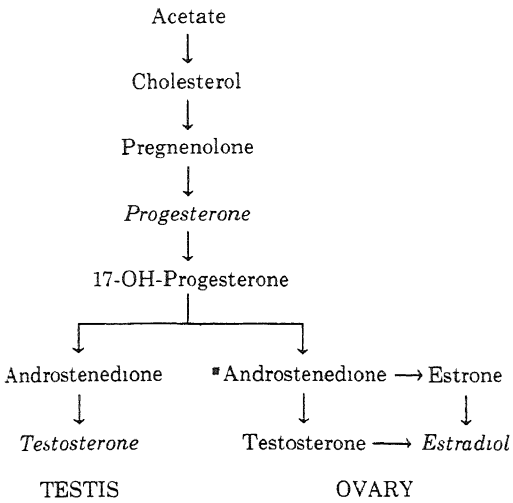

Fig 7 79 Steroid biosynthesis in the testis and the ovary Testosterone is the major secretory product of the testis The progesterone and estradiol are the major secretory products of the ovary

which follows hypophysectomy is associated with virtual inactivity of testicular Leydig cells and reduced testosterone secretion Similarly, LH secretion by the anterior pituitary is reciprocally controlled through the central nervous system by blood levels of testosterone A fall in testosterone concentration results in increased release of LRF into the hypophyseal portal system and subsequent discharge of LH into the general circulation In response to the rise in blood LH, the Leydig cells secrete testosterone which, in turn, inhibits LRF and, as a consequence, LH release (Fig 7 77) In this manner the hypothalamus, the pituitary, and the Leydig cells form a functional axis which serves to maintain testosterone blood levels relatively constant from day-to-day and from week-to-week (Lipsett et al , 1968) There is, however, a slight diurnal variation in blood testosterone with the levels at 8 00 AM being 20% to 25% higher than at 8 00 PM Resko and Eik-Nes, 1966)

Testosterone Transport and Metabolism. Steroids are organic compounds which are relatively insoluble in aqueous solutions and as a result they are transported in blood bound to plasma proteins Blood testosterone is bound with high affinity to testosterone-estradiol-binding globulin (TeBG) (Mercier-Bodard et al , 1970) This is a β globulin which is distinct from cortisol-binding globulin (Fig 7 80), the major transport protein for cortisol, corticosterone, progesterone, and other C-21 steroids. In blood 75 to 85% of testosterone is bound to TeBG whereas 15 to 25% is loosely bound to albumin and 1 to 5% is unassociated with any plasma protein (Bardin and Mahoudeau, 1970) The studies of Vermeulen et al (1969) demonstrate that in man the rate of testosterone metabolism correlates directly with the quantity of free plus albumin-bound testosterone It follows from these observations that the rate of androgen metabolism in donkey and rat are relatively high since these species lack TeBG Furthermore, these studies suggest that TeBG-bound testosterone is not readily available for in vivo metabolism It is possible that the testosterone bound to TeBG is biologically inactive since target tissue metabolism of this androgen is required for the expression of its biologic activity

Metabolism of a steroid may be defined as the irreversible removal of that steroid from the blood When testosterone enters the cell it may be metabolized either *1)* to a more active androgen which exerts its action on that cell or on a tissue in a remote part of the body, or *2)* to a less active androgen suitable for excretion either in the bile or urine (Fig 7 78) It is conceivable that both types of metabolism could occur in a sequential manner in the same cell In any event, irreversible removal from blood

Table 7 10
Testosterone androstenedione and ketosteroids in men prepuberal boys and women

	Men	Boys	Women
Testosterone[a]			
Plasma ng /100 ml	700	40	40
Urinary excretion μg /day	70	4	4
Production rate mg /day	7 0	0 3	0 3
Androstenedione[b]			
Plasma ng /100 ml	120	90	170
Production rate mg /day	2 4		3 4
Ketosteroids[c]			
Urinary excretion mg /day	12–18	2–4	8–15

[a] Testosterone, the most important blood androgen

[b] Androstenedione, a relatively nonandrogenic testosterone precursor

[c] Ketosteroids, a group of relatively nonandrogenic steroids derived from adrenal secretion and testosterone metabolism

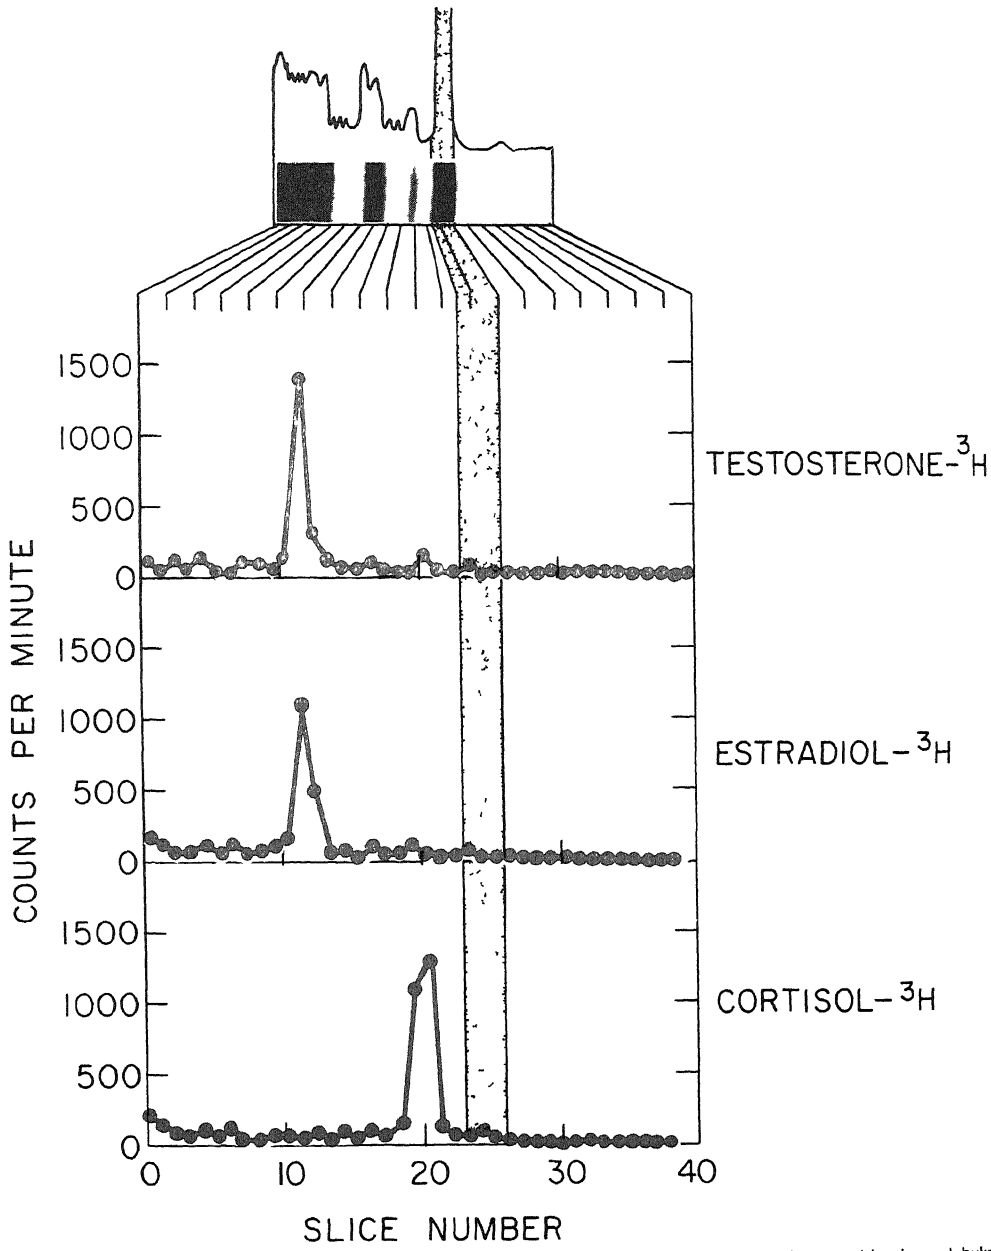

Fig 7 80 Electrophoretic demonstration of testosterone-estradiol-binding globulin and cortisol-binding globulin (bottom chart) Radioactive testosterone estradiol and cortisol were incubated with 3 samples of human plasma which was electrophoresed on polyacrylamide gels The gels were sliced and counted The peaks indicate the mobilities of the specific steroid-binding globulins The shaded bar indicates the mobility of albumin Under the conditions of the study steroid binding to albumin was not demonstrated

is accomplished in both instances by a change in steroid structure so that on re-entry into the blood is as a steroid other than testosterone In the first instance the biologic activity of testosterone is amplified and this type of metabolism occurs in tissues which grow in response to androgens such as prostate and seminal vesicles In the latter instance testosterone is metabolized to steroid sulfates and steroid glucuronides which are excreted from the

body This type of metabolism occurs primarily in the liver (Fig 7 78) (Liao and Fang, 1969)

The Biologic Actions of Androgens. Testosterone and other androgens have some biologic action on virtually every tissue in the body Their more important functions are to *1)* stimulate differentiation of Wolffian ducts, external genitalia, and the hypothalamus in the fetus, *2)* produce linear body growth, nitrogen retention, and muscular development in the adolescent, *3)* stimulate the adult maturation of the external genitalia and accessory sex organs including the penis, scrotum, prostate, and seminal vesicles, *4)* produce a low-pitched voice as a result of enlargement of the larynx and thickening of the vocal chords, *5)* stimulate beard, axillary and pubic hair growth and cause temporal hair recession and balding, and *6)* produce aggressive behavior and facilitate libido and sexual potentia In addition to these well-recognized physiologic responses, androgens stimulate or suppress selective proteins in many organs such as the liver, kidney, and the salivary glands

Mechanism of Androgen Action. Although the exact mechanism of the action for any hormone is not completely understood, considerable advances have been made in the past several years toward elucidation of macromolecular events which occur within the cell when it interacts with a hormone Androgens are thought to act directly on the nucleus of the cell to stimulate replication of nuclear ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). One line of evidence supporting a nuclear site of androgen action is derived from studies of intracellular steroid localization Following an intravenous injection of radioactive testosterone, labeled steroid is retained in the nuclei of androgen sensitive tissues such as prostate and seminal vesicles long after it is cleared from the blood (Bruchovsky and Wilson, 1968) In these tissues testosterone is metabolized to dihydrotestosterone (Fig 7 78) which is bound to a nuclear receptor in the chromatin complex (Fang et al, 1969) The specificity of this receptor for dihydrotestosterone suggests that this steroid might be the intranuclear effector of testosterone action The ability of dihydrotestosterone, rather than testosterone, to enhance cytidine incorporation into nucleic acid of isolated prostatic nuclei further supports this contention (Bashirelahi et al, 1969) From these observations testosterone action on the prostate may be initiated by the following sequence of events testosterone enters the cell from the blood and is metabolized to dihydrotestosterone by 5-α-steroid reductase Dihydrotestosterone is then bound to a receptor which serves as a transport vehicle from the cytoplasm to the nucleus In the nucleus a steroid-receptor complex amplifies gene activity which results in increased nuclear RNA synthesis and eventually increased RNA directed protein synthesis (Liao and Fang, 1969)

HYPOTHALAMO-PITUITARY TUBULAR AXIS

Follicle-Stimulating Hormone (FSH). FSH is secreted from PAS-positive basophils in the anterior pituitary in response to increased secretion of FSH-releasing hormone (FSH-RH) from the hypothalamus FSH is a glycoprotein with an approximate molecular weight of 30,000 Follicle-stimulating hormone, like LH, derives its name from its function on the ovary where it stimulates follicular maturation In the male, FSH stimulates spermatogenesis as evidenced by repair of seminiferous tubules during its administration to hypophysectomized animals It should be noted that the seminiferous tubular structure can also be maintained in hypophysectomized animals by large doses of testosterone provided that its administration is begun immediately after hypophysectomy Under physiologic conditions both FSH and testosterone are required for normal spermatogenesis (Steinberger, 1971)

Seminiferous Tubules. The major mass of the testis is comprised of tightly coiled seminiferous tubules which may reach 70 cm in length The tubules are lined by spermatogonia which undergo mitotic division to give rise to the primary spermatocytes These cells mature through several stages and subsequently undergo reduction of meiotic division so that the resulting spermatids contain 23 rather than 46 chromosomes The spermatids are found near the lumen of the tubule and are transformed without further division into free spermatozoa (Fig 7 81) Approximately 74 days are required for conversion of a relatively undifferentiated spermatogonium into a highly specialized sperm cell which possesses several enzyme sys-

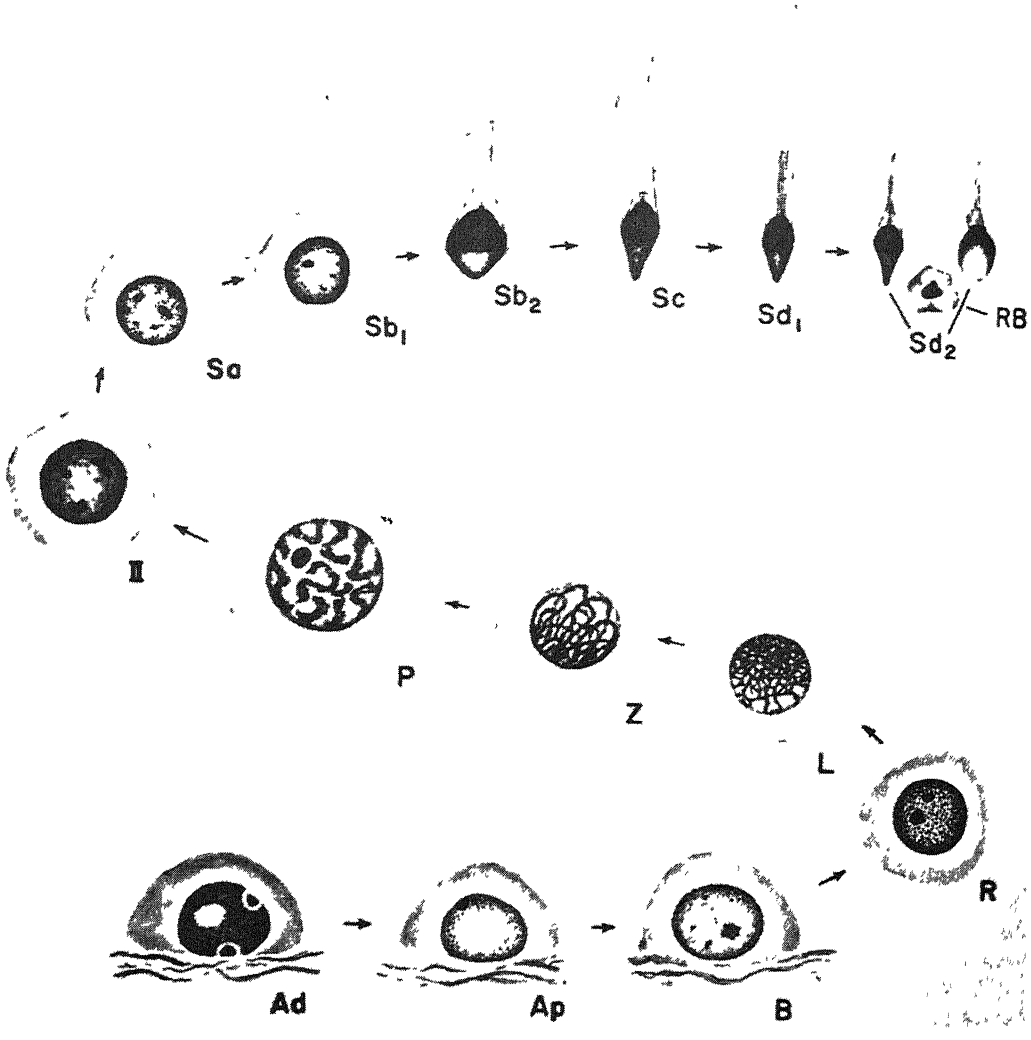

Fig 7 81 Drawings illustrating the main steps of spermatogenesis in man Spermatogenesis starts at the botton left with the dark type A spermatogonium (*Ad*) considered as the stem cell and terminates with the step d (Sd_2) spermatid or spermatozoon at the top right In sequence the other elements are *Ap* pole type A spermatogium *B* type B spermatogium *R* resting (or preleptotene) spermatocytes *L* leptotene spermatocyte *Z* zygotene spermatocyte *P* pachytene spermatocyte *II* secondary spermatocyte *Sa* Sb_1 Sb_2 *Sc* Sd_1 spermatids at various steps of spermiogenesis (From Heller and Clermont 1964)

tems that are required for penetration of the ovum (Heller and Clearmont, 1964)

The structure of the tubule is unique in that the spermatogonia are the only germinal cells which are in contact with the basement membrane The sustentacular cells of Sertoli also lie on the basement membrane of the tubules and these cells send out tentacles through the germinal epithelium so that each germinal cell is surrounded by Sertoli cell cytoplasm This anatomical arrangement has led to the conclusion that Sertoli cells nourish the germ cells as they move away from the basement membrane toward the lumen of the tubule The observation that some Sertoli cell tumors secrete estrogens has led to the conclusion that the normal Sertoli cell has a similar endocrine function There is little evidence, however, to support this conclusion in man

Control of FSH Secretion. Plasma FSH levels rise in men following orchiectomy indicating that a hormonal function from the testis

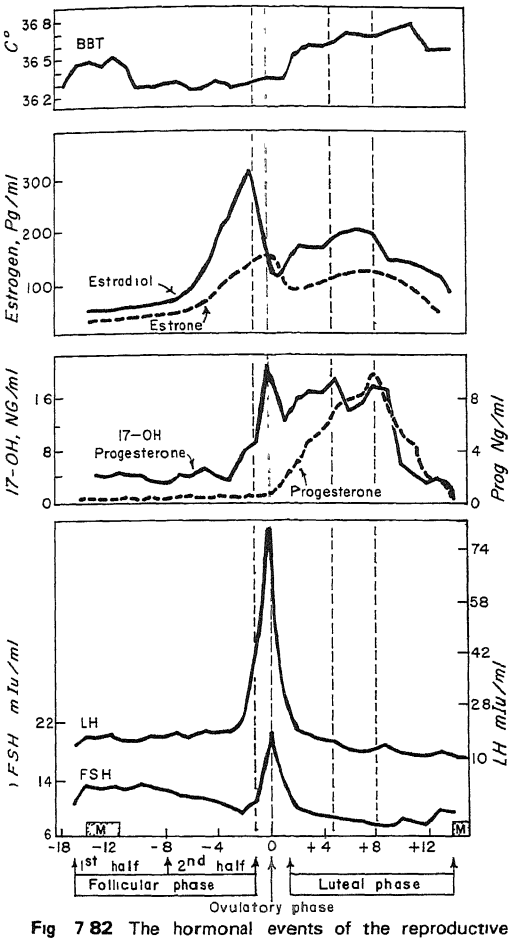

Fig 7 82 The hormonal events of the reproductive cycle are centered on the midcycle LH peak (day 0) Basal body temperatures (BBT) are shown on the top line Plasma levels of lutenizing hormone (LH) and follicle-stimulating hormone (FSH) are shown on the bottom two lines Gonadal steroid levels (estradiol estrone 17-hydroxyprogesterone and progesterone) are shown in the center Days of menstrual bleeding are indicated by M (Redrawn from Ross et al 1970 and Koreman et al 1970)

less than that of estradiol Some important steroidal and nonsteroidal estrogens are shown in Figure 7 83. The important biologic activities of estrogen include: *1*) stimulation of growth of both the myometrium and endometrium, *2*) maintenance of a thick vaginal mucosa and indirectly the acidic vaginal pH, *3*) stimulation of cervical glands to secrete copious quantities of viscous mucous, *4*) stimulation of breast growth and development, *5*) deposition of subcutaneous fat which results in a characteristic feminine habitus, *6*) sensitization of the ovaries to gonadotropins, and *7*) retardation of linear body growth in association with facilitation of epiphyseal closure

Estradiol and estrone are synthesized in the ovary from steroids with 19 carbon atoms The biosynthetic pathway up to the point of androstenedione and testosterone is essentially the same as that in the testis (Fig 7 79) In the final series of reactions the steroid A ring is aromatized with the loss of one methyl group to form the C-18 steroid estrogens (Fig 7 83) The day-to-day fluctuations of plasma estradiol and estrone during the reproductive cycle are shown in Figure 7 82

Progestins. Progestin was the name originally given to the crude extract of the corpora lutea which could prepare and maintain a secretory endometrium during the latter half of the reproductive cycle and during pregnancy Progesterone is the most active principle in these extracts Hormones which have progestational activity are referred to as progestins or gestagens (Fig 7 84)

The biologic actions of progesterone and other gestagens include *1*) antagonism of the growth promoting effect of estrogen on the endometrium and conversion of this rapidly proliferating organ into a secretory structure capable of maintaining an implanted blastocyst, *2*) conversion of the cervical mucous from a very viscous to a nonviscous fluid, *3*) stimulation of mammary gland growth and development, and *4*) inhibition of uterine motility

During the reproductive cycle and in the first trimester of pregnancy, progesterone is secreted almost exclusively by the corpus luteum During the latter two-thirds of pregnancy the placenta assumes this function The adrenal also secretes a small quantity of progesterone In all of these organs, progesterone is synthesized from cholesterol and pregnenolone

HORMONAL CHANGES DURING THE REPRODUCTIVE CYCLE

The changes in the plasma levels of estrogens, progestins, and gonadotropins during a reproductive cycle are shown in Figure 7 82 For descriptive purposes the reproductive cycle can be divided into a follicular phase (which can be subdivided into a first and second half), an ovulatory phase, and a luteal phase (Ross et al, 1970, VandeWiele, et al, 1970)

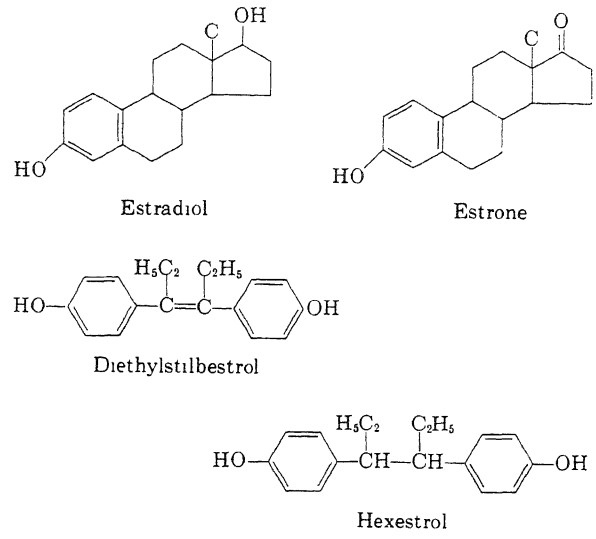

Fig 7 83 Important naturally occurring (top line) and synthetic (bottom lines) estrogens

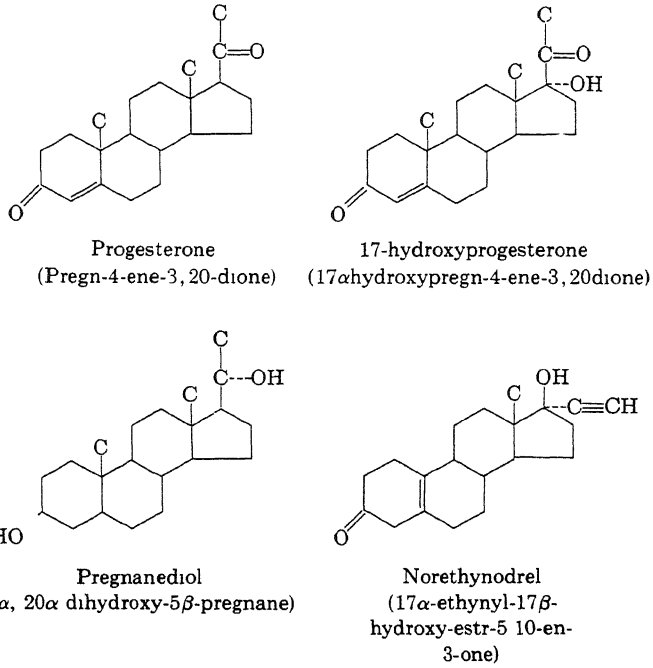

Fig 7 84 Progesterone and two of its metabolites Norethynodrel is a synthetic gestagen in clinical use

Follicular Phase, First Half. This period begins in the late luteal phase of the preceding cycle with a rise in the plasma levels of FSH and a concomitant initiation of follicular growth. LH levels also rise during this phase but the increase starts several days later than the increase in FSH. It is important to note that during the first half of the follicular phase there is no change in the blood levels of estrogens or progestins (Fig 7 82)

Follicular Phase, Second Half. This portion of the follicular phase begins approximately 7 to 8 days before the preovulatory LH surge and is characterized by an increase in

plasma estrogen levels (estradiol and estrone) Estradiol increases slowly at first and then rapidly reaches a maximum on the day before the LH peak The initial rise in estrone is not as great, but estrogen levels reach a peak concomitant with the peak of LH While plasma estrogen levels are increasing, plasma FSH decreases and plasma LH slowly and steadily increases Several days before ovulation there is a rise of 17-hydroxyprogesterone which reaches a maximum on the day of the LH surge It is significant that plasma progesterone levels do not increase during this period

Ovulatory Phase During this period there is a rapid rise in plasma LH levels which leads to the final maturation of the Graafian follicle and follicular rupture some 16 to 24 hr after the LH peak Although there is a simultaneous increase in plasma FSH levels, the role of this pituitary hormone on the ovulatory process is not understood Soon after the beginning of the LH surge and prior to ovulation, plasma estradiol levels drop precipitously and plasma progesterone increases slightly (Fig 7 82)

The preovulatory peaks of estradiol, and 17-hydroxyprogesterone correlate with rapid thecal development and follicular maturation During the final rapid growth of the follicle, the theca interna enlarges and assumes a functional appearance Following ovulation the theca interna cells persist in the corpus luteum Both estrogen and 17-hydroxyprogesterone secretion decrease rapidly in the ovulatory period but both increase again in the luteal phase as the corpus luteum with both its theca interna cells and luteinized follicular cells becomes vascularized While these observations do not prove that estrogens and 17-hydroxyprogesterone are secreted by the theca interna cells, they are nonetheless consistent with that hypothesis (Strott et al , 1969)

Luteal Phase. As noted above, luteinization is initiated by LH Recent studies also have indicated that ova exert an inhibitory influence on follicle luteinization When the ovum is removed from a mature follicle, granulosa cells immediately luteinize and form a corpus luteum By contrast, when the ovum is removed from an immature follicle, the granulosa cells degenerate and the follicle becomes atretic (Nalbandov, 1970) From these studies it was concluded that luteinization occurs spontaneously following expulsion of the ovum from the mature follicle since only the ovectomized follicles luteinized and the neighboring follicles remained unchanged These observations are consistent with those of Channing (1969) who observed that follicular cells placed in tissue culture luteinized spontaneously in the absence of all hormonal stimuli However, the lifespan and function of follicular cells which are luteinized spontaneously either in vivo or in vitro are reduced LH is required for normal corpus luteum survival and function Furthermore, LH administered in high doses can luteinize follicular cells even without ovulation and can produce a luteinized follicle with a trapped ovum (Ludwig and Horowitz, 1969) These observations indicate that either LH or ovum removal can luteinize the ovarian follicle, however, during a normal reproductive cycle both mechanisms are probably operative

The *sine qua none* of the luteal phase is the marked increase in progesterone secretion which reaches a maximum about 8 days after the midcycle LH peak 17-hydroxyprogesterone has a double peak during the luteal phase at 5 and 8 days, respectively, and as noted previously, estrone and estradiol plasma levels increase in parallel with those of the progestins Concomitant with the increase of gonadal steroids, plasma LH and FSH decline throughout most of the luteal phase (Fig 7 82)

The factors which control the lifespan of the corpus luteum in the normal reproductive cycle are ill-defined In many species, termination of luteal function is under control of a luteolytic factor produced by the uterus In the human and monkey there is no evidence for the existence of such a factor (Rowson, 1970)

Control of FSH and LH Secretion. Both FSH and LH are subject to negative feedback control as evidenced from the rise in both of these hormones following castration and from the decrease in their levels following estrogen administration Examination of the hormonal events of the reproductive cycle indicates that control mechanisms in addition to "negative feedback inhibition" are operative This is particularly true in the second half of the follicular phase when FSH decreases and LH increases concomitant with a rapid rise of blood estrogens. This paradox may be explained if one assumes that there are hypothalamic centers for positive and negative feedback control of gonadotropins in man as there are in the rodent (McCann and Porter, 1969) In addition,

to the negative feedback upon gonadotropin secretion, estrogens also exert a positive feedback on LH secretion but not upon FSH The factors which determine whether LH will increase or decrease in response to estrogen administration are not completely understood at the present time Suffice it to say that from the available data it would appear that both a positive and a negative feedback control of LH are operative at different periods during the reproductive cycle

In light of these observations the difference between the behavior of FSH and LH during the late follicular and luteal phases may be rationalized In the second half of the follicular period as estrogens rise, FSH decreases due to the negative feedback effect By contrast, the positive feedback control of estrogen is operative upon LH secretion during this period as the level of this hormone increases Both FSH and LH decline during the luteal phase under the negative feedback inhibition of estrogen and possibly progesterone

In addition to the feedback control of gonadotropins by gonadal steroids, there are also mechanisms by which gonadotropins control their own secretion This latter type of gonadotropin control has been termed the short-loop feedback while the control mechanisms involving gonadal steroids is called the long-loop feedback The following observations in rodents suggest that LH may exert a negative feedback on its own secretion via a "short loop" *1*) implantation of LH in the median eminence of rats results in decreased pituitary LH stores and decreased plasma LH levels, *2*) LRF increases following hypophysectomy (David et al , 1966) At present there is not conclusive evidence for a negative short loop feedback of FSH control (Ojeda and Ramirez, 1969) Although short-loop feedback is assumed to be operative in primates, there are no data to confirm or negate the existence of this type of feedback in man

A midcycle LH surge represents still another facet of the complex machanisms which are operative in the control of gonadotropin secretion in women The available studies support the hypothesis that the rise in estrogens during the later follicular phase triggers the preovulatory LH surge Evidence in favor of this theory has been provided by several investigators who demonstrated that estrogen administration can produce repeated bursts of LH, and in some instances, ovulation Further evidence for estrogen-stimulated LH release is obtained from experiments using antibodies to estradiol in which LH secretion was blocked when the biologic activity of estradiol was neutralized (VandeWiele et al , 1970) Under certain conditions progesterone can stimulate LH release (Swerdloff and Odell, 1969), but a careful analysis of the sequence of hormonal events during the reproductive cycle indicates that progesterone does not rise prior to LH (Fig 7 82) (Ross et al , 1970) Recent studies with progesterone antibodies are also consistent with these observations (Ferin et al , 1969)

Transport and Metabolism of Estradiol and Progesterone. The transport of estradiol and progesterone in blood is similar to that of testosterone A large fraction of estradiol in blood is bound with high affinity to TeBG (Fig 7 80) with smaller fractions associated with albumin and red cells Progesterone and cortisol bind with approximately equal affinities to cortisol-binding globulin (CBG) Since cortisol always circulates in at least a 10-fold greater concentration in plasma than progesterone, relatively more of the binding sites on CBG will be occupied by cortisol than by progesterone Therefore, even though progesterone can bind to a specific plasma transport protein, the majority of progesterone is transported by albumin since the specific binding sites are occupied by another steroid

and a variety of 2-methoxy compounds Estradiol and its metabolic products are conjugated with sulfate and/or glucuronic acid for excretion The keto groups of progesterone are reduced to form pregnanediol (Fig 7 84) which is then excreted as a conjugate Unlike testosterone, estradiol and progesterone are not metabolized to more active steroid products as both of these hormones are biologically active on target tissues in the form in which they are secreted into the blood

Origin of Testosterone in Women The origin of testosterone in women is illustrated in Figure 7 85 and is analagous to the production of estrogens in man Testosterone is secreted into the blood stream from both the ovary and the adrenal cortex Both of these endocrine glands, in addition, produce relatively nonandrogenic steroid precursors or prehormones such as androstenedione and dehydroepiandrosterone Steroid prehormones are then converted to testosterone in liver and pe-

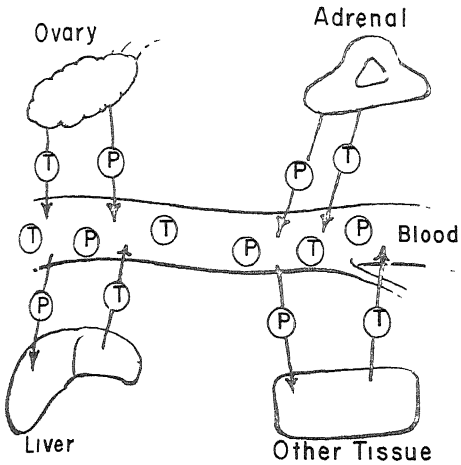

Fig 7 85 The origin of blood testosterone in women Testosterone (*T*) is secreted into the blood by the ovary and adrenal These endocrine glands also secrete precursor steroids or prehormones (*P*) into the blood which are transported to the liver and other tissues where they are converted to testosterone which re-enters the blood

ripheral tissue In normal women androstenedione and dehydroepiandrosterone serve as precursors for 50 and 15%, respectively, of plasma testosterone Since the origin of blood testosterone in normal women is diverse, one can anticipate similar but variable diversity of testosterone production in women with virilizing disorders (Bardin and Mahoudeau, 1970)

Mechanism of Estrogen and Progesterone Action Estradiol and progesterone, like other steroids, are thought to exert their action directly on the nucleus of the cell Using sucrose gradients, Jensen and his colleagues (1968) have demonstrated the sequence of events leading to estradiol interaction with the nucleus of the uterine cell Upon entry into the cell, estradiol is bound to an 8S receptor protein in the cytosol The estrogen is transferred to the nucleus, and in the process the cytoplasmic receptor is altered In the nucleus, estradiol is bound to a 5S receptor and this steroid-receptor complex is believed to activate DNA and RNA synthesis

Progesterone receptors have also been demonstrated in the uterus of a variety of animals These receptors are unique in that their activity is low in premature and castrate animals and is increased by estrogen treatment If a cytoplasmic receptor for progesterone is a prerequisite for progesterone action on the cell, then its maintenance by estrogen can explain the synergism of these two hormones on the uterus

PREGNANCY

Development of the Placenta In the human, fertilization occurs in the fallopian tube There the early zygote divides repeatedly as it makes its way into the uterine cavity 3 or 4 days after fertilization By the time the zygote reaches the uterine cavity it is a solid ball of cells called a morula The morula accumulates fluid between the cells which eventually causes separation of an outer layer of trophoblastic cells and an inner layer of embryonic cells that are attached to the trophoblastic layer in a restricted area The embryo, with its protective layer of trophoblasts, is termed the blastocyst, and by the 7th day after fertilization it is ready for implantation By the 9th day after fertilization, it is possible to detect human chorionic gonadotropin (HCG) in maternal urine This protein is synthesized by the trophoblast and has a hormonal role in the maintenance of the corpus luteum of pregnancy This hormone is made solely by the placenta so that hypophysectomized, pregnant women have normal excretions of HCG Thereafter the placenta continues to mature and serves both endocrine and nutritive functions It is capable of steroid synthesis by 6 weeks and its definitive structure is attained by 12 weeks of pregnancy (Villee, 1969)

Hormones of Pregnancy. During pregnancy the placenta is responsible for the production of a number of steroid and protein hormones which exert a variety of metabolic effects both on the fetus and mother

Progesterone is required throughout pregnancy to maintain a functional rather than a proliferative endometrium During the first few days of pregnancy (from fertilization until just after implantation), the progesterone required for endometrial maintenance is derived from the corpus luteum which is under the control of pituitary LH This control will last approximately 10 to 13 days, and, unless placental HCG is produced in sufficient quantities to maintain the corpus luteum beyond this period, the pregnancy will terminate several days after implantation as a consequence of luteolysis, a fall in progesterone concentration, and menstruation In normal pregnancy, however, corpus luteum maintenance is transferred from pituitary to placental control and progesterone

secretion continues Both progesterone and 17-hydroxyprogesterone increase until peak concentrations are attained at 3 to 4 weeks of gestation (Fig 7 86) Subsequently both steroids decline at the same rate, the plasma progesterone level reaching a nadir at 6 to 8 weeks after which it increases again as a result of placental secretion By contrast, 17-hydroxyprogesterone levels continue to decline Since the placenta does not synthesize significant quantities of 17-hydroxyprogesterone, this steroid is a good index of corpus luteum function during pregnancy These data suggest that the corpus luteum of pregnancy functions maximally during the first 4 weeks following ovulation and that its lifespan may be only about 10 weeks (Yoshimi et al , 1969)

Although the placenta possesses all the enzymes required to form cholesterol from acetate, it appears that maternal plasma cholesterol is the principal precursor of progesterone produced in the placenta Since the placenta cannot 17-hydroxylate progesterone, androgens and estrogens cannot be synthesized directly in the placenta as in the ovary and testis By contrast, these steroids are synthesized in the placenta from steroid precursors produced in the fetus Participation of the fetus and the placenta in the synthesis of hormones has given rise to the concept of the fetoplacental unit which is discussed below

Human Chorionic Gonadotropin is a glycoprotein hormone produced by the trophoblasts of the placenta HCG is chemically and biologically similar to pituitary LH and is believed to maintain the early corpus luteum of pregnancy The level of this hormone rises in maternal blood throughout the early weeks of pregnancy and peaks at 9 weeks when the number of cytotrophoblasts is maximal The fact that plasma progesterone levels decline, indicating involution of the corpus luteum of

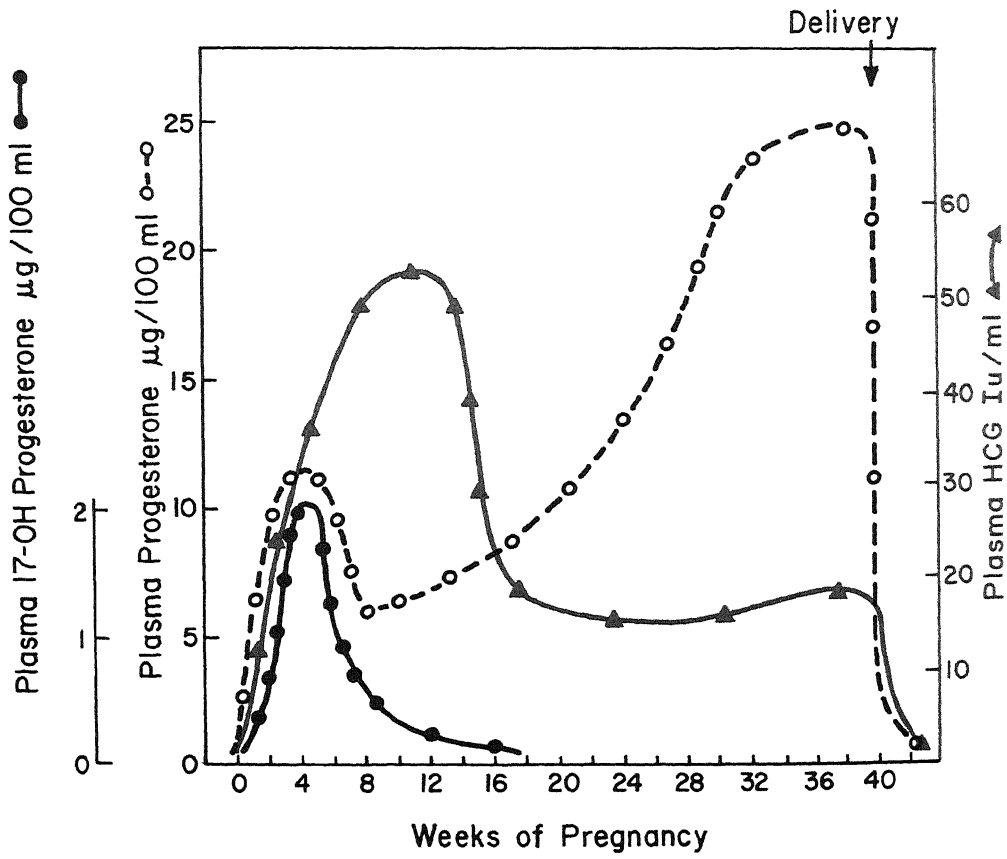

Fig 7.86 Maternal plasma levels of 17-hydroxyprogesterone progesterone and human chorionic gonadotropin (HCG) during pregnancy

pregnancy, while HCG levels are rising indicates that factors other than blood HCG levels are responsible for the duration of corpus luteum function After 9 weeks, plasma HCG levels also decline (Fig 7 86)

Human Placental Thyrotropin is a glycoprotein produced in the human placenta which is chemically similar, but immunologically distinct, from pituitary thyrotropin The existence of this hormone was first demonstrated in women with trophoblastic tumors of placental origin who developed thyrotoxicosis The fact that anencephalic infants have a marked reduction in thyroid size suggests that this hormone does not significantly influence thyroid function of the fetus in utero (Hertz, 1964)

Human Placental Lactogen (HPL) is another placental hormone produced by the trophoblasts as early as 3 weeks after ovulation Very little of this hormone can be detected in a fetus but very large quantities are present in the maternal circulation HPL can be detected in serum of pregnant women as early as 6 weeks of gestation and increases steadily during the first 6 months Blood levels show little day-to-day fluctuation and are not influenced by changes in blood glucose concentrations HPL disappears from the blood promptly after the delivery of the placenta

HPL has prolactin activity on the pigeon crop gland and has diabetogenic properties on mammals Although the exact role of this hormone in human pregnancy is not understood, a number of metabolic changes during gestation may be due to HPL These include hyperinsulinema, accelerated lipolysis, elevation of plasma free fatty acids, inhibition of glucose uptake, and acceleration of gluconeogenesis (Grumbach et al , 1968)

Fetoplacental Units. After conception there is a dynamic nutritional interplay between the fetus and the placenta which assures their mutual growth and development In addition, many studies indicate that the fetus and placenta function as a unit for synthesis and metabolism of steroid hormones This conclusion is supported by the fact that both the fetus and placenta have incomplete steroidogenic systems so that each complements the other in the process of estrogen biosynthesis Large quantities of dehydroepiandrosterone sulfate and 16-hydroxydehydroepiandrosterone sulfate are synthesized by the fetus Both steroids are transported to the placenta where the sulfate is removed (Fig 7 87) Dehydroepiandrosterone is then converted to androstenedione and testosterone which are aromatized to estrone and estradiol, respectively 16-α-hydroxy dehydroepiandrosterone is converted to 16-α-hydroxy testosterone which is then aromatized to estriol Estrogens synthesized by the fetoplacental unit enter the maternal circulation and comprise a major fraction of the estrogens of pregnancy From an analysis of Figure 7 87 it is easy to understand why fetal death is associated with a decline in maternal estrogen levels

Breast Development The secretory tissue of the breasts or mammary glands consists of elongated slender ducts whose walls have numerous pouches—the alveoli The walls of the alveoli are composed of a basement membrane, a layer of myoepithelial cells, and an inner layer of columnar epithelium The epithelial cells are the secreting elements of the breasts

There are three stages of phases of breast development Prior to puberty, breast growth is isometric to that of body growth At puberty, both the ductal system and the supporting adipose tissue grow much faster than the body in general due to increased secretion of ovarian estrogens Women without ovaries, therefore, develop breasts of normal size and consistency only when treated with estrogens The final stage of breast development occurs during pregnancy This phase is initiated by rapid growth of ducts and alveoli which differentiate so that milk synthesis and secretion can occur While the hormone-dependent growth of breast tissue during puberty appears relatively straightforward, breast growth during pregnancy is exceedingly complex

Surprisingly little is known about the hormonal requirements in women for breast growth and differentiation during pregnancy However, the hormonal requirements for growth of mouse mammary gland and milk synthesis have been well-defined in tissue culture and indicate the need for multiple hormones Growth of ducts and alveoli to midpregnancy can be achieved by administration of estrogen and progesterone to the rodent provided the pituitary and adrenals are intact These organs provide growth hormone and glucocorticoid, respectively, which are required for mammary gland growth If the mammary gland of an animal in midpregnancy is placed

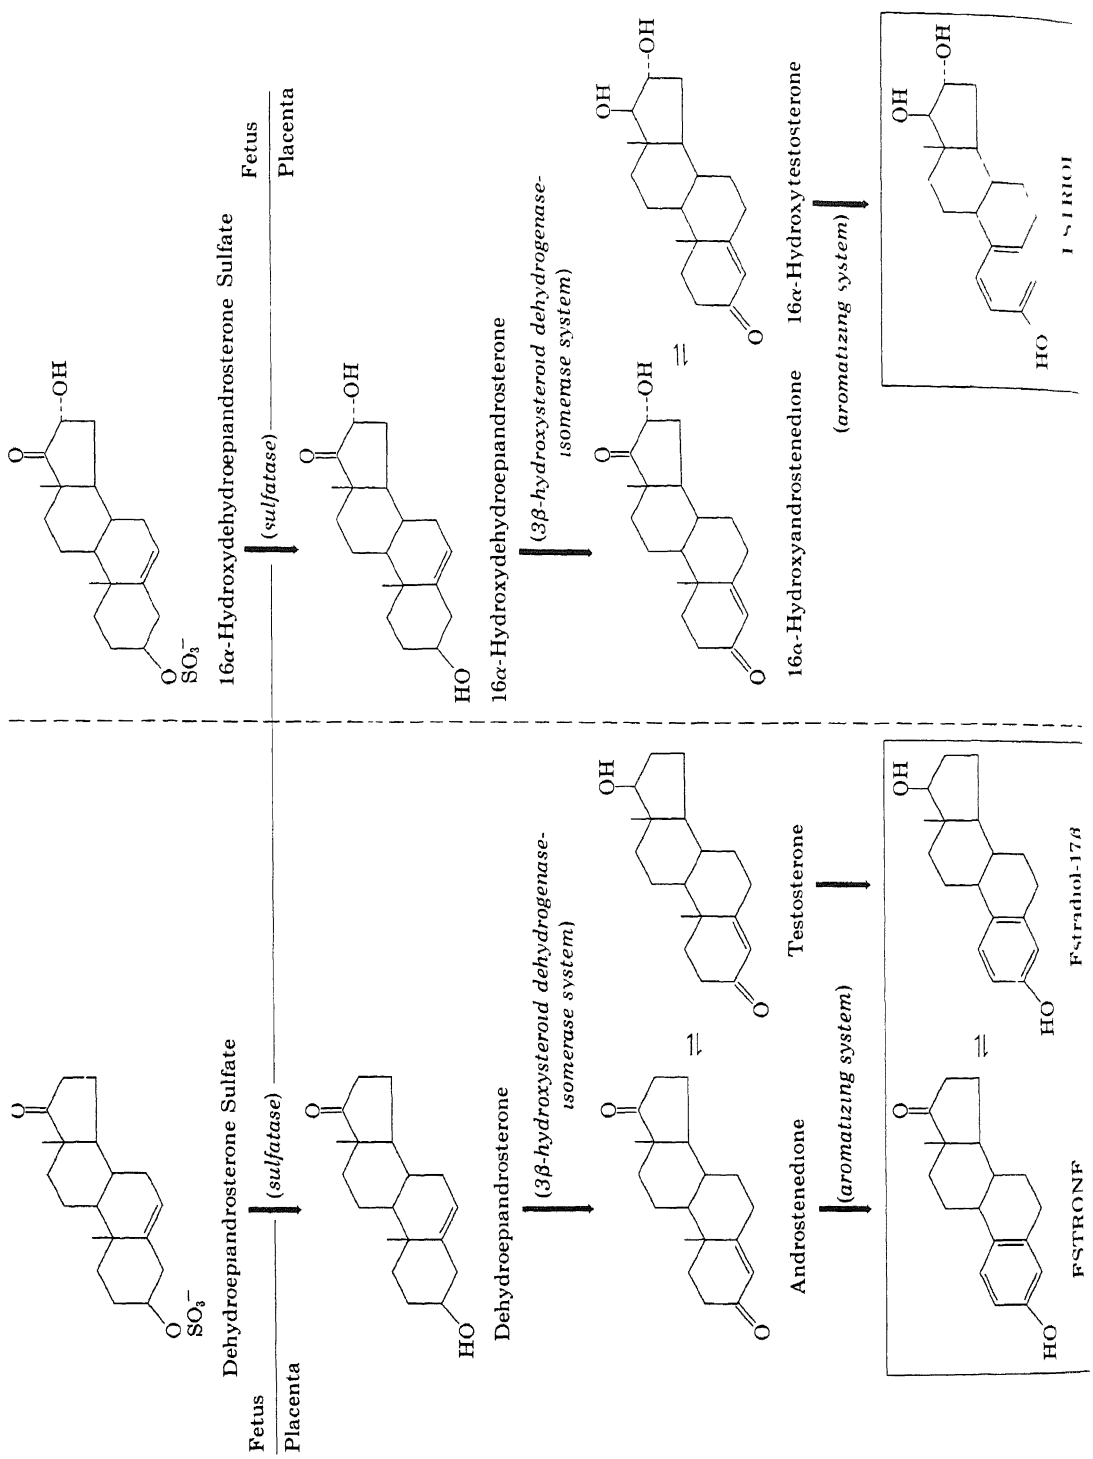

Fig 7 87 Synthesis of estrogen by the human placenta The pathways for the conversion of C19 steroid sulfates to estrogens are shown The major estrogens secreted by the placenta are boxed in (From Villee 1969)

in tissue culture, insulin, glucocorticoid, and prolactin are required to produce mammary gland differentiation and milk synthesis (Topper, 1970) While there are species differences in the hormonal requirement for mammary growth and development, gonadal adrenal, and pituitary hormones have been necessary in all animals studied to date

Although milk synthesis and secretion in women begins about the 5th month of pregnancy, the initiation of copious lactation is a consequence of delivery Milk release or "letdown" from the breast at the time of nursing is accomplished by the action of oxytocin on the myoepithelial cells of the alveoli Oxytocin is in turn produced in the hypothalamus and is released from the neurohypophysis

7 CONTROL OF CARBOHYDRATE METABOLISM IN MUSCLE

In muscle tissue, the rate of glycolysis varies with the degree of mechanical activity, with the nutritional or hormonal state of the animal, and with the type and function of the muscle For example, white skeletal muscle has few mitochondria, contracts very rapidly but can sustain a continuous contraction for only a short time This type of muscle depends on glycolysis as a primary source of adenosine triphosphate (ATP) Red skeletal muscle contracts slower but for a longer time, is rich in mitochondria, and derives most of its ATP through oxidation of fatty acid and glucose Cardiac muscle is a type of red muscle Mitochondria make up about 40% of the total volume of cardiac muscle and, under normal conditions, oxidative metabolism accounts for almost all of the ATP that is produced Glycolysis becomes an important source of ATP in red muscle only when the oxygen supply is limited, as during strenuous exercise in skeletal muscle or coronary occlusion in cardiac muscle

Under most conditions, glucose and fatty acids are the major fuels used by muscle, but lactate, pyruvate, ketone bodies and, to a minor extent, amino acids are all potential sources of energy In a well-oxygenated red muscle, all of these substrates are completely oxidized in the citric acid cycle resulting in formation of reduced nicotinamide adenine dinucleotide (NADH) which serves as the immediate energy source for ATP production by oxidative phosphorylation The rate of utilization of any one substrate depends upon the concentration of the substrate in the plasma, availability of alternative substrates, degree of mechanical activity, availability of oxygen, and plasma levels of hormones When glucose, insulin, fatty acids, and oxygen are present in normal amounts in arterial blood, oxidation of glucose accounts for only 20 to 30% of the total oxidative metabolism of the heart, while oxidation of fatty acids accounts for the remainder When insulin levels are low and fatty acids are high, as in fasting or uncontrolled diabetes, the heart utilizes fatty acids and ketone bodies almost exclusively On the other hand, when blood glucose and insulin are high, as after a carbohydrate meal, oxidation of glucose may account for a larger portion of cardiac metabolism Utilization of one substrate in preference to another indicates that regulation of overall metabolism involves a complicated network of interactions of one pathway with another which brings about an integration of all pathways, and insures that the rate of each is coordinated with the metabolic needs of the cell as a whole

Although this chapter is concerned with the regulation of glucose metabolism in muscle, many of the regulatory mechanisms that are discussed apply to other tissues as well Glucose utilization by adipose tissue and the influence of glycolysis on fatty acid release are discussed in Chapter 11

General Considerations of Metabolic Regulation

In general, complicated metabolic pathways are regulated as units A unit often represents a sequence of reactions between major branch points in a pathway For example, glucose metabolism appears to be regulated as three units (Fig 7 88) The glucose-activation unit is comprised of membrane transport and intracellular phosphorylation of glucose to glucose-6-P Glucose-6-P represents the first branch point in the pathway and may be used for glycogen synthesis, for synthesis of other metabolites via the pentose cycle, or for production of ATP by conversion to pyruvate or acetyl CoA through the main glycolytic pathway Glycogen metabolism is a cyclic process involving both synthetic and degradative enzyme systems Functionally, both enzyme systems are regulated as a glycogen homeostatic unit

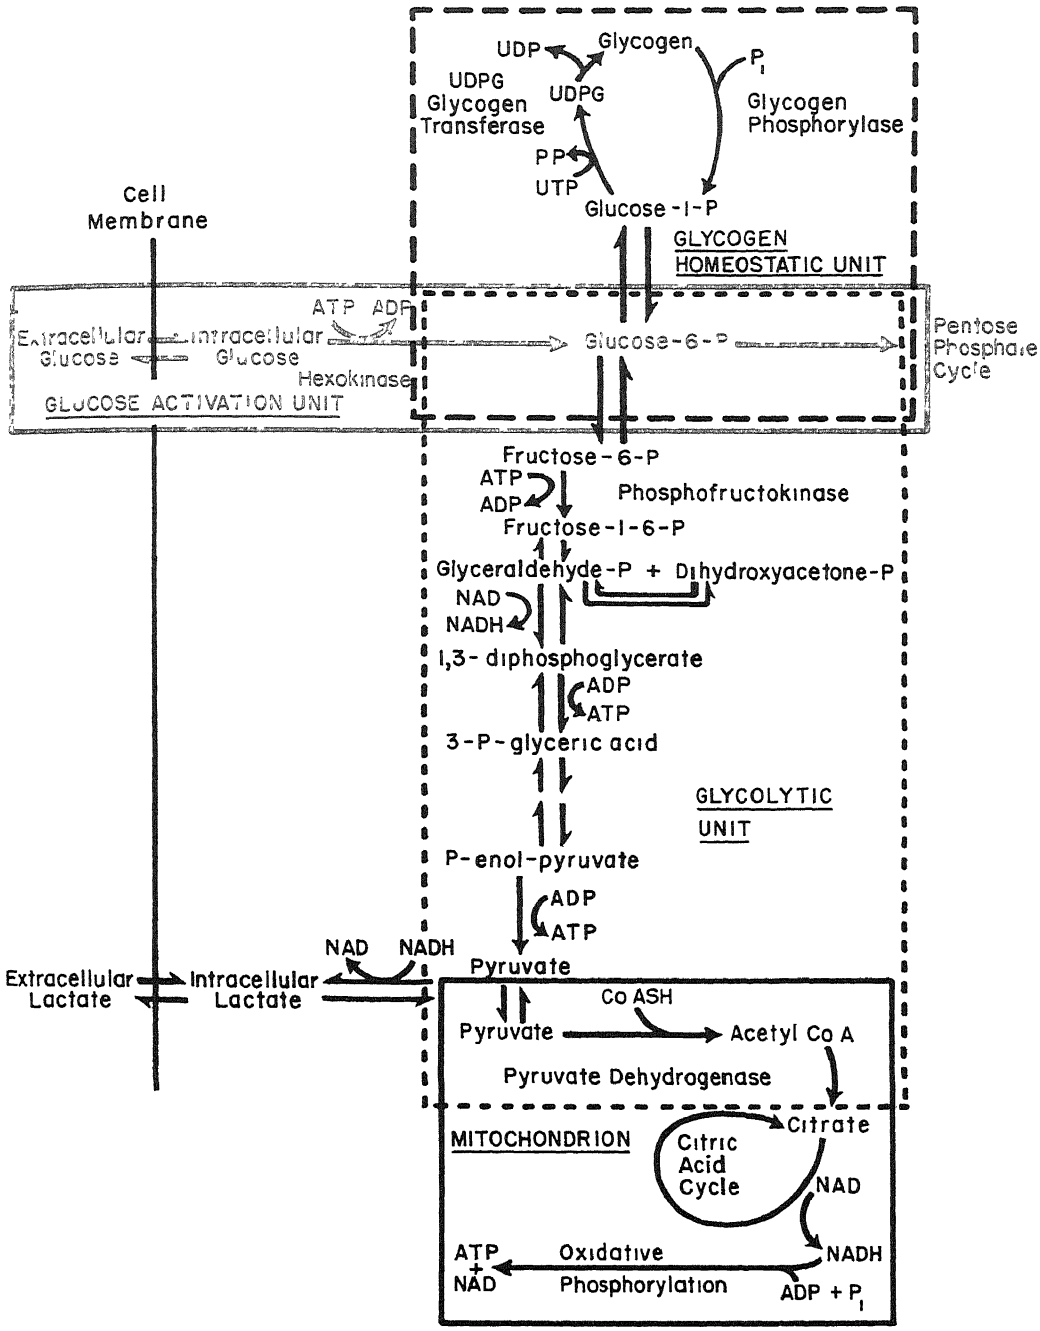

Fig 7 88 Glycolytic control units

When synthesis is stimulated, glycogenolysis is inhibited and visa versa Acetyl CoA represents the next major branch in glycolysis after glucose-6-P and the series of reactions from glucose-6-P to acetyl CoA is regulated as a glycolytic unit Acetyl CoA can be oxidized through the citric acid cycle or can be used for synthetic processes Conversion of pyruvate to lactate does not represent a major branch point in glycolysis Lactate production in anaerobic muscle provides a mechanism for oxidizing the NADH produced at the glyceraldehyde-3-P reaction and allows glycolytic production of ATP to continue in the anaerobic

cell Lactate formed by anaerobic muscle is transported to the liver where it is converted to glucose by gluconeogenesis In aerobic tissue, the lactic dehydrogenase reaction can be reversed and the pyruvate that is produced is oxidized via the citric acid cycle

"Metabolic units" are regulated by control of one or more enzymes within the sequence of reactions, often through feedback inhibition of either the first step or the first irreversible step in the sequence The inhibitor may be the immediate product of the reaction or a more distant product of the pathway For example, hexokinase is inhibited by glucose-6-P, the immediate product of the reaction, but phosphofructokinase is inhibited by ATP, the ultimate product of glycolysis and of aerobic metabolism This enzyme is also inhibited by citrate which is synthesized from acetyl CoA and is therefore a product of glycolysis Pyruvate dehydrogenase is inhibited by acetyl CoA, the immediate product of the reaction, and by ATP, the final product of pyruvate oxidation

TYPES OF ENZYME CONTROL

Flow through a series of reactions may be controlled by several factors *1*) Availability of the initial substrate can regulate the overall rate Glucose utilization by muscle can be controlled to a significant extent by the plasma concentration of glucose The plasma concentration is in turn regulated by dietary intake and hepatic and renal production of glucose In addition, the rate of membrane transport can be modified by insulin and metabolic factors at any level of plasma glucose *2*) An important factor regulating flux through a metabolic pathway is the presence of enzymes that are under allosteric control and are strategically located within the pathway Regulatory enzymes of this type control the overall flux through a pathway or unit and also control the concentrations of intermediates within the pathway Phosphofructokinase often controls the overall rate of glycolysis and regulates the tissue levels of fructose-6-P and glucose-6-P. Regulatory enzymes catalyze nonequilibrium reactions, but not all nonequilibrium reactions are regulated A nonequilibrium reaction may be identified in the tissue by measuring the concentrations of all substrates, cofactors, and products of the reaction The ratio of the algebraic product of all concentrations of reaction products to the algebraic product of all concentrations of substrates is then compared with the same ratio measured in vitro for the purified enzyme (i e , the apparent equilibrium constant) If the in vivo ratio is less than the apparent equilibrium constant measured in vitro, the enzyme is said to catalyze a nonequilibrium reaction This indicates that some factor (allosteric regulator) present in the tissue is influencing the activity of the enzyme On the other hand, if a reaction proceeds at equilibrium, the rate increases when there is more substrate or less product and is slower when there is less substrate or more product (mass action effect), and cannot control the overall rate of a pathway *3*) Flux through a metabolic pathway may be changed by variations in the absolute amount of one or more enzymes in the pathway This mechanism appears to be important in long-term control of metabolic pathways in certain tissues In muscle, however, total activities of most of the regulatory enzymes that have been studied do not change under conditions where large changes in the rate of the reactions occur These findings indicate that carbohydrate metabolism in muscle is regulated primarily by availability of substrate and control of nonequilibrium reactions

REGULATORY REACTIONS OF THE GLUCOSE-ACTIVATION UNIT

Movement of glucose across muscle cell membranes occurs by a process called carrier-mediated transport or facilitated diffusion Glucose transport is freely reversible and serves to equilibrate intracellular and extracellular concentrations of glucose Since metabolic energy is not used, this process is an example of passive transport Active transport moves substances against a concentration gradient with the expenditure of metabolic energy Glucose transport is active only in the kidney and intestine

Passive transport of glucose is illustrated schematically in Figure 7 89 In this model, free glucose combines with a mobile protein component of the cell membrane ("carrier") The carrier itself can move through the membrane and is freely accessible to glucose on either side When glucose combines with the carrier on the outside of the cell, the complex renders glucose sufficiently lipid soluble to allow the sugar-carrier complex to pass through the lipid bilayer portion of the mem-

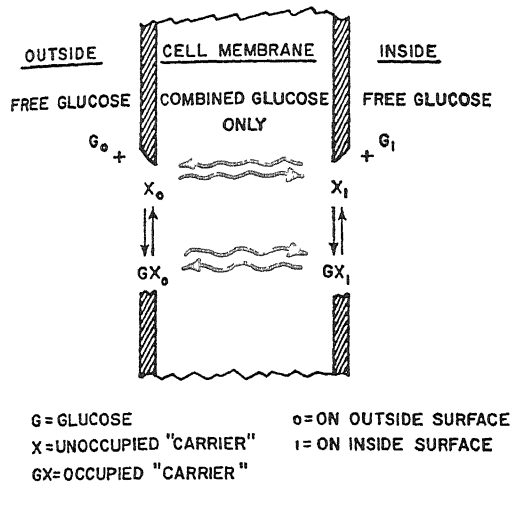

Fig 7 89 A model of passive glucose transport (From Park et al 1968)

brane The complex then dissociates and free glucose is released on the inside of the cell Intracellular glucose can combine with free carrier on the inner surface of the membrane and be transported out of the cell

Several types of experiments support this model of carrier transport *1*) Artificial lipid bilayer membranes formed from lipids extracted from cell membranes allow glucose to penetrate at a rate several hundred times slower than movement of sugar through a biological membrane Simple diffusion through the lipid bilayer, therefore, cannot account for the observed rates of glucose movement into living cells *2*) Glucose transport can be saturated as increasing concentrations of sugar are supplied This indicates that glucose combines with a component of the membrane that is present in limited amount When all of the carriers are occupied, transport is limited by the number of carriers and their mobility in the membrane *3*) Glucose transport is stereospecific as indicated by the rapid entry of D-glucose into muscle cells and by the exclusion of the L-isomer These observations also provide support for the suggestion that the carrier is a protein since proteins can selectively bind stereoisomers of small molecules *4*) Glucose transport is inhibited by sulfhydryl-blocking agents suggesting that a protein is involved in the penetration process *5*) Several sugars share the same carrier system and compete with each other for the available binding sites *6*) Countertransport, a special case of competitive inhibition, provides the strongest support for carrier mobility This phenomenon is demonstrated by allowing intracellular and extracellular concentrations of a nonmetabolized sugar, such as 3-O-methyl glucose, to equilibrate across the cell membrane and then by adding a metabolizable sugar, such as glucose, to the ouside of the cells Following addition of glucose, 3-O-methyl glucose is transported out of the cells against a concentration gradient (Fig 7 90) If both glucose and 3-O-methyl glucose are included in the buffer from zero time, entry of 3-O-methyl glucose is slower indicating that these sugars compete for the same transport system This phenomenon can be understood by reference to the carrier model (Fig 7 89) When the extracellular compartment contains only 3-O-methyl glucose, this sugar combines with the carrier and is transported into the cell where it accumulates As the concentration of 3-O-methyl glucose builds

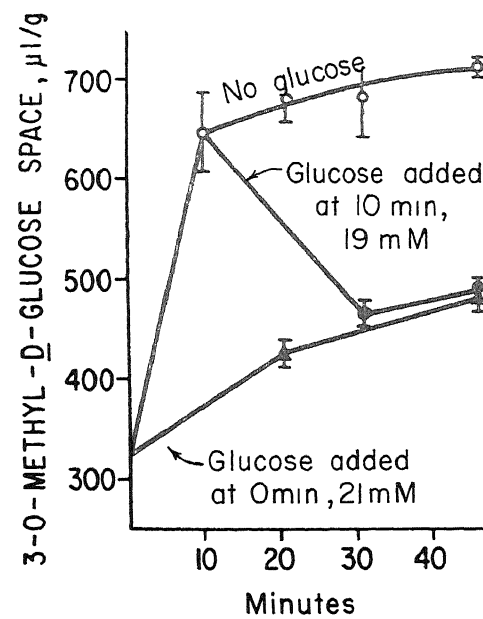

Fig 7 90 Countertransport of 3-O-methyl D-glucose in the isolated perfused rat heart on addition of D-glucose to the perfusate Hearts were perfused for the times indicated with buffer containing 3-O-methyl D-glucose-^{14}C (0 75mM) In one group of hearts perfused with 3-O-methyl glucose perfusion was switched after 10 min to buffer containing 21 mM D-glucose in addition and perfusion was continued for either 20 or 35 min (●) Additional groups were perfused with 0 75 time (▲) The vertical line through each point indicates two standard errors of the mean (From Morgan et al 1964)

up inside the cell, more sugar is available for outward transport When the concentrations are equal on both sides of the membrane, outward transport equals inward transport If glucose is now added to the extracellular compartment, it competes with 3-O-methyl glucose for binding sites on the outer surface of the membrane and reduces the inward movement of 3-O-methyl glucose As glucose is transported into the cell, however, it is phosphorylated and is not available to compete with 3-O-methyl glucose for outward transport Since more free carriers are available for binding of 3-O-methyl glucose on the inner side of the membrane than on the outer, 3-O-methyl glucose exit is faster than entrance, which results in movement of the nonmetabolized sugar against a concentration gradient Energy for this movement comes from the glucose concentration gradient

Transport is a major rate-limiting step for glucose utilization and control at this point often regulates the entire pathway In the absence of insulin, extracellular glucose can be abnormally high and yet the intracellular glucose concentration remains so low that it cannot be measured Under these conditions, transport is a nonequilibrium reaction and limits overall glucose utilization since hexokinase can phosphorylate glucose only as fast as transport supplies the sugar When transport is stimulated by insulin, free glucose may build up in the cell, which allows transport to operate near equilibrium and shifts the restraint on glucose activation to the hexokinase reaction Transport is regulated by a number of factors in addition to insulin as illustrated in Table 7 11) In these experiments, the rate of equilibration of intracellular water with 3-O-methyl glucose during 7 min of perfusion functions as an index of transport rate Transport occurs at a slow rate in aerobic hearts that are developing low levels of ventricular pressure (60 mm Hg) An even lower rate is seen when palmitate is added to the perfusate The increase in muscular work associated with greater ventricular pressure development (100 mm Hg) accelerates 3-O-methyl glucose entry, but this acceleration is blocked if palmitate is present in the perfusate Insulin accelerates sugar transport, but the hormone effect is less if palmitate is present. Perfusion of the heart under anaerobic conditions accelerates entry of sugar into the cells. Palmitate does not interfere with the anaerobic stimulation of transport which suggests that fatty acid must be oxidized to inhibit this step in glucose metabolism These studies indicate that transport is regulated by insulin, muscular work, availability of fatty substrates, and degree of oxygenation of the heart These factors interact to produce a fine control of transport rate

Table 7 11
Effects of ventricular pressure development substrates anoxia and insulin on 3-O-methyl glucose transport in perfused rat hearts

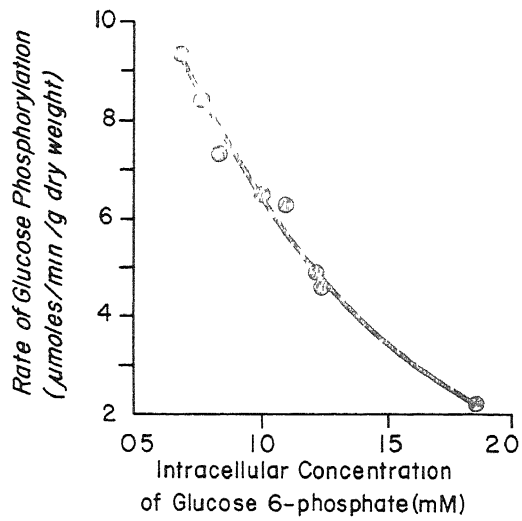
From Neely et al , 1969

The molecular mechanisms involved in control of transport are unknown The action of insulin is thought to involve binding of the hormone to the outer surface of the cell membrane where it modifies the membrane components in such a way that the glucose-carrier complex can move through the membrane at a faster rate Acceleration of glucose transport by hypoxia or muscular work and inhibition of the process when fatty acids are oxidized are thought to be mediated by changes in intracellular levels of specific activators or inhibitors of transport Muscular work not only accelerates glucose transport in the absence of insulin but renders the transport process more sensitive to suboptimal concentrations of the hormone This combination of a direct acceleration by muscular work and increased sensitivity to insulin may explain the improved utilization of glucose by diabetics during exercise

Once glucose is within the cell, it must be

phosphorylated before it can be utilized further This reaction is catalyzed by hexokinase An important physiological property of this enzyme is inhibition by glucose-6-P (Crane and Sols, 1953) When the supply of glucose-6-P is more than adequate to meet the needs of the cell, the level increases and regulates its own production by inhibiting hexokinase The relationship between the rate of glucose phosphorylation and intracellular glucose-6-P concentration is shown in Figure 7 91



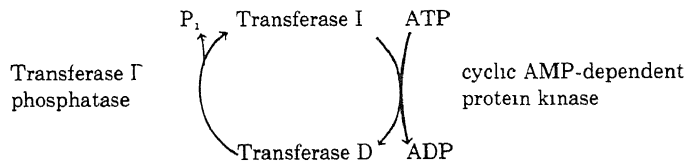


Fig 7 91 Relationship between intracellular glucose 6-phosphate concentration and rate of glucose phosphorylation in perfused rat heart (From England and Randle 1967)

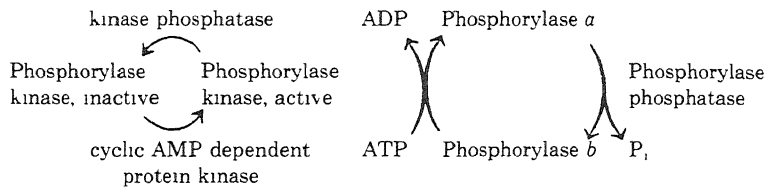
GLYCOGEN HOMEOSTATIC UNIT



Glucose-6-P occupies the first branch point in glucose metabolism For glycogen synthesis it is first converted to glucose-1-P which combines with uridine triphosphate (UTP) to form uridine diphosphoglucose (UDPG) (Fig 7 88) The glucosyl unit of UDPG is transferred to glycogen by UDPG-glycogen transferase This enzyme is the site of regulation of glycogen synthesis by both hormonal and nonhormonal factors Transferase is a complicated enzyme which exists in two forms, transferase D and transferase I The D form is dependent upon the presence of glucose-6-P for activity while the I form has activity independent of this regulator The activity of the D form is inhibited by ATP so that variations in tissue levels of ATP and glucose-6-P increase or decrease the activity of this form Another important mechanism for control of transferase activity is interconversion of the two forms of the enzyme, as follows

Transferase I is phosphorylated to the D form by a protein kinase that is dependent upon cyclic adenosine monophosphate (cyclic AMP) Conversion of D to I involves dephosphorylation of the D form by a specific phosphatase These second-stage interconverting enzymes are the sites of much of the hormonal and nonhormonal control of glycogen synthesis Epinephrine causes net glycogenolysis by increasing intracellular cyclic AMP which activates conversion of transferase I to D and, as will be discussed, conversion of phosphorylase *b* to *a* Insulin increases glycogen synthesis by two mechanisms *1*) Conversion of transferase to the I form appears to be an effect of the hormone on protein kinase to increase its dependence on cyclic AMP, and thus to decrease its activity Increased levels of transferase I result (Fig 7 92) *2*) Insulin accelerates membrane transport and provides more substrate for hexokinase which increases the level of glucose-6-P The higher levels of glucose-6-P increase the activity of transferase D and, as will be discussed, reduce the activity of phosphorylase *b*

The net effect of insulin in the intact tissue is to increase glycogen levels The second-stage interconverting enzymes are also under nonhormonal control Increased levels of glycogen inhibit the phosphatase and reduce the amount of transferase in the I form (Fig 7 93) These changes decrease the rate of glycogen synthesis and set an upper limit on the level of glycogen that the cell can attain

Glycogenolysis is catalyzed by glycogen phosphorylase This enzyme, like UDPG-glycogen transferase, exists in two forms, phosphorylase *a* and *b*

Phosphorylase *b* is the dephosphorylated form and is active only in the presence of 5'AMP The *b* form is phosphorylated by a specific kinase enzyme, that requires Ca^{++}, and is converted to phosphorylase *a* The *a* form is active in the absence of 5'AMP Phosphorylase, like transferase, is subject to both hormonal and nonhormonal control

Many of the regulatory enzymes that exist in two forms have been called active and inactive In general, this is an unfortunate misnomer because both forms of the enzymes are capable of catalyzing their respective reactions The term "active" really means that this form of the enzyme is independent of control by allosteric regulators The so-called inactive form is inactive under some conditions that exist in cells because of the presence of allosteric inhibitors For example, phosphorylase *b* is activated by 5'AMP and is capable of as much activity per unit of enzyme protein as phosphorylase *a* This activity is not expressed in the tissue, however, because of high levels of inhibitors (ATP and glucose-6-P) normally found in cells With decreased levels of these inhibitors or increased levels of 5'AMP, phosphorylase *b* is activated (Fig 7 94) Variations in the tissue levels of ATP, AMP and glucose-6-P can control the rate of glycogenolysis by their action on phosphorylase *b* without interconversion of the enzyme forms Under most conditions phosphorylase is present in the cell predominantly in the *b* form and this mechanism appears to be important in regulating the utilization of glycogen The relationship between the tissue levels of glucose-6-P and the rate of glycogen utilization in heart muscle is shown in Figure 7 95 The tissue level of glucose-6-P was altered by perfusing hearts with various substrates When the level of glucose-6-P is low, glycogen breakdown is fast and, when glucose-6-P is high, net glycogen synthesis occurs This relationship between glucose-6-P and glycogen is due to effects of glucose-6-P on both activation of UDPG-glycogen transferase and inhibition of phosphorylase b

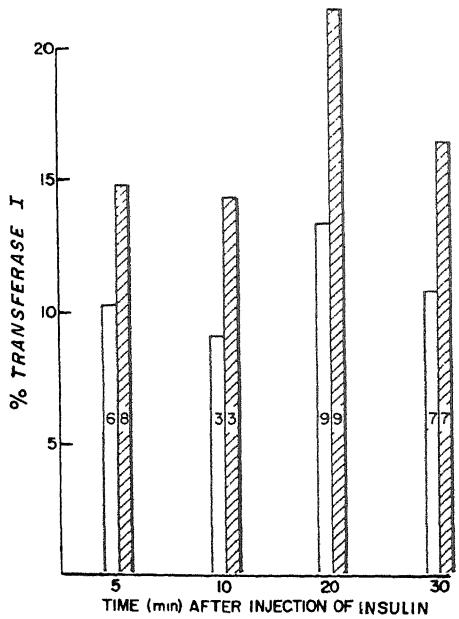


Fig 7 92 Per cent transferase I activity in extracts of rat skeletal muscle after intraperitoneal injection of saline (unshaded bars) or insulin (shaded bars) The numbers of experiments in each group are indicated (From Larner et al , 1968)

Interconversion of phosphorylase *a* and *b* is also an important physiological regulatory mechanism The activity of phosphorylase *b* is expressed as a defense against low energy levels in the cell only after the fact In contrast, phosphorylase activity and glycogen utilization increases in anticipation of energy requirements by converting the enzyme to the *a* form Phosphorylase *a*, the so-called active form is not subject to allosteric regulation as is the *b* form (Fig 7 94) By conversion to the *a* form, phosphorylase activity can be increased even in the presence of high levels of ATP and glucose-6-P and before there is an actual energy deficit Epinephrine is released into the blood in anticipation of muscular activity (flight-or-fight response) and this hormone promotes glycogenolysis by bringing about conversion of phosphorylase to the *a* form This action of epinephrine is mediated through increased levels of cyclic AMP in the tissue as indicated by the temporal sequence of changes in cyclic AMP and phosphorylase activity (Fig

7 96) The second-stage interconverting enzyme, phosphorylase kinase, also exists in two forms, so-called active and inactive A third-stage interconverting enzyme, protein kinase, phosphorylates inactive phosphorylase kinase and in so doing converts it to the active form This third-stage enzyme is activated by cyclic AMP With epinephrine treatment, the level of cyclic AMP is elevated and protein kinase is activated This enzyme then converts inactive phosphorylase kinase to the active form Phosphorylaese kinase catalyzes the phosphorylation of phosphorylase *b* and converts it to the *a* form which in turn brings about an increased rate of glycogenolysis

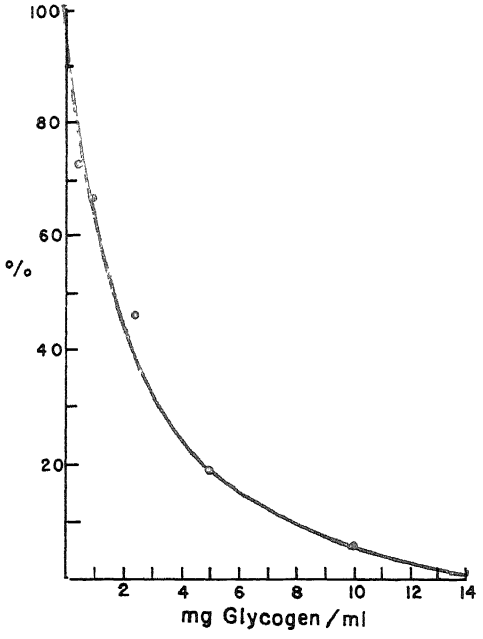

Fig 7 93 The inhibition of transferase phosphatase by glycogen (From Larner et al 1968)

Muscular contraction itself caused an increased conversion of phosphorylase to the *a* form in skeletal muscle In Figure 7 97 is shown a time course of phosphorylase conversion to the *a* form after onset of muscular contraction Two factors may account for this conversion of phosphorylase *b* to *a* during muscular contraction *1*) Phosphorylase *b* kinase is activated by calcium and depolarization of the muscle cell membrane releases calcium into the sarcoplasm (Krebs et al, 1968) The so-called inactive form of phosphorylase *b* kinase is activated by magnesium There is very little free magnesium in the cell and most of the ATP is in the form of ATP-Mg^{++} complex With ATP breakdown during muscular contraction, the free magnesium released from the ATP-Mg^{++} complex may activate phosphorylase *b* kinase (Villar-Palasi and Wei, 1970)

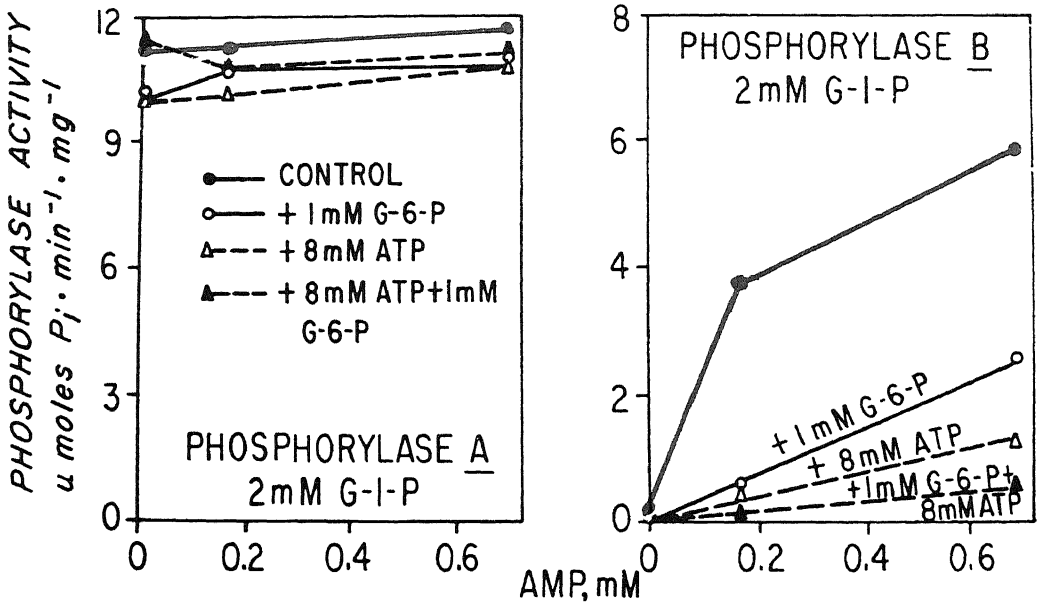

Fig 7 94 Effect of ATP and glucose-6-P on activity of phosphorylases *a* and *b* at various levels of AMP Assays were performed in the direction of glycogen synthesis by measuring release of inorganic phosphate (From Morgan and Parmegiani 1964)

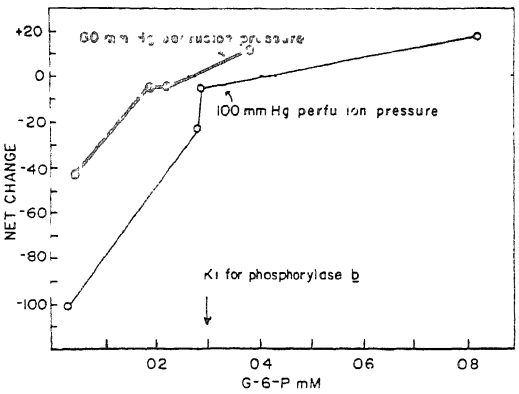

Fig 7 95 Relationship between net glycogen change and glucose 6 P concentration in perfused rat heart (From Neely et al 1968)

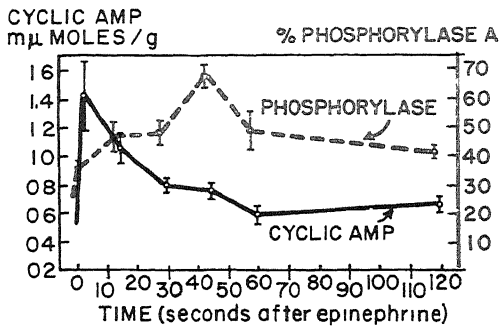

Fig 7 96 Effect of epinephrine on cyclic AMP concentration and phosphorylase activity in isolated rat hearts (From Robison et al 1965)

CONTROL OF THE GLYCOLYTIC UNIT

Phosphofructokinase catalyzes the first irreversible step in the glycolytic unit (glucose-6-P to acetyl CoA) Phosphofructokinase is a classic example of a regulatory enzyme and its activity controls the overall rate of glycolysis under many conditions The enzyme is subject to allosteric regulation by a variety of small molecules Its activity is inhibited by ATP and citrate (Fig 7 98) and is accelerated by P_i, 5'AMP, adenosine diphosphate (ADP), and cyclic AMP (Fig 7 99) This is the primary site of glycolytic inhibition by aerobic respiration When oxidative metabolism is proceeding normally, the tissue level of ATP is high and the levels of ADP, AMP, and P_i are low and phosphofructokinase is inhibited Inhibition of glycolysis by oxidation of fatty acids involves high tissue levels of ATP and citrate and low levels of AMP and P_i When the oxygen supply to muscle is limited, phosphofructokinase is activated by decreased levels of ATP and increased levels of 5'AMP and P_i

Pyruvate dehydrogenase catalyzes the conversion of pyruvate to acetyl CoA in the mitochondria Pyruvate dehydrogenase is a complex enzyme which is subject to allosteric control Activity of the enzyme is inhibited by high levels of NADH and acetyl CoA, both of which are products of the reaction (Randle et al, 1966) The enzyme is also inhibited by

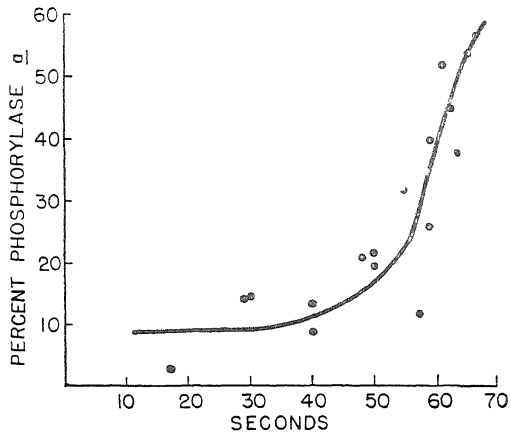

Fig 7 97 Time course of appearance of phosphorylase *a* in response to repetitive stimulation of frog sartorii at 20° C The muscles were stimulated 6 times per second with 15 volt shocks of 2 msec duration to contract against a 2-g preload The series of contractions was halted by freezing at the indicated time (From Danforth and Helmreich 1964)

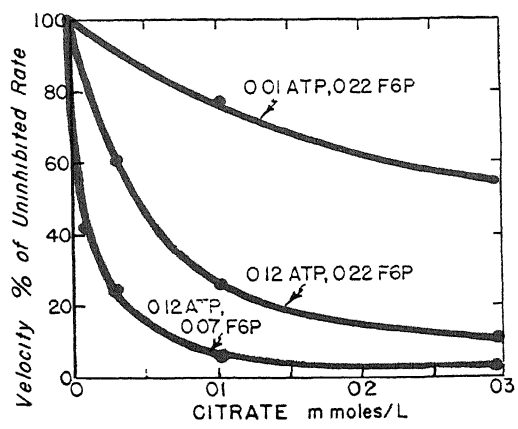

Fig 7 98 Velocity of phosphofructokinase as a function of citrate concentration at several ATP and fructose-6-P levels (From Passonneau and Lowry 1963)

ATP, the end product of pyruvate oxidation β-Oxidation of fatty acids is the major source of acetyl CoA in the mitochondria and, therefore, supplies a direct inhibitor of pyruvate dehydrogenase Inhibition by acetyl CoA and NADH has an important function in anaerobic muscle If oxygen supply is limiting, acetyl CoA cannot be used by the citric acid cycle and its production from pyruvate is inhibited NADH cannot be oxidized in the anaerobic tissue and its level builds up Inhibition of pyruvate dehydrogenase results in a higher level of pyruvate which is converted to lactate by lactic dehydrogenase This conversion of pyruvate to lactate reoxidizes the NADH produced in glycolysis and allows glycolysis to continue with anaerobic production of ATP

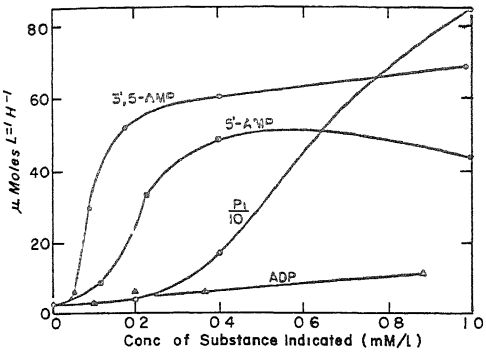

Fig 7 99 Effect of P_i 5′ AMP ADP and cyclic AMP on the activity of phosphofructokinase The other concentrations of reactants were ATP 2 3 mM Mg 5mM fructose-6-P 0 1mM The P concentrations as indicated are drawn to a 10-fold smaller scale (From Passonneau and Lowry 1962)

Pyruvate dehydrogenase, like UDPG-glycogen transferase and phosphorylase, is regulated by a phosphorylation-dephosphorylation mechanism (Reid, 1969) Phosphorylation, which is catalyzed by pyruvate dehydrogenase kinase, inactivates the enzyme while dephosphorylation by pyruvate dehydrogenase phosphatase activates the enzyme Activation of pyruvate dehydrogenase from pig heart is stimulated by cyclic AMP (Wieland and Siess, 1970) Pyruvate dehydrogenase and pyruvate metabolism may, therefore, be under hormonal control by interconversion of two forms of the enzyme

Table 7 12
Effects of various physiological states on glucose utilization by heart muscle[a]

Physiological State	Glucose-Activation Unit	Glycogen-Homeostatic Unit	Glycolytic Unit
Fasting, uncontrolled diabetes, hypophysectomized diabetic animal treated with growth hormone and cortisone	Slow due to low plasma insulin and high free fatty acids, impaired sensitivity to insulin	Stores glycogen due to high glucose-6-P levels resulting from inhibition of the glycolytic unit at phosphofructokinase	Inhibited at phosphofructokinase and pyruvate dehydrogenase by high levels of citrate and acetyl CoA
Hypophysectomized-diabetic animal	Slow due to low plasma insulin but insulin sensitivity is increased	Uses glycogen due to low glucose-6-P levels	Lower levels of citrate and acetyl CoA allow glycolysis to proceed
Increased heart work	Fast due to effect of heart work on transport and increased insulin sensitivity These effects may be blocked if free fatty acid levels are high	Uses glycogen due to low glucose-6-P levels which result from activation of the glycolytic unit	Activated by lower tissue levels of citrate and acetyl CoA and higher levels of P_i
Hypoxia resulting from coronary insufficiency	Fast due to stimulation of glucose transport and to increased sensitivity to insulin	Uses glycogen due to lower ATP and glucose-6-P levels and to higher levels of AMP and P_i	Activated by lower tissue levels and ATP and higher levels of P_i and 5′AMP

[a] Changes are related to activities of the various units in the postabsorptive state

Integrated Control of Carbohydrate Metabolism

Regulation of the glucose-activation, glycogen-homeostatic, and glycolytic units is integrated to allow for production of ATP as needed but to prevent useless consumption of glucose. As summarized in Table 7.12, fasting, uncontrolled diabetes, and hormone-treated hypophysectomized diabetic animals are characterized by slow rates of glucose utilization resulting from low plasma levels of insulin and high levels of free fatty acid. Inhibition of both the glycolytic and glucose-activation units is present. The heart stores much of the glucose that is taken up as glycogen due to high tissue levels of glucose-6-P. Plasma of hypophysectomized diabetic animals does not contain as much free fatty acid so that both glucose activation and glycolysis can proceed at a faster rate. These animals are characterized by large variations in the rate of glucose utilization due to greatly increased sensitivity of transport to stimulation by insulin. Increased heart work and hypoxia are characterized by activation of all three units. The work effect can be blocked by high levels of fatty acids but the effect of hypoxia cannot.

Regulation of carbohydrate metabolism in skeletal muscle is similar to regulation in heart muscle in most respects. The major difference is in the extent to which fatty acid oxidation is able to inhibit the glucose-activation and glycolytic units. In heart muscle, fatty acid is a powerful inhibitor while in skeletal muscle, oxidation of this substrate does not account for as large a percentage of oxygen consumption and does not result in as profound an inhibition of carbohydrate metabolism. As a consequence, skeletal muscle of fasting or diabetic animals uses more glucose and stores less glycogen than heart muscle.

11 / CONTROL OF FATTY ACID METABOLISM IN ADIPOSE TISSUE

Adipose tissue contains the largest store of fuel of any tissue in the body The average person carries a 40-day reserve which is stored as triglycerides (Dole, 1965) The major physiological function of adipose tissue is maintenance of blood free fatty acid (FFA) levels to insure a constant supply of oxidizable substrate This function involves *1*) removal of fatty acids and their precursors from plasma, 2) storage of these fuels as triglycerides during periods of substrate excess, and *3*) breakdown of triglycerides with release of FFA into the plasma during periods of increased energy demands or deficiency of exogenous substrates The major metabolic pathways that are involved in fatty acid metabolism in adipose tissue are outlined in Figure 7 100 Most of the conversion of glucose to fatty acids that occurs in the body occurs in this tissue Fatty acids which have been synthesized by the liver or absorbed by the intestine are also taken up and stored as triglyceride Fatty acids are present in plasma either as the FFA-albumin complex or as triglycerides attached to lipoproteins or present in chylomicrons Lipoprotein lipase hydrolyzes serum triglycerides at the capillary membrane to give FFA and glycerol Upon appropriate metabolic or hormonal signals, stored triglyceride which is present in the fat cell can be hydrolyzed and the fatty acid and glycerol returned to the plasma

Storage of excess calories in the form of triglyceride rather than carbohydrate or protein has several advantages Oxidation of protein or carbohydrate yields about 4 kcal /g , whereas oxidation of fatty acids yields 9 kcal /g Storage of protein or carbohydrate also requires accumulation of intracellular water while triglyceride may comprise as much as 90% of the net weight of adipose tissue (Cahill et al , 1970) In terms of tissue accumulated per calorie, there is about 1 g /kcal for carbohydrate or protein and about 0 1 g /kcal for fat This difference in caloric content is reflected in body weight loss during fasting For the 1st day or two a person uses more carbohydrate and protein and looses weight rapidly, but upon extended fasting a larger portion of the metabolic needs are derived from fatty acids and the rate of weight loss decreases During even the early stages of fasting, however, a major part of the CO_2 produced by the body comes from oxidation of fatty acids directly or from oxidation of ketone bodies that are derived from fatty acids (Fig 7 101) As starvation progress, all of the substrate oxidized by carcass and viscera comes from fatty acids and ketoacids while about ⅔ of the substrate used by brain is derived from ketoacids (Fig 7 102)

This chapter will be concerned with the regulation of fatty acid synthesis, storage, and mobilization in adipose tissue by hormonal and nonhormonal mechanisms For a detailed discussion of this topic, the student is referred to two recent publications (Renold and Cahill, 1965, Jeanrenaud and Hepp, 1970)

REGULATION OF FATTY ACID SYNTHESIS

Since the function of the adipocyte is storage and mobilization of lipids, metabolic activity of the cell is specially adapted for this function and consequently some regulatory mechanisms are more pronounced or even unique to this tissue Glucose is the precursor of greatest physiological importance for lipid synthesis It is used as a source of acetyl CoA, energy and reducing power for fatty acid synthesis, and as a source of α-glycerol-P for fatty acid esterification (Fig 7 100) Insulin plays a dominant role in regulating lipogenesis by its action on glucose transport Low levels of insulin increase the conversion of ^{14}C-glucose to fatty acids (Fig 7 103) This effect of insulin is

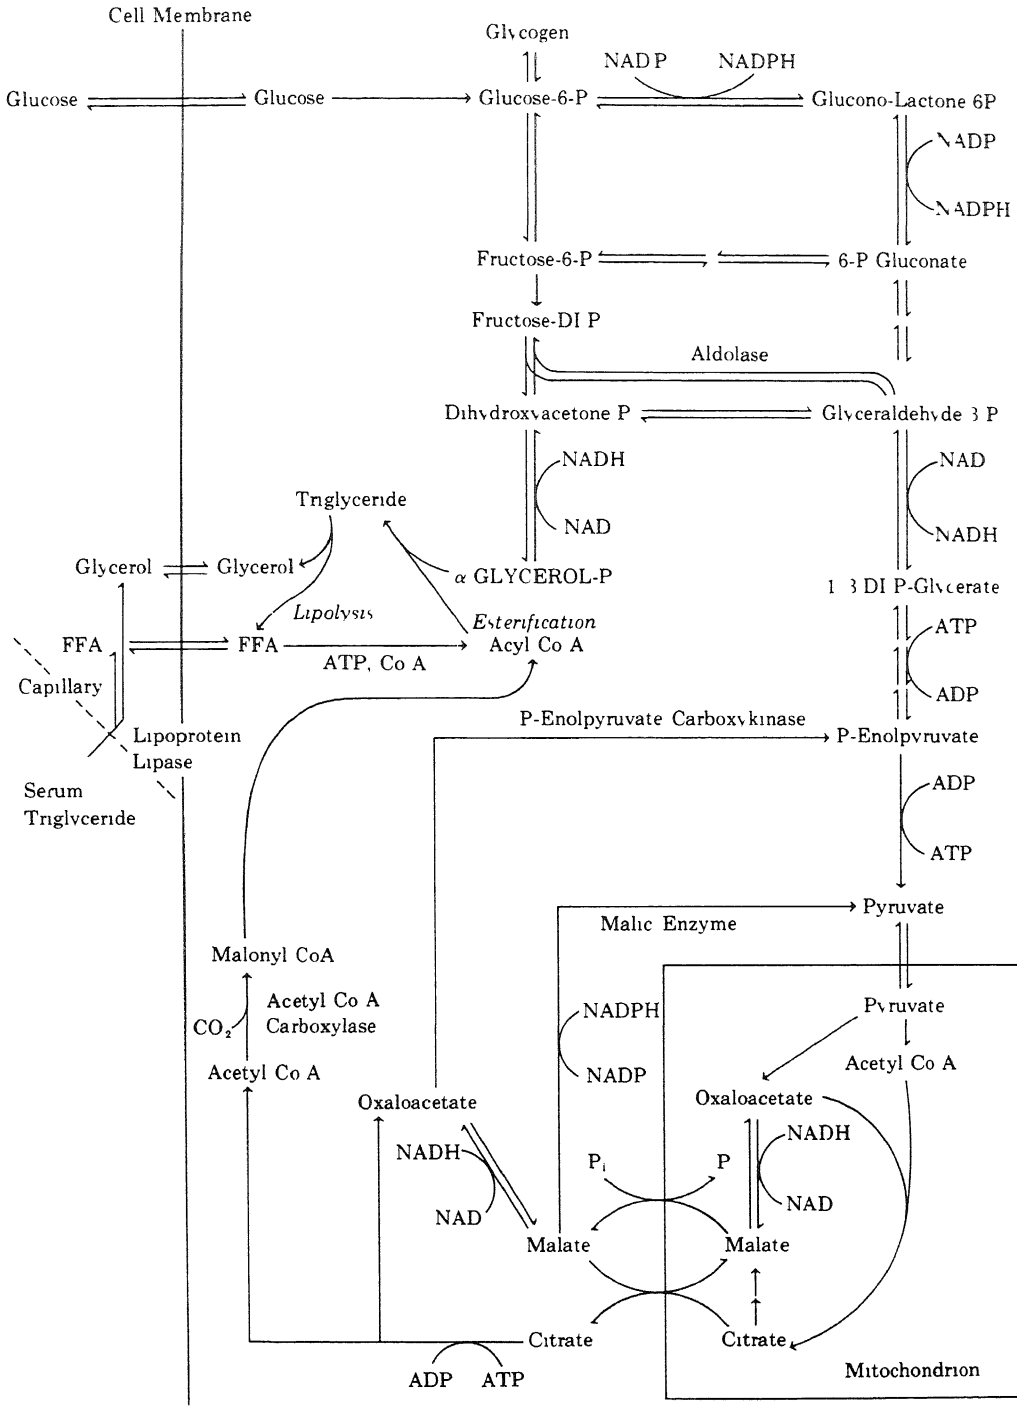

Fig 7 100 Pathways regulating fatty acid metabolism in adipose tissue

associated with an increased glucose uptake The effect of insulin on fatty acid synthesis is greatly reduced in fasting animals The mechanism of the reduction will be discussed presently Other steps in glucose utilization may be controlled by hormones For example, epinephrine increases glucose uptake in conjunction with activation of lipolysis This effect

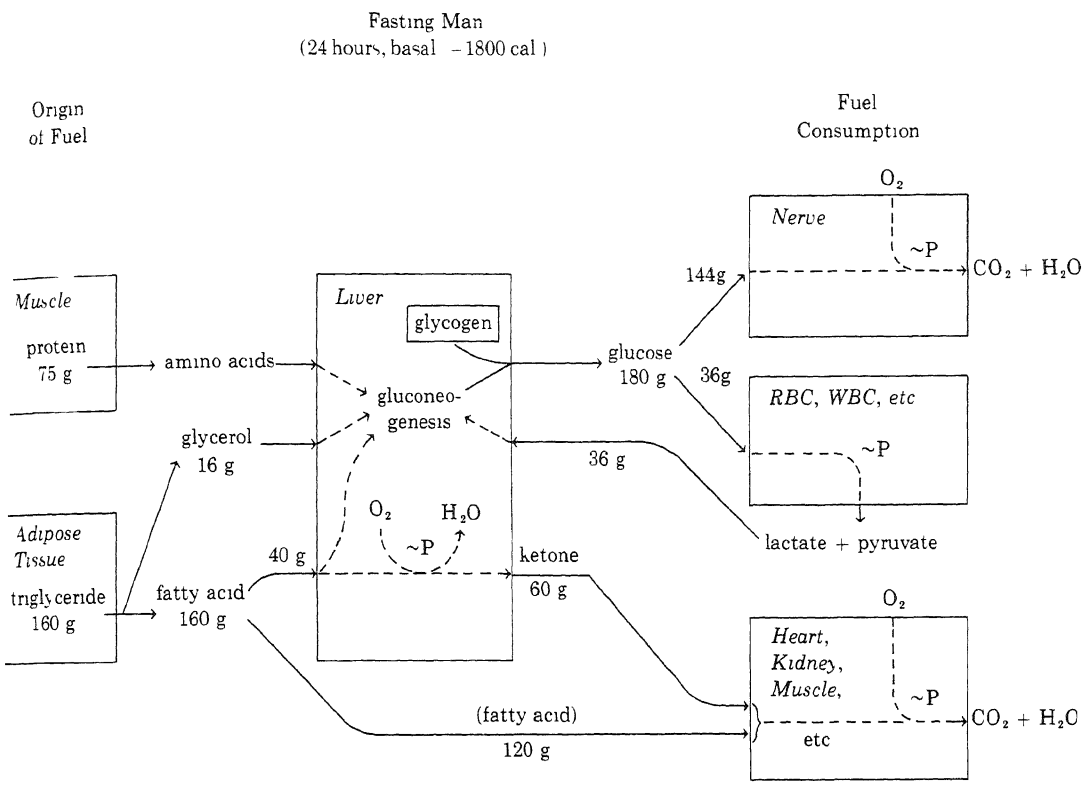

Fig 7 101 Generalized scheme of daily fuel metabolism in a fasting man (From Cahill et al 1970)

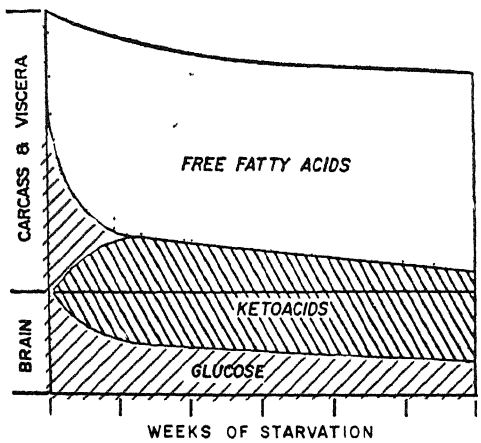

Fig 7 102 Substrate oxidation in fasting man Schematic representation of the transition from glucose to fatty acid utilization by the carcass and viscera and from glucose to ketoacids by the brain (From Cahill et al 1970)

involves activation of phosphofructokinase by decreased levels of adenosine triphosphate (ATP) and increased levels of cyclic adenosine monophosphate (cyclic AMP) This enzyme, like that discussed for muscle, is inhibited by ATP and citrate and is activated by cyclic AMP, AMP, adenosine diphosphate (ADP), and P_i (Denton and Martin, 1970)

Conversion of glucose to pyruvate occurs in the cytoplasm Pyruvate enters the mitochondria where it is converted to acetyl CoA Since fatty acid synthesis occurs in the cytoplasm, transport of acetyl CoA out of the mitochondria must occur (Fig 7 100) Mitochondrial membranes are impermeable to acetyl CoA which necessitates conversion of this lipid precursor to other compounds that can penetrate the membrane Conversion to acetyl carnitine, catalyzed by acetyl CoA-carnitine transferase, accounts for only a small per cent of acetyl transfer due to low activity of the enzyme The major mechanism for transport of acetate units involves conversion to citrate which is transported to the cytoplasm in exchange for malate (Fig 7 100) Citrate is converted to acetyl CoA and oxaloacetate in the cytoplasm by an ATP-dependent citrate lyase Transport of acetyl CoA from mitochondria to cytoplasm does not limit conversion of glucose to fatty acid (Flatt, 1970) This conclusion is based on the observation that addition of pyruvate in

the presence of glucose increases fatty acid synthesis indicating that the capacity of mitochondria to synthesize and export acetyl CoA is greater than the rate observed with glucose alone

Oxaloacetate arising from citrate cleavage must be transported back into the mitochondria to sustain citrate synthesis Conversion to malate in the cytoplasm, which is then exchanged for more citrate, serves to *1)* maintain the intramitochondrial pool of citric acid cycle intermediates, and *2)* to shuttle reducing power into the mitochondria When glucose is converted to fatty acids, production of reduced nicotinamide adenine dinucleotide (NADH) in the cytoplasm exceeds its utilization (Flatt, 1970) Excess reducing power is transferred to

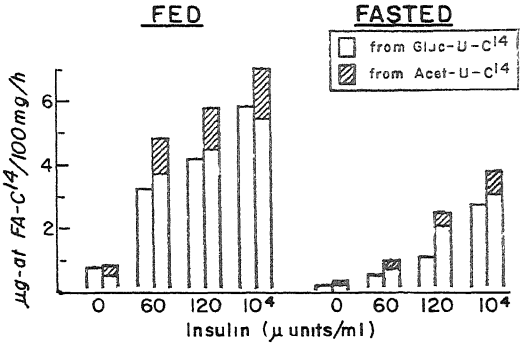

Fig 7 103 Incorporation of glucose-C and acetate-C into fatty acid by adipose tissue of fed rats or rats starved for 48 hr In each pair of columns open areas show the incorporation of glucose-C during incubation with glucose-U-^{14}C (left column) or with glucose-U-^{14}C in the presence of unlabeled acetate (right column) Incubation with unlabeled glucose and acetate-U-^{14}C in the medium gave the incorporation shown by hatched areas these are represented on the top of the right-hand column to show the total rate of fatty acid synthesis in the presence of the two substrates (From Flatt 1970)

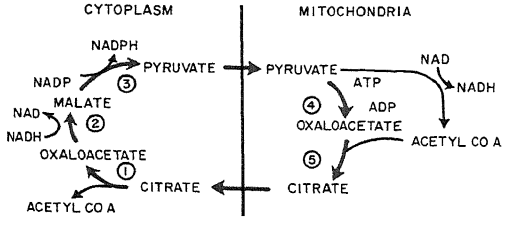

Fig 7 104 Malate cycle Enzymes involved in the cycle are indicated as follows *1)* citrate lyase *2)* malic dehydrogenase, *3)* malic enzyme *4)* pyruvate carboxylase- and *5)* citrate synthetase (Adapted from Flatt 1970)

the mitochondria by converting oxaloacetate to malate in the cytoplasm and malate back to oxaloacetate in the mitochondria (Fig 7 100) Only a small part of the oxaloacetate formed in the cytoplasm by citrate cleavage is needed, however, to transfer reducing power into the mitochondria (Denton and Martin, 1970) This means that there must be other mechanisms *1)* to get oxaloacetate into the mitochondria for citrate synthesis, and *2)* to get malate out of the mitochondria for countertransfer with citrate The most important pathway for transfer of oxaloacetate into the mitochondria is the "malate cycle" (Fig 7 104) Oxaloacetate produced in the cytoplasm is converted to malate by malic dehydrogenase Malate is then converted to pyruvate by NADP-malic dehydrogenase (malic enzyme) and pyruvate is carboxylated via pyruvate carboxylase to yield oxaloacetate in the mitochondria, thus completing a cycle This pathway results in transfer of reducing power from NADH to NADP in the cytoplasm where it can be used for fatty acid synthesis The activity of malic enzyme correlates with the rate of lipogenesis The activity is decreased during fasting or diabetes and is increased following insulin treatment Malate is transferred into the cytoplasm by a separate dicarboxylate carrier which involves exchange with phosphate (Fig 7 100)

Cytoplasmic acetyl CoA is converted to fatty acids by carboxylation to malonyl CoA Acetyl CoA carboxylase, the enzyme catalyzing this reaction, has been proposed as a regulator of fatty acid synthesis since under some conditions it appears to be controlled by tissue levels of citrate (an activator) and fatty acyl CoA (an inhibitor) Under most conditions where there is a change in the rate of fatty acid synthesis, no consistent relationship between the levels of these effectors and the rate of fatty acid synthesis can be found Regulation at this step may be important, however, during stimulation of fatty acid synthesis by insulin In this instance, triglyceride synthesis is stimulated through increased levels of α-glycerol-P and ATP which results in lower levels of fatty acyl CoA These changes may allow acetyl CoA carboxylase to proceed faster

Reducing power for fatty acid synthesis is supplied by two processes *1)* The pentose phosphate pathway produces two molecules of NADPH for each revolution of the cycle *2)* Conversion of malate to pyruvate in the

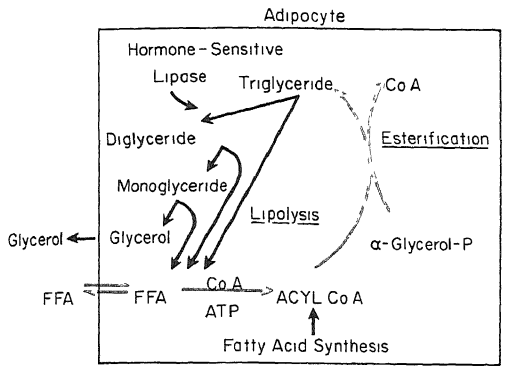

Fig 7 105 The triglyceride homeostatic unit

"malate cycle" produces one NADPH for each acetyl CoA transported out of the mitochondria (Fig 7 104) Capacity for producing cytoplasmic reducing power during conversion of glucose to fatty acid is more than is required for fatty acid synthesis (Flatt, 1970) Some of the reducing power can be used in the production of α-glycerol-P, but most of the NADH is available for ATP production by oxidative phosphorylation Unlike most synthetic pathways which utilize energy, conversion of glucose to fatty acids is an energy-generating process and with high levels of insulin, the maximal rate of fat synthesis from glucose may be limited by the tissue's ability to utilize the excess energy

TRIGLYCERIDE HOMEOSTASIS

Synthesis and hydrolysis of triglycerides involve separate synthetic and degradative pathways that are termed esterification and lipolysis, respectively The two pathways form a cyclic process of synthesis and breakdown which is in a dynamic state at all times (Fig 7 105) Net release or deposition of FFA depends on the relative rates of the two pathways Each triglyceride contains 3 molecules of fatty acid esterified to the hydroxyl groups of one glycerol molecule FFA must be activated to form fatty acyl CoA at the expense of ATP before esterification occurs The driving energy for esterification is furnished by hydrolysis of these high energy CoA bonds and of the high energy phosphate bond of α-glycerol-P Hydrolysis of triglyceride yields fatty acid and glycerol in a ratio of three to one Enzymatically, this process occurs in a steplike manner, one fatty acid being released at a time A separate enzyme is responsible for each step As a group, these enzymes are called lipases

Regulation of esterification occurs primarily by indirect mechanisms related to production of substrates α-glycerol-P is required for esterification and must be produced from glucose or pyruvate since glycerol kinase, the enzyme responsible for direct phosphorylation of glycerol, is not present in adipose tissue The action of insulin to increase esterification can be explained in part by increased levels of α-glycerol-P secondary to increased glucose transport and higher levels of dihydroxyacetone-P and NADH Another source of α-glycerol-P is by a process called "glyceroneogensis" by analogy to gluconeogenesis Adipose tissue has the capacity to carry out the reactions of the gluconeogenic pathway as far as production of fructose-di-P (Fig 7 100) Fructose diphosphatase is not present so that formation of glucose or glycogen cannot occur The series of reactions involved in glycereoneogenesis is as follows

$$\text{pyruvate} \rightarrow \text{oxaloacetate} \xrightarrow{\text{P enol pyruvate carboxykinase}} \rightarrow \rightarrow \rightarrow$$

$$\text{P-enol pyruvate} \rightarrow \text{dihydroxyacetone-P} \downarrow \alpha\text{-glycerol-P}$$

This pathway is probably utilized only during glucose deficiency such as starvation or diabetes and functions to protect the cell against uncontrolled breakdown of triglycerides (Table 7 13) Increased conversion of pyruvate to glycerol is accompanied by increased activity of P-enol pyruvate carboxykinase which indicates that this enzyme may be an important regulator of glyceroneogenesis Addition of pyruvate to adipose tissue, in vitro, reduces the rate of FFA release by increasing esterification which can be accounted for by increased formation of α-glycerol-P (Reshef et al , 1970) Since fructose diphosphatase is not present in adipose tissue, conversion of triose-P to fructose-di-P during glyceroneogenesis is unnecessary This conversion is prevented by a decline in the activity of aldolase during fasting or diabetes

Fatty acids for esterification are supplied from three main sources. *1*) synthesis from glucose, *2*) uptake from blood, and *3*) hydrolysis of stored triglyceride Regulation of the activity of lipoprotein lipase is involved in controlling the supply of fatty acids from the

Table 7 13
Glyceroneogenesis in adipose tissue in fasting and diabetes[a]

Treatment	Pyruvate Incorporation		Enzyme Activity

*Pyruvate incorporation was measured by incubation of rat epididymal fat tissue for 2 hr in buffer containing ^{14}C-pyruvate To compare the incorporation values with the enzyme activities, all results are expressed in nmoles of pyruvate/min mg total tissue protein Values given are means ± S E Asterick denotes significant difference from control

blood (Robinson and Wing, 1970) This enzyme acts at the capillary endothelium to hydrolyze chylomicron and lipoprotein triglyceride to free fatty acids and glycerol (Fig 7 100) The activity is increased during incubation of adipose tissue from starved animals, which initially contains low enzyme activity (Fig 7 106) This increase can be prevented by including inhibitors of protein synthesis in the incubation If these inhibitors are added to tissue from fed rats which contain high levels of activity, a rapid decline in lipoprotein lipase occurs These findings indicate that synthesis of new enzyme or cofactor may be involved in this control mechanism In addition, insulin increases the activity of lipoprotein lipase, and epinephrine and other hormones that accelerate lipolysis inhibit the activity These hormone effects may involve changes in levels of cyclic AMP since addition of the nucleotide also inhibits lipoprotein lipase Thus, lipoprotein lipase appears to be controlled by *1)* rapid turnover of a protein component of the system, and *2)* regulation of the activity by cyclic AMP Activity is increased during periods of excess substrate supply which makes more FFA available for esterification and is decreased during starvation when lipolysis is stimulated in the fat cell

Hydrolysis of triglyceride is an important source of intracellular FFA Increased lipolysis stimulates esterification somewhat due to increased availability of fatty acyl CoA This phenomenon is seen when lipolysis is increased by epinephrine addition to fat cells Both glycerol and FFA are released, but glycerol release is relatively greater due to re-esterification of a

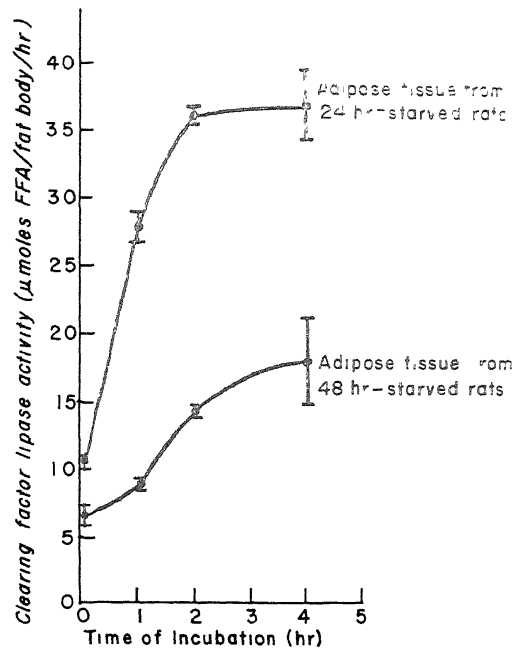

Fig 7 106 Rise in clearing factor lipase activity when adipose tissue from starved rats is incubated in vitro (From Robinson and Wing 1970)

portion of the FFA (Steinberg and Vaughn, 1965) This finding emphasizes the cyclical nature of the triglyceride homeostatic unit

Fatty acids that are supplied for esterification from the blood or from stored triglyceride must be activated to form fatty acyl CoA This reaction requires ATP and yields AMP and P-P Hormonal stimulation of lipolysis in fat cells is accompanied by a fall in ATP levels,

particularly when glucose is omitted from the incubation medium ATP levels increase markedly when glucose is added Therefore, availability of fatty acyl CoA may be regulated in two ways *1)* by control of the glycolytic and fatty acid synthetic pathways, and 2) by control of energy production within the cell

REGULATION OF LIPOLYSIS

Lipolysis can be regulated in two ways *1)* by an indirect mechanism involving changes in the production or removal of the products and substrates of the reactions, and *2)* by direct regulation of lipases FFA is an inhibitor of lipolysis Thus, dietary intake of fatty acid, increased synthesis from glucose, or hormonal activation of lipoprotein lipase will elevate intracellular levels of FFA and reduce the rate of lipolysis Direct hormonal regulation of lipolysis occurs at the level of the triglyceride lipase This is the rate-limiting enzyme in the lipolytic pathway since the hydrolytic rate from diglyceride to free glycerol is approximately 10 times faster than the rate from triglyceride to diglyceride Therefore, release of the first fatty acid is followed by a rapid complete hydrolysis to FFA and glycerol

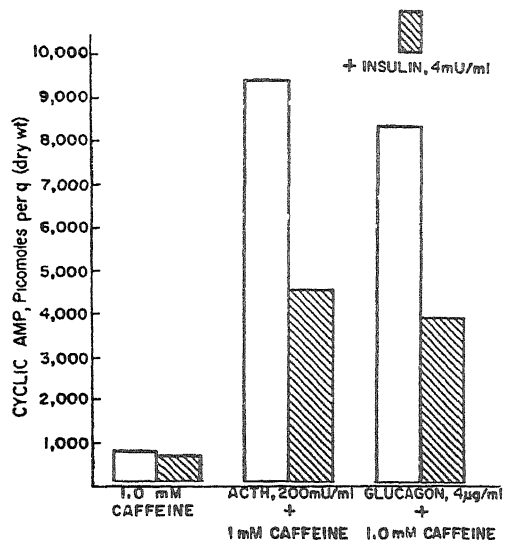
Activity of triglyceride lipase is regulated by a large number of hormones (Table 7 14) For this reason, triglyceride lipase is referred to as "hormone-sensitive lipase " There are at least 12 hormones that are known to stimulate lipolysis in adipose tissue Epinephrine, norepinephrine, glucagon, adrenocorticotropic hormone (ACTH), secretin, thyroid-stimulating hormone (TSH), and luteinizing hormone (LH) are examples of lipolytic hormones The action of these hormones is mediated by stimulation of adenyl cyclase which results in increased levels of cyclic AMP The effect of ACTH and glucagon on cyclic AMP levels and the antagonism of this effect by insulin are shown in Figure 7 107 The contention that lipolytic hormones act through increased levels of cyclic AMP is supported by the direct effect of cyclic AMP to mimic the hormonal effect In addition, agents which inhibit phosphodiesterase, the enzyme which degrades cyclic AMP, increase intracellular cyclic levels and intensify the hormonal effect The lipolytic response to hormones and cyclic AMP reaches maximum within a few minutes. In addition to activation of triglyceride lipase, lipolytic hormones accelerate glucose transport and ion fluxes across the membrane

Table 7 14
Activation of lipase activity by pretreatment of fat pads with lipolytic hormones[a]

Hormone	*n*	Lipase Activity (μmoles glycerol liberated/60 min $\times$ g fresh wt)
None	18	2 49 ± 0 84
Epinephrine 10 μg/ml	24	3 98 ± 0 81
Glucagon 4 μg/ml	12	4 34 ± 0 75
ACTH 0 2 U/ml	7	7 6 ± 0 4
TSH 10 μg/ml	3	5 8 ± 1 0

From Loffler and Weiss, 1970

[a] Lipase activity was estimated by measuring release of glycerol



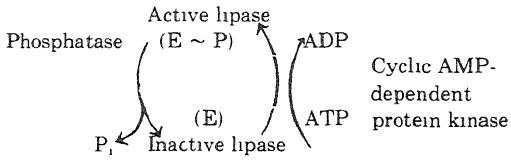


Fig 7 107 Effects of insulin on cyclic AMP levels in fat cells incubated with ACTH or glucagon Caffeine was added to minimize destruction of cyclic AMP by the phosphodiesterase (From Butcher et al 1968)

Hormone-sensitive lipase, like many other regulated enzymes, exists in active and inactive forms Activation involves phosphorylation of the inactive form that is catalyzed by a protein kinase which is dependent upon cyclic AMP (Corbin and Krebs, 1969, Hultunen et al , 1970) When activation occurs, radioactive phosphate from ATP is incorporated into the

lipase (Fig 7 108) The time course of phosphorylation parallels that for activation The following cycle of activation and inactivation is proposed for the hormone-sensitive lipase

The close similarity of this cycle to the cycle of reactions involved in control of phosphorylase activity (chap 10) should be apparent

Growth hormone and glucocorticoids also increase lipolysis but the mechanisms of action are quite different from those described for epinephrine and glucagon Growth hormone stimulates cyclic AMP production in isolated fat cells after a lag of at least 1 hr The hormone effect can be blocked by inhibitors of ribonucleic acid (RNA) and protein synthesis, indicating that new enzyme formation is involved The effect of growth hormone is increased by addition of glucocorticoids In addition to potentiating the effects of growth hormone, glucocorticoids play a "permissive" role in the effects of epinephrine, ACTH, and other hormones on lipolysis

The major antilipolytic hormone is insulin In addition to its effect on glucose transport which results in stimulation of lipogenesis, the hormone directly inhibits production of free fatty acid and glycerol in adipose tissue, even

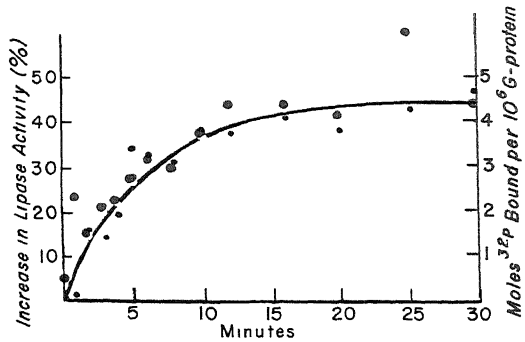

Fig 7 108 Time course of activation and phosphorylation of highly purified lipase in the presence of rabbit muscle protein kinase Aliquots were removed for determinations of lipase activity and protein-bound ^{32}P at indicated time intervals (From Hultunen et al 1970)

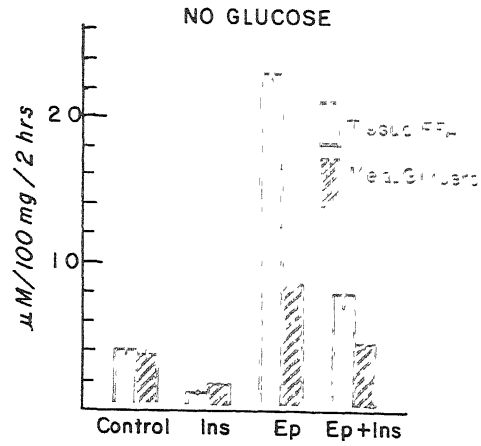

Fig 7 109 Effects of epinephrine and insulin on free fatty acid and glycerol production of adipose tissue (From Jungas and Ball 1963)

in the absence of glucose (Fig 7 109) Appearance of FFA and glycerol occurs at a low rate during control incubations, but this rate is inhibited about 50% by insulin Epinephrine accelerates production of FFA and glycerol and insulin inhibits appearance of both products This antilipolytic effect of insulin is mediated through a decrease in levels of cyclic AMP (Fig 7 107) As a result of reducing cyclic AMP levels, insulin also stimulates lipoprotein lipase The net effect, therefore, is an increase in fat deposition that is accomplished by sparing of triglyceride stores, by accelerating incorporation of plasma triglyceride into cell stores, and by accelerating conversion of glucose into fat

INTEGRATED CONTROL OF FAT METABOLISM

Control of fatty acid metabolism in adipose tissue serves to maintain a constant supply of oxidizable substrate in the plasma The major hormones involved in these controls include insulin, growth hormone, glucocorticoids, and catecholamines Net fatty acid storage or release reflects the balance between esterification and lipolysis (Table 7 15) Esterification is rapid when insulin, glucose and fatty acid are present in plasma in optimal amounts These rapid rates result from *1)* conversion of glucose to fatty acid, *2)* an optimal supply of α-glycerol-P, and *3)* increased lipoprotein lipase activity which facilitates uptake of lipid from the

Table 7 15
Integrated control of fat metabolism during fasting feeding and diabetes[a]

Physiologic States	Plasma Levels of Hormones and Substrates	Lipolysis	Esterification
Fasting, uncontrolled diabetes, hypox diabetic treated with growth hormone and cortisone	Insulin levels are low fatty acid levels are high, plasma triglycerides are high, ketone bodies are high	Stimulated due to release of insulin inhibition, together with higher levels of steroids and growth hormone Cyclic AMP levels increase	Slow due to low rate of glycolysis and fatty acid synthesis α-glycerol-P levels are low and endogenous fatty acid oxidation occurs to meet energy demands
Hypophysectomized diabetic	Insulin, ACTH, cortisone, and growth hormone levels are low Glucose levels may be high	Slower than uncontrolled diabetic due to release of lipase stimulation by pituitary and adrenal cortical hormones	Slow due to low plasma insulin Glucose conversion to fat impaired
Caloric excess	High glucose, fat, and insulin	Slow due to antagonistic effects of insulin and FFA	Fast due to increased glucose uptake resulting in conversion to α-glycerol-P and fatty acid Fatty acid taken up and esterified

[a] Changes are related to conditions in normal, fed animals

plasma Under these circumstances, lipolysis is inhibited by the antagonistic effects of insulin During starvation, insulin levels are low and growth hormone levels are elevated As a result, lipolysis is more rapid than esterification Large changes in the rates of lipolysis and esterification occur in starvation, diabetes, feeding, and in other hormone-deficiency states

12 CONTROL OF GLUCONEOGENESIS, KETOGENESIS, AND LIPOGENESIS IN

Gluconeogenesis

The central nervous system, the red blood cells, and possibly other tissues depend almost entirely on glucose as an energy source Maintenance of adequate glucose levels in the blood, on which the life of the animal depends during starvation, requires emergency and long-term adaptation systems Blood glucose is maintained during the postabsorptive state first by the breakdown of liver glycogen (glycogenolysis) and secondly by the process of glucose formation from nonglucose precursors This process is termed gluconeogenesis and is quantitatively the more important The rate of glucose production by gluconeogenesis can vary from 0 to above 300 g /24 hr in the adult human subject (Table 7 16) Only liver and kidney tissue appear to have the enzymatic capacity to carry out gluconeogenesis (Krebs, 1964, Scrutton and Utter, 1968) Based on the difference in organ weight and assuming similar overall gluconeogenic capacity in both tissues, the liver would be expected to contribute 90 to 95% of the total glucose production by the body in the postabsorptive state

GLUCONEOGENIC PATHWAY

A diagram of the gluconeogenic pathway is shown in Figure 7 110. To gain a clearer definition of the important features of the pathway, the relationship of glucose synthesis to other metabolic processes is not indicated, although such interactions may be important in the regulation of gluconeogenesis as will be discussed later Glucose can be formed from a variety of precursors which enter the gluconeogenic pathway at different points The pathway represents the major means of removing from the blood excessive quantities of lactate produced by the muscles during exercise and glycerol released from adipose tissue during fat mobilization It also represents an important catabolic pathway for many of the amino acids

Gluconeogenic tissues appear to be unique in that they possess the enzymatic potential for both glucose degradation via the glycolytic pathway and glucose synthesis Although the rate of glycolysis in these tissues is assumed to be low so that there is little impedance to the synthesis of glucose, necessity for the control of the direction of glucose metabolism is obvious The conversion of pyruvate to glucose is catalyzed by several of the enzymes of the glycolytic pathway and represents, therefore, a reversal of glycolysis There are three steps in the glycolytic pathway which are irreversible, however, and therefore different enzymes are required in order to bypass these steps in tissues that have gluconeogenic capacity The irreversible steps often represent the rate-limiting enzymes in metabolic pathways and provide key sites for regulation of glycolytic and gluconeogenic flux The thermodynamically irreversible steps of glycolysis and gluconeogenesis are shown in Figure 7 111 The enzymes that catalyze these steps in glucose synthesis from pyruvate are pyruvate carboxylase, phosphopyruvate carboxykinase, fructose-1, 6-diphosphatase and glucose-6-phosphatase Their activity is either very low or completely absent in all tissues except liver and kidney It can be seen in Figure 7 110 that the portion of the gluconeogenic pathway between pyruvate and phosphopyruvate represents a special problem since it involves both intra- and extramitochondrial reactions The enzyme pyruvate carboxylase appears to be compartmentalized within the mitochondrion Pyruvate must therefore enter the mitochondrion, perhaps by a carrier-mediated process, where it is carboxylated to oxalacetate by pyruvate carboxylase Oxalacetate must then be transferred out of the mitochondrion, since the enzyme phospho-

pyruvate carboxykinase, which converts oxalacetate to phosphopyruvate is located in the cytosol However, the mitochondrial membrane is relatively impermeable to oxalacetate so that this intermediate must be converted to aspartate, malate and/or fumarate which pass through the membrane and are reconverted to oxalacetate in the cytosol (Lardy, 1966) In the case of malate, this may also provide a reducing equivalent shuttle across the mitochondrial membrane The mitochondrial membrane is impermeable to reduced nicotinamide adenine dinucleotide (NADH) which is produced during fatty acid oxidation and which is used in the conversion of oxalacetate to malate In the cytosol malate is converted to oxalacetate yielding NADH which is then available to facilitate the conversion of 1,3-diphosphoglyceric acid to glyceraldehyde 3-phosphate (Fig 7 110)

Table 7 16
Gluconeogenesis in the postabsorptive state and after a prolonged fast

GENERAL FEATURES OF CONTROL

The role of gluconeogenesis in the maintenance of the blood glucose level requires that the activity of the pathway is sensitive to changes in the hormonal and dietary status of the animal Control of gluconeogenesis occurs at many levels but the nature of many of the control mechanisms is not well-understood Studies on the control of gluconeogenesis have dealt mainly with the process in liver and the material presented here will be limited to results obtained with this organ In general, control may occur in peripheral tissues to alter the supply of glucose precursors or effectors (hormones, fatty acids, etc) to the liver or may operate in the liver to control the uptake of precursors or their conversion to glucose Rapid alterations in the rate of gluconeogenesis may result from changes in the blood levels of substrates or hormones reaching the

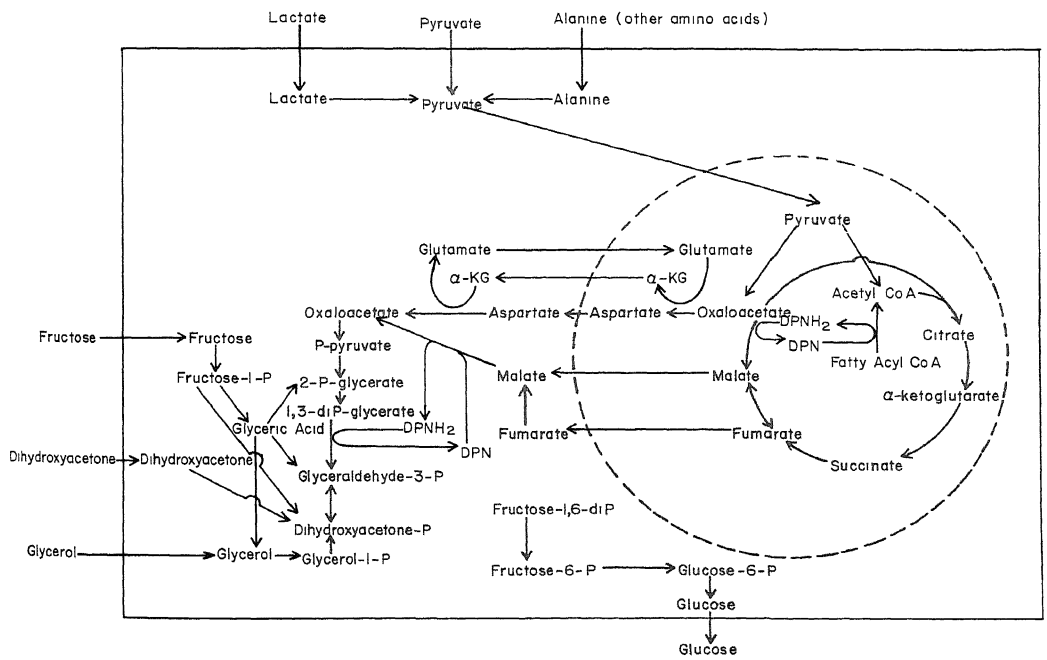

Fig 7 110 Diagram of the pathways of gluconeogenesis from lactate pyruvate alanine fructose and dihydroxy acetone in the liver A liver cell is represented by the rectangle and a mitochondrion by the circle

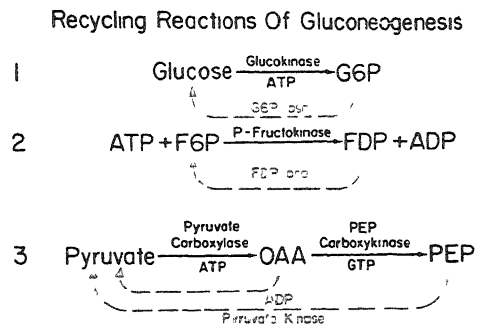

Fig 7 111 Thermodynamically irreversible steps of glycolysis and gluconeogenesis (From Williamson 1967)

liver or by allosteric-type regulation of the activity of gluconeogenic enzymes Slower alterations are observed which result from changes in the maximal gluconeogenic capacity of the tissue and which represent changes in the rate of enzyme synthesis (Weber, 1963) For example, stimulation of gluconeogenesis occurs during muscular exercise as a result of increased lactate production and during starvation as a result of increased availability of the gluconeogenic amino acids and glycerol However, during prolonged exposure to conditions requiring elevated rates of gluconeogenesis, increases in the maximal capacity of the tissue are observed The gluconeogenic flux is also regulated by the hormonal balance of the animal (e g , the rate is increased in diabetes)

Investigators have used whole animals, isolated perfused liver and kidney preparations, tissue slices, tissue homogenates, mitochondrial preparations, purified enzyme systems, and the measurement of adaptive enzyme changes in attempting to understand the control of gluconeogenesis (for review, see Newsholme and Gevers, 1967) Changes in gluconeogenic rates or capacities observed in the whole animal are difficult to interpret since both the gluconeogenic and the peripheral tissues may be involved Isolated perfused organ systems offer a number of advantages for studying the control of gluconeogenesis Hormones and substrates are delivered to the cells by the normal capillary bed, and therefore a direct effect on that tissue can be demonstrated since other tissues or organs are not included within the circulation In addition, samples of the tissue and perfusate can be obtained rapidly and with ease for the estimation of enzyme activities, metabolic intermediates, and substrate levels Rates of gluconeogenesis observed in perfused rat liver and kidney are in the same range as those estimated from studies of whole animals and suggest that the perfused preparations approximate the in vivo situation

CONTROL BY SUBSTRATE AVAILABILITY

Studies of Exton et al (1967, 1970) show that the gluconeogenic capacity of the liver is not saturated by the concentrations of gluconeogenic precursors normally present in the blood, indicating that the rate of glucose synthesis by the liver could be controlled by variations in plasma levels of lactate, pyruvate, amino acid, and glycerol (Fig 7 112 and 7 113) When the liver is presented with a mixture of physiological substrates at their normal blood concentrations, amino acids make the greatest contribution to glucose synthesis (Table 7 17) Any physiological change which would increase the blood lactate above its resting level of 1 mM should lead to increased glucose formation by the liver (Fig 7 113) Increased lactate production during exercise and during increased sympathetic nervous activity would be

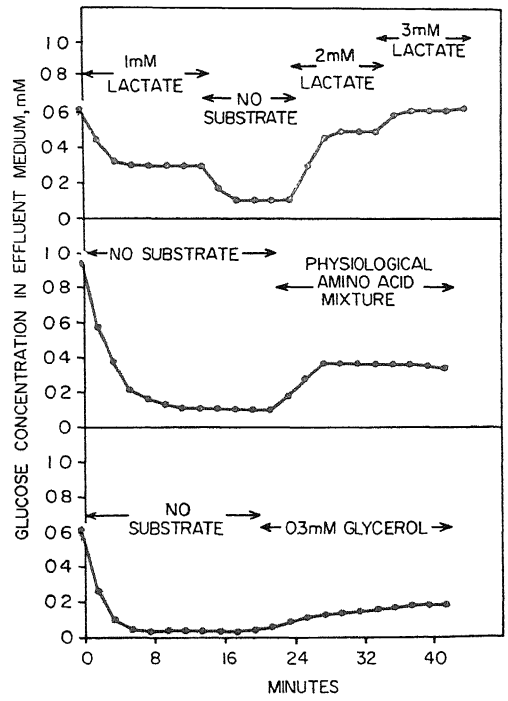

Fig 7 112 Effects of altering concentrations of substrates within the physiological range on gluconeogenesis Livers from fasted rats were perfused with nonrecirculating medium (From Exton et al 1970)

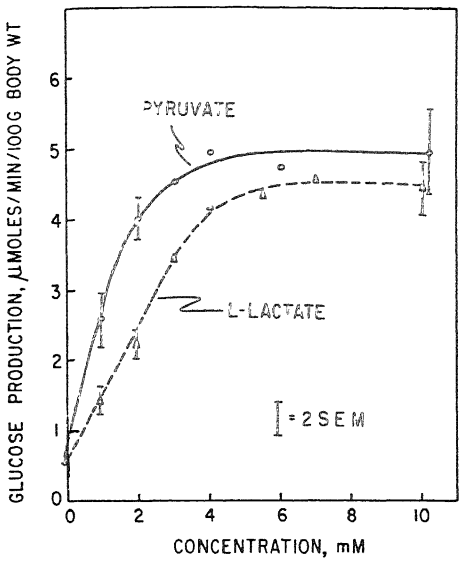

Fig 7 113 Relationship between gluconeogenesis and lactate or pyruvate concentration Livers from fasted rats were perfused with nonrecirculating medium containing lactate or pyruvate at the concentrations shown (From Exton and Park 1967)

accompanied by glucose synthesis, thus minimizing lactic acidosis and replenishing the glycogen stores of muscle and liver This process is known as the Cori cycle and, although it is physiologically important, it does not, strictly speaking, lead to formation of "new glucose" since lactate is itself derived from glucose (Cori, 1931) When the dietary supply of glucose does not satisfy the metabolic demands of the animal (e g , starvation, low carbohydrate diet), the gluconeogenic substrates utilized for the synthesis of new glucose are *1*) glycerol released from the triglyceride stores of adipose tissue, and *2*) amino acids derived from muscle protein In this respect protein is quantitatively the most important source of glucose for survival during fasting

The fact that hepatic gluconeogenesis can be markedly altered by variations in the levels of substrates within the physiological range illustrates the importance of regulation of amino acid and glycerol release from peripheral tissues in control of gluconeogenesis The prominent role of amino acids as substrates for gluconeogenesis suggests that the control of their release from muscle tissue would provide an important point of regulation Net amino acid release from peripheral tissues can result from hormonal control of either the rate of protein synthesis or the rate of protein degradation (chap 13) in that tissue Most studies have failed to differentiate between these effects

Insulin stimulates amino acid uptake and incorporation into protein in muscle and lowers the plasma α-amino nitrogen level The combination of a reduced availability of amino acids to the liver with a direct suppressing action of the hormone on hepatic gluconeogenesis (to be discussed in a subsequent section) renders insulin very inhibitory to amino acid gluconeogenesis The increased gluconeogenesis observed with diabetes is undoubtedly due partly to the mobilization of tissue protein which gives rise to increased plasma levels of most amino acids

Glucocorticoids exhibit a net protein catabolic effect in vivo They decrease amino acid uptake and incorporation into muscle protein and increase plasma α-amino nitrogen in eviscerated animals Glucocorticoids also stimulate utilization of amino acids by liver, but their peripheral effects appear to be stronger than their hepatic effects since they increase the plasma levels of most amino acids in adrenalectomized animals

Growth hormone increases amino acid uptake and incorporation into protein in muscle and decreases plasma α-amino nitrogen Inhibition of amino acid gluconeogenesis would therefore be expected, but the hormone has been observed to increase hepatic glucose output in intact dogs and in the perfused rat liver Further studies are necessary to define

Table 7 17
Rates of gluconeogenesis from substrates at concentrations found in rat blood plasma

Substrate	Rate of Glucose Production
	μmoles/ 100 g /hr
Lactate, 1 0 mM	51
Pyruvate, 0 1 mM	12
Amino acids[a]	91
Glycerol, 0 3 mM	18
Sum of above	172
Mixture of above substrates	170

From Exton and Park, 1967
[a] Amino acids were present at the concentrations found in rat blood plasma

the effect of growth hormone on amino acid gluconeogenesis

Effects of epinephrine and norepinephrine on peripheral amino acid release are uncertain

In fasting, release of amino acids from peripheral tissues is important for hepatic gluconeogenesis The situation seems quite complex, at least in man (Marliss et al , 1970) Early in starvation, the plasma levels of many amino acids increase and gluconeogenesis is activated This indicates increased protein catabolism probably due to decreased insulin secretion When starvation is prolonged, protein is conserved, the plasma levels of most amino acids decline, and gluconeogenesis is markedly attenuated The rate-limiting process at this time appears to be the release of substrate from peripheral tissues since exogenous amino acid is rapidly converted to glucose, suggesting that hepatic gluconeogenic mechanisms remain intact The decreased rate of gluconeogenesis during prolonged fasting is accompanied by the adaptation of the brain to utilize ketone bodies (acetoacetate and β-hydroxybutyrate) in addition to glucose (Owen et al , 1967)

Studies of the individual amino acids as gluconeogenic substrates indicate that alanine is the major precursor of glucose in the liver with lesser contributions from serine, proline, threonine, glutamate, glutamine, and asparagine (Ross et al , 1967) Other studies indicate that plasma alanine concentrations undergo the greatest alterations when release of amino acids from peripheral tissue is affected (Felig et al , 1970) These findings have led to the proposal of the existence of an "alanine cycle" which could be of importance in nitrogen metabolism As depicted in Figure 7 114, the transfer of amino groups from several amino acids to pyruvate results in the formation of alanine in extrahepatic tissues The donor amino acids come from blood or tissue protein and pyruvate is formed from blood glucose or tissue glycogen Newly formed alanine and alanine derived from protein breakdown is released and carried to the liver where it is used for the synthesis of urea (which is excreted) and glucose (which returns to the peripheral tissue) This process provides a means by which amino acids can be rapidly catabolized in extrahepatic tissues without the release of toxic amounts of ammonia

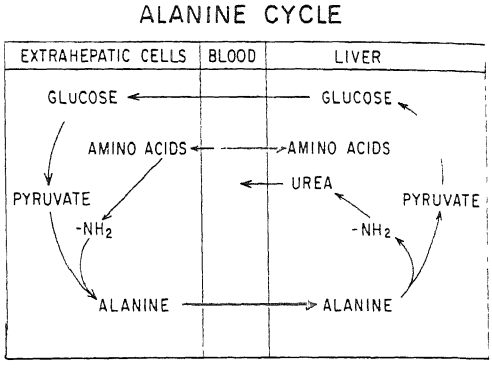

Fig 7 114 Diagrammatic representation of the postulated role of alanine in the transfer of amino groups from extrahepatic tissues to the liver (From Mallette et al 1969)

HORMONAL CONTROL OF GLUCONEOGENESIS

Control of gluconeogenesis by the direct action of hormones on the liver has been studied intensively in the isolated perfused rat liver It has been possible to demonstrate that several hormones act directly at the hepatic level and that some of these (glucagon, epinephrine, insulin) act within seconds or minutes while others act more slowly (glucocorticoids) The slower effects may involve changes in enzyme synthesis while the fast effects involve regulation of the intracellular level of adenosine 3′,5′-monophosphate (cyclic AMP) This compound has been implicated in the regulation of a number of cellular processes (chap 1)

Glucagon plays a major role in the regulation of blood glucose levels through its effects on hepatic glycogenolysis and gluconeogenesis In fact, it probably has no action of physiological importance outside the liver and pancreas The effect of the hormone on glycogenolysis was recognized early (for review, see Sutherland and Rall, 1960), and recent studies have confirmed that glucagon is also an important regulator of the gluconeogenic pathway The hormone increases the conversion of lactate, pyruvate, alanine, and bicarbonate to glucose in the perfused liver The effect is apparent within 40 sec after addition to the perfusate and concentrations of the hormone within the physiological range are effective (Fig 7 115) The effects of glucagon are thought to result from activation of membrane bound adenyl cyclase with the ensuing intracellular accumu-

lation of cyclic AMP The following lines of evidence indicate that the effect of glucagon on gluconeogenesis is mediated by increased cyclic AMP levels *1*) the hormone is capable of stimulating gluconeogenesis only in concentrations which increase tissue level of cyclic AMP, 2) the increase in cyclic AMP precedes the activation of gluconeogenesis, *3*) direct addition of cyclic AMP to the perfusate mimicks the effects of glucagon, and *4*) exogenous cyclic AMP produces the same changes in metabolite levels in the gluconeogenic pathway as does glucagon (i e , a "crossover point" is observed between pyruvate and P-pyruvate, the site of the rate-limiting reactions from lactate, pyruvate, or alanine gluconeogenesis) (Fig 7 116) The stimulatory effects of glucagon and cyclic AMP on the conversion of pyruvate to phosphopyruvate appear to be too rapid to involve changes in enzyme synthesis As shown in Figure 7 110, the conversion of pyruvate to phosphopyruvate is thought to involve a mitochondrial enzyme, pyruvate carboxylase, and a cytosol enzyme, phosphopyruvate carboxykinase A stimulation could involve either or both of these enzymes or alternatively could represent a change in the rate of flux of intermediates across the mitochondrial membrane A direct effect of glucagon or cyclic AMP on the activity of either enzyme has not been demonstrated In addition to these effects, glucagon and cyclic AMP stimulate the entry of alanine into the liver cell There is some evidence for an effect of cyclic AMP on the transfer of substrates across mitochondrial membranes, but the importance of this effect has not been examined in detail

Numerous studies suggest that increased

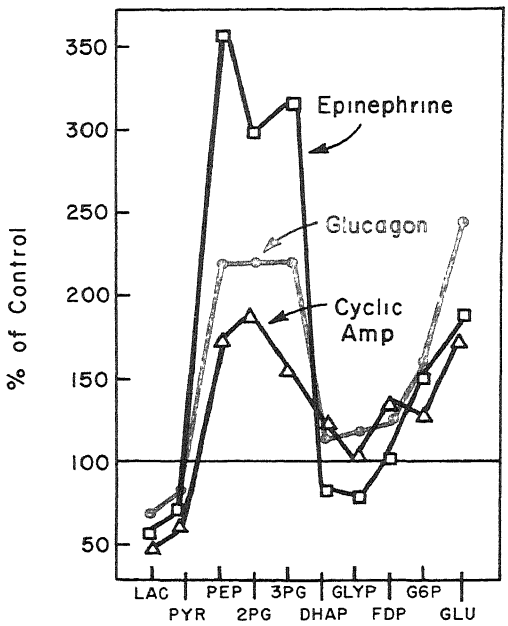

Fig 7 116 Effects of glucagon epinephrine and cyclic AMP on levels of gluconeogenic intermediates in perfused livers from fasted rats Values are expressed as percentages of those found in livers perfused with lactate alone Concentrations of additions were glucagon 1 × 10^{-8}M epinephrine 1 × 10^{-6}M cyclic AMP 1 × 10^{-3}M The intermediates listed along the abscissa are lactate (LAC) pyruvate (PYR) P-pyruvate (PEP) 2-P-glycerate (2PG) 3-P-glycerate (3PG) dihydroxyacetone-P (DHAP) glycerol-1-P (GLYP) fructose-1 6-di-P (FDP) glucose-6-P (G6P) and glucose (GLU) This is a method employed to identify the specific step in the gluconeogenic pathway which is stimulated by glucagon epinephrine and cyclic AMP Measurement of changes in the concentration of intermediates along the pathway when the rate of flux is altered should indicate the rate-limiting reactions Stimulation of the pathway may lead to depletion of substrate proximal to the site of regulation and accumulation of substrate distal to this site The step at which the change from depletion to accumulation occurs is called the crossover point and identifies the rate-controlling reaction The data presented in this figure indicate that glucagon epinephrine and cyclic AMP all enhance the rate of gluconeogenesis by stimulating the conversion of pyruvate to P-pyruvate (Drawn from data presented by Exton and Park 1969)

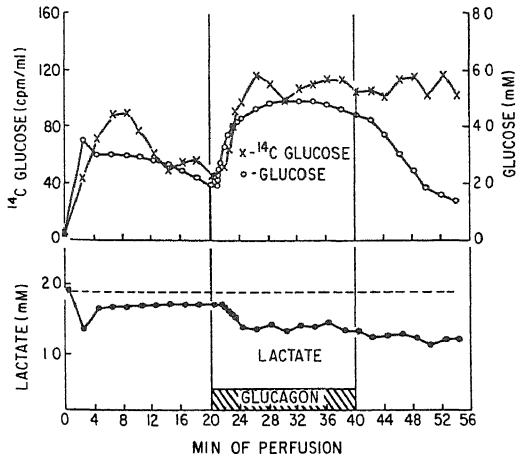

Fig 7 115 Effects of glucagon on glucose output lactate uptake and glucose-^{14}C synthesis in livers from fed rats perfused with nonrecirculating medium containing lactate-^{14}C Glucagon was infused from 20 to 40 min to produce a concentration 1 × 10^{-8}M in the influent medium (From Exton and Park 1968)

availability of fatty acids coupled to enhanced fatty acid oxidation stimulates hepatic gluconeogenesis (Williamson et al, 1966, 1969a, 1969b) Stimulation of two sites in the gluconeogenic pathway has been implicated *1)* mitochondrial enzyme, pyruvate carboxylase which is absolutely dependent upon acetyl CoA for activity, and *2)* the triose phosphate step, glyceraldehyde-P dehydrogenase, which requires reduced nicotinamide adenine dinucleotide (NADH) (Fig 7 110) Increased amounts of both acetyl CoA and NADH are generated during accelerated β-oxidation of fatty acids This has led to the suggestion that the effect of glucagon on gluconeogenesis is the result of increased fatty acid oxidation due to activation of a hepatic lipase enzyme (Struck et al, 1965) According to this proposal, glucagon would increase the intracellular level of cyclic AMP which would activate an hepatic lipase Increased lipase activity would accelerate hydrolysis of endogenous triglyceride and enhance β-oxidation of fatty acids and result in generation of both acetyl CoA and NADH The following lines of evidence support this proposal *1)* glucagon pretreatment reduces hepatic fat content and increases lipase activity of crude liver homogenates, *2)* addition of fatty acids to isolated liver preparations can stimulate gluconeogenesis under some conditions, and *3)* acetyl CoA levels correlate with the rate of gluconeogenesis

Although this proposal is held in high esteem by a number of investigators, others question it as an adequate explanation of the gluconeogenic action of glucagon The following findings do not fit with the proposal *1)* glucagon frequently has no effects on ketogenesis even though it markedly stimulates glycogenolysis and gluconeogenesis, *2)* fatty acids are never as effective as glucagon in stimulating gluconeogenesis in the perfused liver even though they increase ketogenesis to a much greater degree than does glucagon, *3)* the gluconeogenic effect of fatty acids is additive with that of glucagon, and *4)* fatty acids produce different changes in the levels of gluconeogenic intermediates than does glucagon It seems likely that further research will determine which mechanism is of physiological importance

An additional possibility for the site of action of glucagon is the pyruvate dehydrogenase complex Recent evidence suggests that this enzyme exists in an active dephosphorylated form and that its activity disappears upon phosphorylation (Linn et al, 1969) According to this scheme, cyclic AMP would activate the protein kinase responsible for phosphorylating the active form of the enzyme to render it inactive Thus, cyclic AMP would diminish carbon flow through pyruvate dehydrogenase and direct it toward glucose synthesis However, attempts to demonstrate such an effect of cyclic AMP have not been successful to date

Effects of epinephrine and norepinephrine on glycogenolysis and gluconeogenesis are similar to those produced by glucagon and are thought to involve the same mechanisms of action (i e, via cyclic AMP) The concentrations of epinephrine and norepinephrine required to elicit maximal effects in the perfused liver are considerably higher than the observed plasma levels of these hormones, raising the possibility that hepatic glucose production may not be controlled by circulating levels of catecholamines as has been suggested However, this does not negate the important role of the sympathetic nervous system in the regulation of glucose output by the liver in which catecholamine is released from sympathetic nerve endings

Insulin inhibits gluconeogenesis As mentioned earlier, it diminishes the supply of gluconeogenic substrates from tissues such as muscle and fat and, in addition, the hormone directly inhibits glucose synthesis in the liver Insulin deficiency (diabetes) and short-term starvation (a relative insulin lack) cause increased gluconeogenesis The mechanisms involved in these effects were suggested from studies using animals made acutely diabetic by injection of anti-insulin serum (Jefferson et al, 1968) Perfused livers from rats treated with anti-insulin serum showed increased rates of glycogenolysis and gluconeogenesis and these effects were abolished by insulin addition in vitro The similarity of the effects produced by anti-insulin serum to those caused by exogenous cyclic AMP led to an investigation as to whether these effects resulted from an increase in the tissue level of cyclic AMP It was found that anti-insulin serum caused a progressive rise in liver cyclic AMP over 1 hr of treatment which persisted during a subse-

quent perfusion Insulin added to the perfusate reduced the elevation in cyclic AMP caused by anti-insulin serum treatment and produced a small reduction in the level of the nucleotide in livers from untreated animals It was also found that liver cyclic AMP levels in vivo were doubled when diabetes was induced by alloxan and were increased by 60% by starvation but could be rapidly lowered to normal by insulin injection These studies suggest that insulin can exert direct inhibitory effects on gluconeogenesis and glycogenolysis by lowering the level of cyclic AMP Other hepatic actions of insulin may also be related to the reduction in cyclic AMP but this is uncertain at this time In addition, these studies suggest that the stimulation of gluconeogenesis during diabetes and short-term starvation can be ascribed partly to the increase in cyclic AMP However, changes in the levels of enzymes also play an important role in the long-term adaptations of diabetes and starvation

A role for the glucocorticoids in the regulation of hepatic glucose synthesis was suggested by early studies which showed that the fatal hypoglycemia of fasted adrenalectomized animals was due to a failure of gluconeogenesis The mechanism of action of adrenal steroids on gluconeogenesis is unclear, however As discussed earlier, glucocorticoids influence the flow of glucogenic substrates to the liver In addition they appear to have direct effects on liver The direct effects of adrenal steroids on the liver may involve changes in enzyme synthesis Recent studies have shown that adrenal deficiency has little effect on gluconeogenesis in fed animals but causes the pathway to be unresponsive to the elevated level of cyclic AMP associated with starvation and diabetes This has led to the suggestion that adrenal steroids exert mainly a "permissive action" on gluconeogenesis so that their effects do not become evident unless the tissue level of cyclic AMP is increased as a result of another hormone action (e g , glucagon) The following evidence supports this suggestion *1*) glucagon is ineffective in stimulating glucose synthesis in livers from fasted adrenalectomized rats, *2*) treatment with glucocorticoids in vivo or in vitro restores to normal the gluconeogenic response to glucagon, and *3*) the activation of adenyl cyclase by glucagon is not impaired in the absence of glucocorticoids

Growth hormone, thyroxine, and other hormones may play a role in the regulation of gluconeogenesis but their mechanisms of action are not known at this time

Ketogenesis

Ketogenesis is the term applied to the metabolic process involving the production of the ketone bodies, acetoacetate, acetone, and β-hydroxybutyrate It is a normal function of the liver to produce these metabolites for peripheral utilization Whenever ketogenesis by the liver exceeds ketone body utilization by other tissues, these compounds accumulate in the extracellular fluid leading to a state termed ketosis This situation has important clinical significance since high levels of ketone bodies cause acidosis and exert toxic effects on tissues such as the brain On the other hand, the ability of the liver to produce ketone bodies instead of carbon dioxide as an end product of metabolism has important physiological significance in coordinating the energetic needs of the organism as a whole Acetoacetate and β-hydroxybutyrate are used by muscle and perhaps other tissues as a source of energy in preference to other substrates Therefore, from a physiological point of view, the liver is converting the energy available in long-chain fatty acids to a more readily utilizable nutrient for other tissues

The metabolic pathway for ketogenesis in the liver is shown in Figure 7 117 It can be seen that ketogenesis is inseparable from the β-oxidation of fatty acids and that the enzymatic machinery is localized mainly within the mitochondria (Bressler, 1963, Wieland, 1968) Acetyl CoA, an intermediate derived mainly from the β-oxidation of long-chain fatty acids, is the immediate precursor of acetoacetate Formation of the ketone bodies is initiated by the condensation of two molecules of acetyl CoA to form acetoacetyl CoA This step is catalyzed by the enzyme β-ketoacylthiolase. The next step in the enzymatic formation of acetoacetate involves the condensation of another molecule of acetyl CoA with acetoacetyl CoA to give β-hydroxy-β-methyl-glutaryl-CoA (HMG-CoA) Enzymatic cleavage of this molecule yields acetoacetate and acetyl CoA This process is called the HMG-CoA cycle

The other two ketone bodies are derived

PATHWAY OF KETOGENESIS

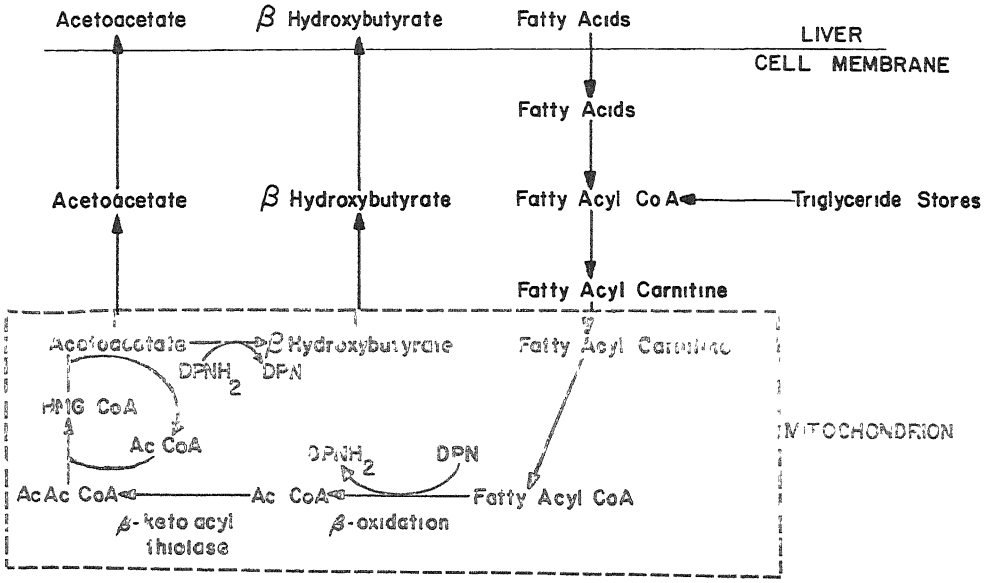

Fig 7 117 Diagram of the pathways of ketogenesis from fatty acids in the liver

from acetoacetate Acetone apparently originates by spontaneous decarboxylation of acetoacetate Reduction of acetoacetate in the NADH-dependent reaction catalyzed by the enzyme β-hydroxybutyrate dehydrogenase gives rise to β-hydroxybutyrate This compound comprises 65 to 75% of the total ketone bodies present in blood

Before acetoacetate can enter oxidative metabolism in peripheral tissues, it must be reactivated to acetoacetyl CoA by an enzymatic conversion involving succinyl CoA The liver is relatively incapable of carrying out this reaction For peripheral utilization, β-hydroxybutyrate is oxidized to acetoacetate which then undergoes the reactions described above

In general, the production of ketone bodies is stimulated whenever the availability of carbohydrate is relatively (e g , diabetes) or absolutely (e g., fasting) deficient The degree of ketosis that develops depends on the disproportion between fat catabolism and carbohydrate utilization A number of circumstances which may contribute to the development of ketosis are listed in Table 7.18 It is clear that the rate of ketone body production is a function of *1*) the rate of mobilization of free fatty acids from adipose tissue, *2*) the rate of uptake and accumulation of lipid by the liver, *3*) the rate of fatty acid oxidation in relation to carbohydrate availability in the liver, and *4*) the rate of carbohydrate utilization by all the tissues of the body In addition, the blood concentration of ketone bodies is a function of the rate of their utilization by muscle and other extrahepatic tissues Therefore, ketogenesis and the development of ketosis may be affected by regulation at a number of levels Since the liver takes up triglycerides and fatty acids in proportion to their concentrations in the blood, any of the factors which control the release of fatty acids from adipose tissue would be involved in the regulation of ketogenesis

Lipogenesis

During feeding there is need to store much of food energy for use in the postabsorptive state by converting it to fat, an energy store form Lipogenesis is the process concerned with conversion of glucose and metabolites such as pyruvate and acetyl CoA to triglyceride (Fig 7 118) Since gluconeogenesis and lipogenesis share all of the reversible enzymes between phosphopyruvate (PEP) and glucose-6-P, it is apparent that when one process is active the other must be suppressed

In the fed state, blood levels of glucose and insulin are high and there is decreased availability of fatty acids to the liver These conditions favor restraint of gluconeogenesis and provide more substrate for lipogenesis by increasing intracellular glucose concentrations in the liver An increased phosphorylation of glucose by glucokinase yields glucose-6-P which is converted to pyruvate Pyruvate enters the mitochondria and undergoes oxidation to acetyl CoA, the major substrate for fat synthesis Since acetyl CoA does not diffuse readily into the cytosol, where fatty acid synthesis occurs, it must be converted to citrate by condensation with oxaloacetate within the mitochondria Conversion of pyruvate to acetyl CoA, rather than to oxalocetate, is favored by the low intramitochondrial acetyl CoA levels that exist in the fed state Decreased availability of fatty acids to the liver results in a fall in intracellular fatty acyl CoA concentration which in turn leads to decreased intramitochondrial oxidation of fatty acids and a fall in intramitochondrial acetyl CoA levels This favors a decrease in the activity of pyruvate carboxylase, the enzyme responsible for catalyzing formation of oxaloacetate, and a release of inhibition of pyruvate dehydrogenase, which allows for more rapid formation of acetyl CoA and subsequently citrate Citrate is transported into the cytosol where it is cleaved to acetyl CoA and oxaloacetate by the citrate cleavage enzyme This enzyme, in addition to providing acetyl CoA for cytoplasmic fat syn-

[a] A list of some of the circumstances in which lipid catabolism is disproportionately great in relation to carbohydrate utilization and in which, therefore, ketosis may be expected to occur

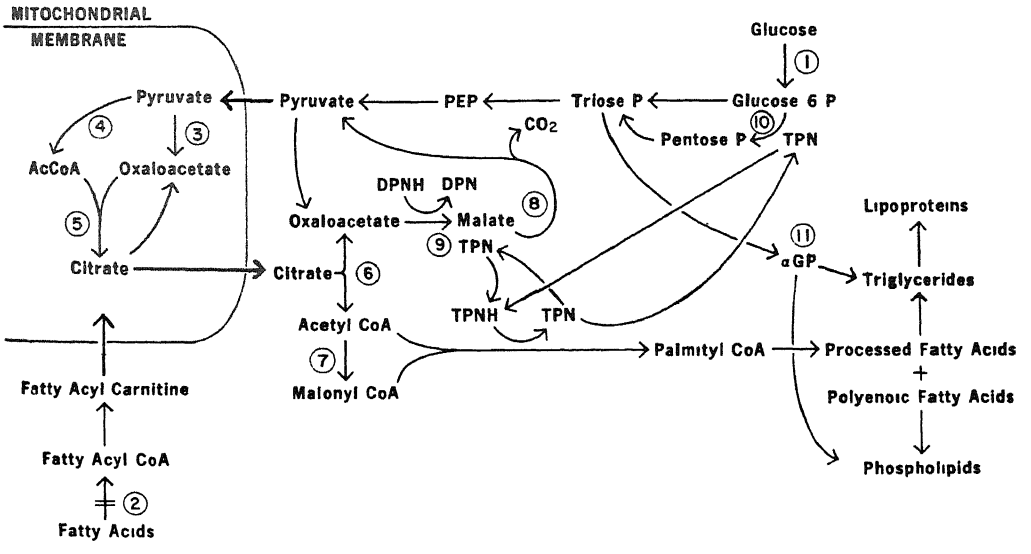

Fig 7 118 Control of the lipogenic pathway Conditions favoring lipogenesis *1)* increased glucokinase activity *2)* decreased availability of fatty acids *3)* pyruvate carboxylase activity decreased, *4)* pyruvate dehydrogenase inhibition released *5)* citrate synthetase active *6)* citrate cleavage enzyme *7)* acetyl-CoA carboxylase inhibition released *8)* malic enzyme active *9)* initiation of transhydrogenase sequence yielding TPNH *10)* pentose phosphate shunt pathway active yielding TPNH *11)* rapid generation of α-glycerophosphate (From Tepperman and Tepperman 1970)

thesis, functions together with the NADP-requiring malic enzyme to retrieve pyruvate for recycling and to produce NADPH which is required to supply reducing equivalents for lipogenesis. Additional NADPH is generated through the pentose shunt.

The rate-limiting reaction in the lipogenic pathway is catalyzed by acetyl CoA carboxylase. This enzyme is competitively inhibited by high intracellular concentrations of fatty acyl CoA esters. Since these decrease in the fed state, inhibition of acetyl CoA carboxylase is released and fatty acid synthesis is favored. Inhibiting concentrations of fatty acyl CoA do not accumulate during active fatty acid synthesis because the rapid rate of generation of α-glycerophosphate favors sequestration of newly synthesized fatty acids into triglyceride.

The rate of lipogenesis is controlled by the nutritional state of the animal. The rate is high in the fed state and is depressed during restricted food intake, by a high fat diet, or by a deficiency of insulin, as in diabetes. The steps that are numbered in Figure 7.118 indicate acute changes which favor an increased rate of lipogenesis. In fasting, lipogenesis is inhibited by *1*) decreased availability of glucose and decreased glucokinase levels; *2*) decreased availability of α-glycerophosphate; and *3*) increased levels of fatty acyl CoA which inhibits acetyl CoA carboxylase and provides for higher intramitochondrial levels of acetyl CoA. In addition to these acute mechanisms, the rate of lipogenesis can be affected by changes in synthesis of other enzymes in the pathway.

13 / HORMONAL CONTROL OF GROWTH AND PROTEIN METABOLISM

Hormonal control of protein and nucleic acid metabolism is expressed in the growth of single cells, organs, and the body Effects of hypophysectomy, thyroidectomy, and castration to retard growth indicate that hormonal control is extensive With the exception of growth hormone, structure, synthesis, release, and general metabolic effects of these hormones have been considered in earlier chapters In this chapter, control of growth and protein metabolism will be discussed, and general features of the action of growth hormone will be described

GROWTH HORMONE

Growth hormone is synthesized and stored in acidophilic cells of the anterior pituitary Secretion granules containing the hormone have been isolated Release of hormone by these cells is controlled by growth hormone-releasing factor (GRF) (chap 2) Human growth hormone is made up of 188 amino acids and has a molecular weight of 21,500 (Fig 7 119) Development of an immunoassay for growth hormone has permitted studies of various factors that control growth hormone release by GRF These factors fall into three groups *1*) Decreased energy supply, as encountered in fasting, exercise and hypoglycemia, increases plasma growth hormone levels in direct relation to the fall in blood sugar (Fig 7 120) Release of growth hormone in situations of reduced energy supply results in release of fatty acid from adipose tissue and reduction in glucose utilization by muscle through restraint of membrane transport and intracellular glucose phosphorylation Patients that lack pituitary function have a prolonged period of hypoglycemia following insulin administration (Fig 7 121) Treatment with cortisone and thyroxine partially restores this defect, but growth hormone is required for a rapid return of blood sugar toward normal 2) Increased levels of plasma amino acids resulting from protein feeding or intravenous injection of amino acids increase plasma levels of growth hormone Arginine is particularly potent in its ability to release growth hormone, and, as shown in Figure 7 122, infusion of arginine increases plasma growth hormone levels to the same extent as insulin hypoglycemia Release of hormone in response to higher plasma levels of amino acids favor increased synthesis of protein and returns plasma amino acid levels to normal by facilitating entry of these compounds into cells *3*) Stress, such as surgical procedures, increases growth hormone release (Baylis et al , 1968)

Growth hormone is required for normal growth during adolescence Small stature may result from many factors, however, including nutritional, genetic, and other types of hormonal unbalance Deficiency of growth hormone results in dwarfism, while overproduction causes gigantism Gigantism due to growth hormone is characterized by uniform growth of all body components The extent of growth hormone deficiency in children of short stature can be estimated by stimulation of growth hormone secretion with infusions of arginine or insulin Peak levels of growth hormone that are achieved are an index of the adequacy of secretion (Parker and Daughaday, 1968) Treatment of hormone-deficient patients with human growth hormone increases growth from 1 to 2 cm /year to 7 to 12 cm /year Since effects of growth hormone are species specific, bovine or porcine hormone have little or no effects on growth in man

Excessive growth hormone secretion in adult life results in a condition known as *acromegaly* This condition is characterized by *1*) increased plasma levels of growth hormone (from 0 to 4 to 10 to 600 mμg /ml), 2) overgrowth of the bones of hands, feet, and face; and *3*) overgrowth of viscera, hair, and soft tissues of the body An adenoma of the anterior lobe of the

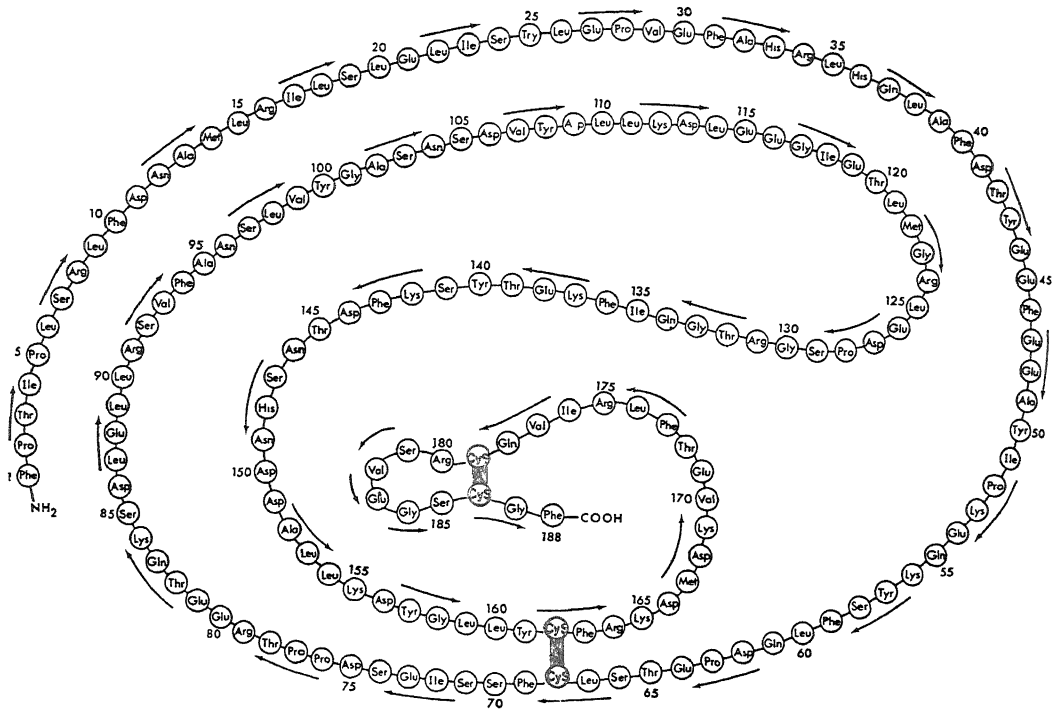

Fig 7 119 Amino acid sequence of human growth hormone Human growth hormone is a single polypeptide chain with two disulfide bridges When the disulfide bridges are reduced with mercaptoethanol in 8M urea and alkylated with iodoacetamide no loss of growth-promoting activity is found After partial digestion of the molecule with either pepsin or chymotrypsin biological activity in unchanged These findings suggest that it may be possible to synthesize a smaller peptide with growth-promoting activity (From Li 1968)

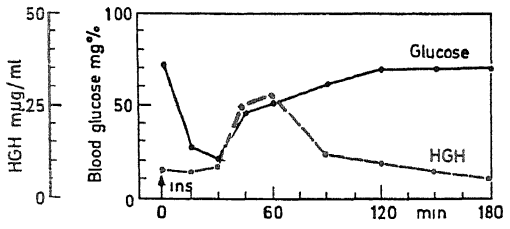

Fig 7 120 Effect of insulin hypoglycemia (0 05 units/kg body weight) on HGH concentration in plasma in a healthy subject (From Luft and Cerasi 1968)

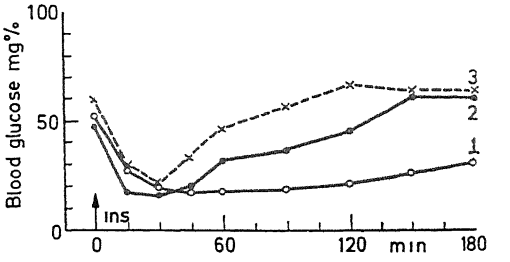

Fig 7 121 Insulin tolerance test (0 05 units/kg body weight) in a patient with panhypopituitarism *1)* without replacement *2)* on cortisone + thyroxine *3)* on cortisone + thyroxine + growth hormone (From Luft and Cerasi 1968)

pituitary is usually responsible for the hypersecretion of hormone Increased length of the long bones does not occur since the epiphyseal plates are already fused. Glycosuria and hyperglycemia are common and a condition indistinguishable from diabetes of pancreatic origin may be present. The acromegalic patients that develop hyperglycemia have a hereditary predisposition to diabetes and are unable to respond to the increased demands for insulin with an increased rate of secretion

Biological actions of growth hormone include a wide range of effects that cannot be explained by a single action of the hormone Addition of growth hormone to isolated muscles or adipose tissue of hypophysectomized rats accelerates entry of both amino acids and sugars into the cell (Fig 7 123) These effects are much less marked when muscles from normal animals are used These "insulin-like" effects of growth hormone may have little or

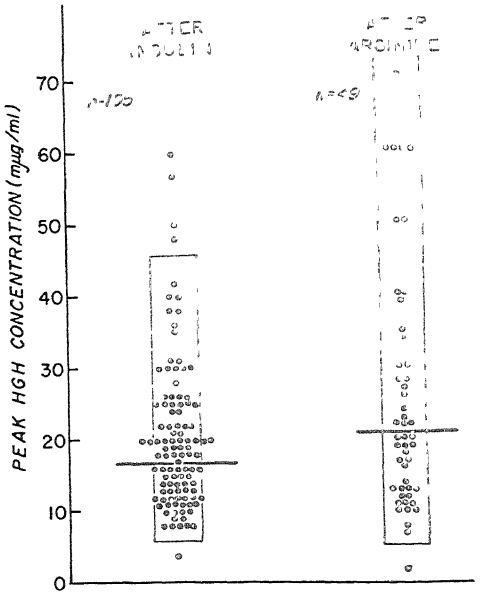

Fig 7 122 Comparison of peak growth hormone concentration of serum following insulin induced hypoglycemia and arginine infusion (From Parker et al 1967)

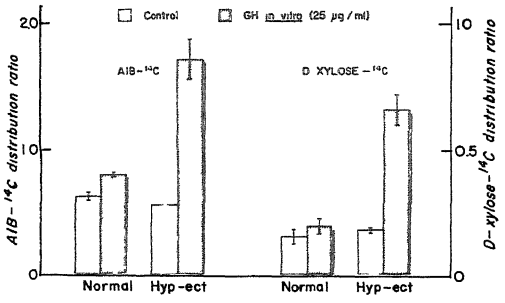

Fig 7 123 Effects of growth hormone in vitro on the uptake of α-aminoisobutyric acid (AIB-^{14}C) and of D-xylose-^{14}C by isolated diaphragms from normal and hypophysectomized rats (From Ahren and Hjalmarson 1968)

no physiological significance Administration of growth hormone to hypophysectomized rats for longer times decreases the sensitivity of glucose transport to stimulation by insulin (Fig 7 124) This effect is potentiated by the simultaneous administration of hydrocortisone An additional factor responsible for the diabetogenic effect of growth hormone is a block in glucose phosphorylation Even if sufficient insulin is administered to overcome the insensitivity of transport to insulin, glucose utilization is restrained by the block in phosphorylation As seen in Fig 7 125, phosphorylation activity is normal in the heart of hypophysectomized diabetic rats but is impaired in the heart of intact diabetic rats A severe block in

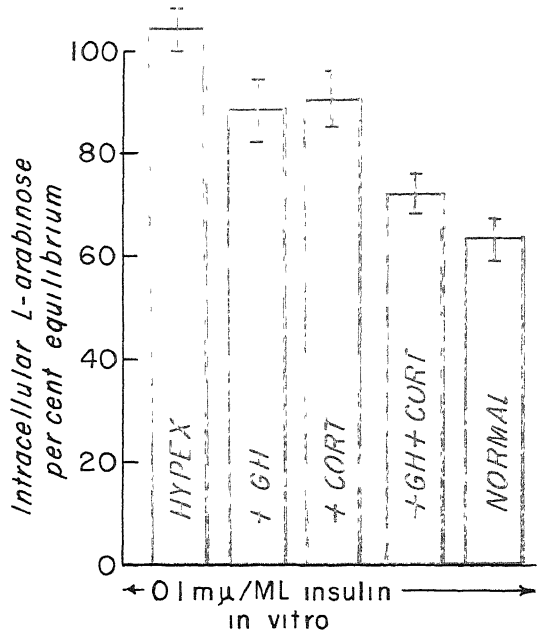

Fig 7 124 The late effect of growth hormone (GH) and hydrocortisone (Cort) in vivo on the sensitivity of transport to insulin as measured by L-arabinose accumulation Growth hormone was injected into hypophysectomized rats in a dose of 0 1 mg/100 g and cortisone in a dose of 2 5 mg/100 g 24 hr before the heart was removed for testing (From Park et al 1961)

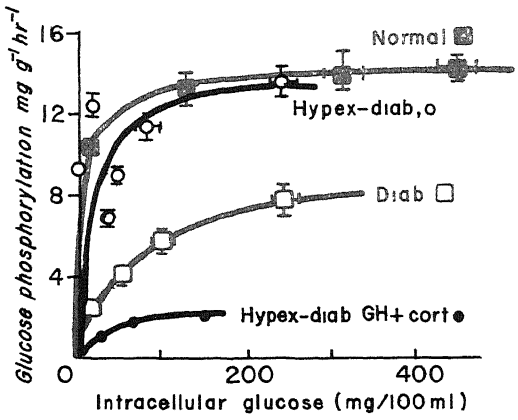

Fig 7 125 Effects of alloxan diabetes hypophysectomy growth hormone and hydrocortisone on the kinetics of glucose phosphorylation in the perfused heart Where indicated growth hormone (GH) and hydrocortisone (Cort) were injected over a 24-hr period before removal of the hearts for testing (From Morgan et al 1961)

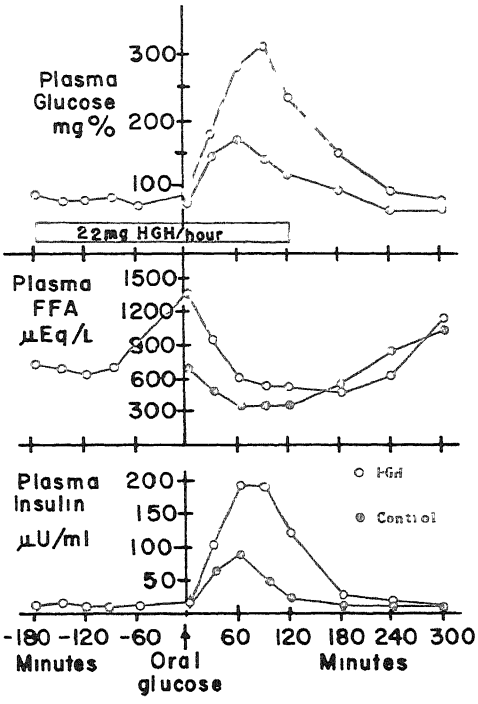

Fig 7 126 The effect of human growth hormone on glucose tolerance plasma free fatty acid (FFA) and insulin in a human subject (From Kipnis 1965)

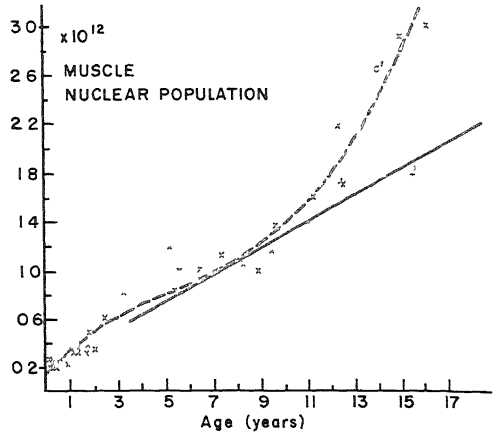

Fig 7 127 Relationship between nuclear number in the musculature is shown with chronological age for boys and girls Clearly the male adolescent growth spurt is more remarkable and associated with increase of nuclear number (From Cheek and Hill 1970)

phosphorylation develops when hypophysectomized diabetic rats are treated with growth hormone and hydrocortisone Since fatty acids reduce insulin sensitivity of glucose transport and block glucose phosphorylation (chap 10) impairment of these steps in growth hormone-treated animals may be related to the lipid-mobilizing effects of growth hormone Administration of human growth hormone to normal men for 3 hr increases plasma levels of free fatty acids (Fig 7 126) When a glucose tolerance test follows, plasma glucose increases to higher levels in hormone-treated subjects than in controls, despite higher plasma levels of insulin The return of plasma glucose to basal levels is slower after hormone treatment, which indicates a reduced sensitivity to insulin Whether growth hormone also has direct effects on muscle to control the rate of glucose transport and phosphorylation is undecided

Effects of growth hormone to accelerate growth appear to involve stimulated rates of ribonucleic acid (RNA) and protein synthesis These effects will be discussed along with the effects of other hormones on these pathways.

CONTROL OF CELLULAR GROWTH

Growth depends upon either an increase in the number (hyperplasia) or size (hypertrophy) of body cells Some tissues, such as muscle, loose the capacity for cell division while other tissues, such as liver, retain this capacity in adult life Since the size of any cell is limited, growth due to increments in the number of body cells is more striking An increase in cell size and number accounts for growth of muscles during adolescence (Cheek and Hill, 1970) As seen in Figure 7 127, the adolescent growth spurt in boys is accompanied by an increase in number of muscle nuclei as compared to girls On the other hand, muscle cell size increases more rapidly in girls and by 10 years of age, the girl has attained maximal size for muscle cells The boy does not catch up until 15 years of age (Fig 7 128) Ovariectomy produces a pattern of muscle growth characteristic of the male in rats while adrenalectomy and castration of the male retard cell growth to some extent

Cell size and number are controlled by growth hormone, insulin, and thyroxine Rats that are hypophysectomized have reduced numbers of muscle cells (Table 7 19) Similarly, reduced numbers of nuclei are found in muscle of boys with pituitary insufficiency An increase in cell number and decrease in cell size result from injections of growth hormone Children with hypothyroidism also have re-

duced numbers of muscle cells and larger cells These changes can be reversed by treatment with thyroxine On the other hand, treatment with insulin does not decrease cell size In liver, both insulin and growth hormone increase weight, RNA, and protein, but only growth hormone produces a larger increase in deoxyribonucleic acid (DNA) These findings suggest that insulin is the key to cytoplasmic growth while growth hormone is required for nuclear proliferation

TURNOVER OF CELL PROTEIN

Cytoplasmic growth is determined by the turnover of cell protein Turnover is controlled by factors affecting both protein synthesis and degradation (Fig 7 129) Since half-lives of protein in mammalian cells (4 to 6 days) are far shorter than half-lives of the cells, changes in these rates will influence cell size, protein concentration, and the nature of protein Definitive demonstrations of continual protein turnover were not made until radioactive tracer methods became available in the late 1930's (Schoenheimer and Rittenberg, 1940, Schoenheimer, 1942) Radioactive amino acids have been used to investigate the effects of hormones on protein turnover as exemplified by studies in hypophysectomized rats using ^{14}C-leucine (Goldberg 1969a) Muscle protein was labeled by a single injection of tracer 48 hr prior to induction of muscle growth Retention of radioactivity in the protein is regulated by the rate of protein degradation while the fall in specific activity of prelabeled protein is controlled by the rate of protein synthesis Contrasting effects of work-induced and hormone-induced growth are shown in Figure 7 130 Both factors increase size of the soleus but only work-induced growth is associated with increased retention of radioactivity in muscle protein Both factors decrease the specific activity of muscle proteins These studies indicate that work-induced growth of the soleus involves both inhibition of protein degradation and stimulation of protein synthesis Growth hormone appears to affect only the rate of synthesis

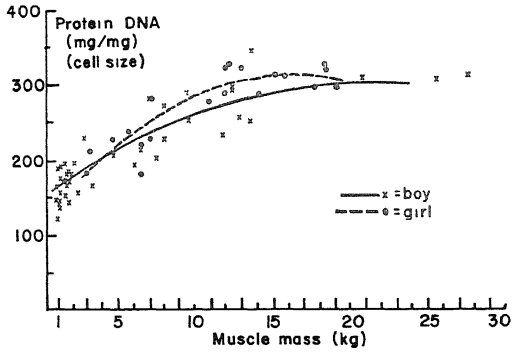

Fig 7 128 Muscle cell size (protein-to-DNA) is related to body size (muscle mass) for boys and girls during growth Note that growth by increments in cell size is less remarkable than by nuclear number increase Note also that females accelerate the growth of muscle cell size faster than boys although the latter eventually catch up (From Cheek and Hill 1970)

Decrease in muscle size occurs rapidly following disuse or denervation or following administration of large doses of adrenal steroids For atrophy to occur, protein degradation must exceed protein synthesis Decreased size of soleus and plantaris is seen following denervation or cortisone treatment (Fig 7 131) In each case, these factors facilitate degradation

Table 7 19
Hypophysectomized rats—effect of hormone therapy[a]

Animal	Muscle		Liver		
	Protein to DNA	No nuclei in muscle mass	Total protein	Total DNA	Protein to DNA
	mg /g	$N \times 10^9$	*mg*	*mg*	*mg /mg*

Hypox + Ins	175	5 29	903	13 2	68 7

From Cheek and Hill, 1970
[a] Cell size is indicated by the protein DNA ratio, and cell number by the nuclear count

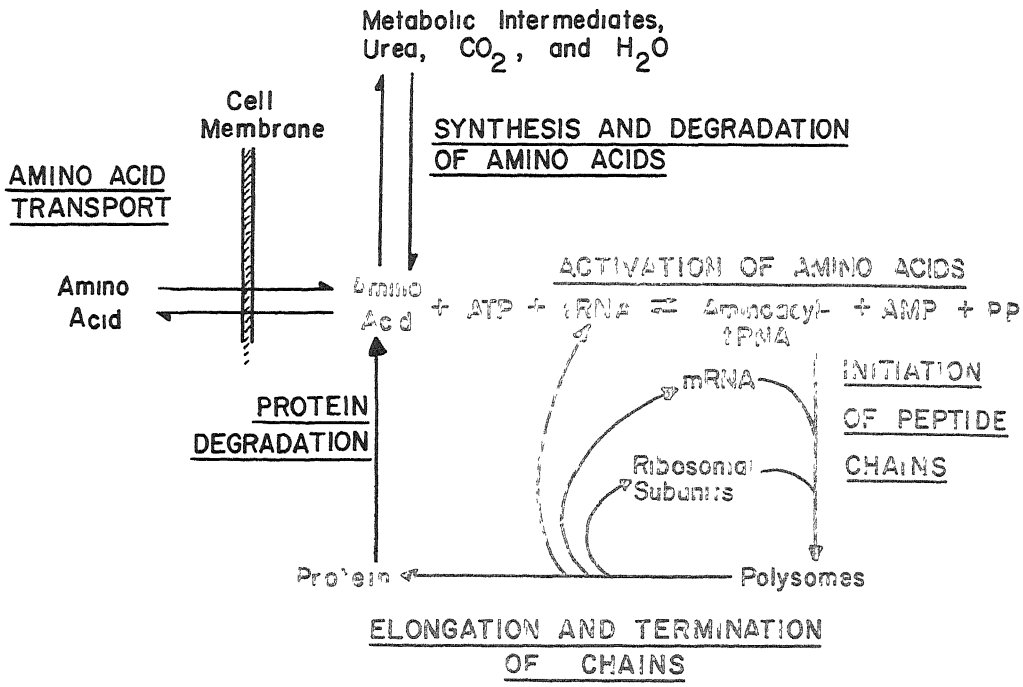

Fig 7 129 Steps involved in control of cell protein levels In this scheme synthesis of protein from the intracellular amino acid pool is considered to consist of the following steps *1)* activation of amino acids *2)* initiation of peptide chains on ribosomes and *3)* elongation and termination of peptide chains Amino acids may be added to this pool either by *1)* membrane transport *2)* intracellular synthesis from metabolites or *3)* protein degradation

of prelabeled protein Since the specific activity of the protein from denervated or cortisone-treated muscle is as high as the controls, inhibition of protein synthesis is indicated Inhibition of protein synthesis in steroid-treated animals may involve reduced rates of amino acid transport (Kostyo and Redmond, 1966) and of subsequent incorporation into protein (Wool and Weinshelbaum, 1959, Korner, 1967).

Insulin inhibits protein degradation in skeletal muscle and liver Decreased release of free amino acids from the forearm of postabsorptive man follows infusion of insulin into the brachial artery (Pozefsky et al , 1969) Insulin and free amino acids retard protein degradation in the perfused rat liver (Mortimore and Mondon, 1970, Woodside and Mortimore, 1970) Effects of the hormone on protein synthesis will be discussed later in this chapter

PROTEIN DEGRADATION

Protein degradation involves essentially all cell proteins, structural and enzymatic, and occurs within the cells Rates of degradation can vary markedly from one enzyme to another and can be altered by availability of substrate and other factors (Schimke, 1970) The rate is determined by properties of the protein as a substrate for a nonspecific degradative system as indicated by the first order relationship between rate and protein concentration Changes in the distribution of substrates and cofactors such as occur under various hormonal and nutritional conditions may lead to a variety of effects on specific enzymes to alter the rate of degradation Schimke et al (1964) provided the first clear example that substrate could modify the rate of degradation when tryptophan was found to retard degradation of tryptophan pyrrolase

The biochemical systems involved in protein degradation are poorly understood at present Lysosomes have been shown to digest phagocytized material as well as intracellular protein in viable cells (deDuve and Wattiaux, 1966, deReuck and Cameron, 1963) Increased acid phosphatase, a lysosomal enzyme, is present within the fibers of denervated muscle On the other hand, increased proteolysis in muscle of

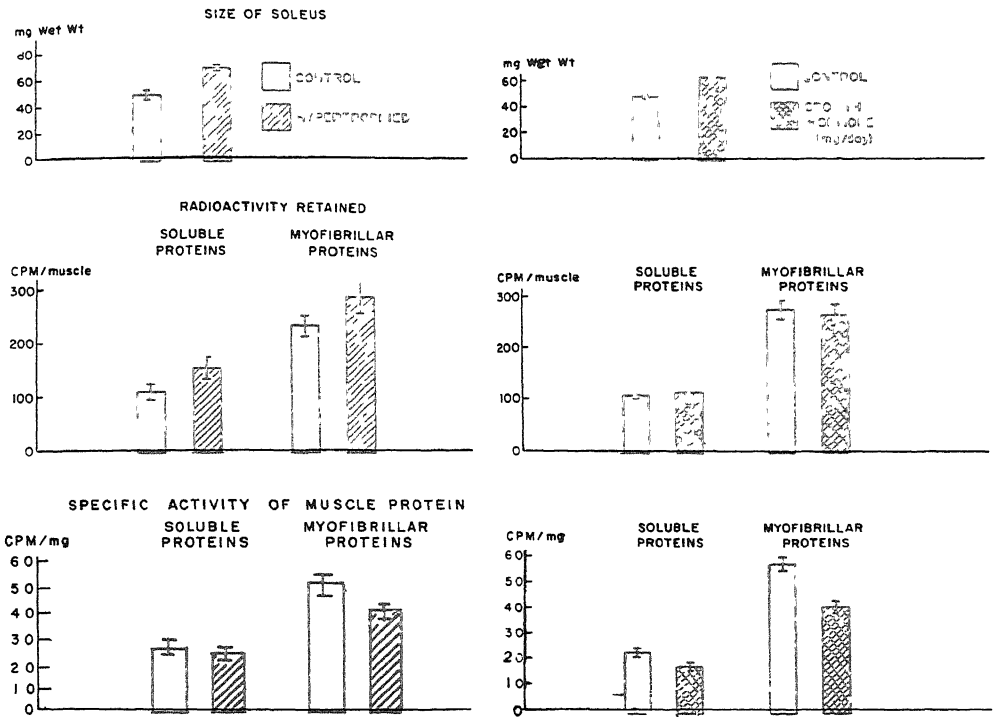

Fig 7 130 Effects of work hypertrophy and growth hormone on labeled proteins in soleus muscles of hypophysectomized rats Animals were sacrificed 6 days after unilateral tentomy of the gastrocnemius Results are compared with contralateral control Growth hormone was injected for 7 days and results compared to untreated hypophysectomized animals (From Goldberg 1969a)

cortisone-treated animals is not associated with increased activity of acid hydrolases (Buchanan and Schwartz, 1967) In contrast, these enzymes are raised in muscle extracts immediately following adrenalectomy These observations suggest that increased protein catabolism induced by denervation and cortisone is mediated by different mechanisms

PROTEIN SYNTHESIS

Protein synthesis may be regulated by factors affecting levels of structural components of the pathway, by supply of substrates, or by regulation of enzymes involved in protein synthesis Increased quantities of transfer RNA or ribosomes provide greater synthetic capacity while increased levels of messenger RNA may result in both qualitative and quantitative changes in the type of protein that is made Numbers of ribosomes are reduced in muscle and liver of hypophysectomized animals (Korner, 1964) Treatment of the animal with growth hormone restores these levels to normal Similarly, RNA content of muscle from diabetic animals is below normal and may contribute to the reduced rate of protein synthesis

In microorganisms, half-life of messenger RNA is in the range of seconds or minutes, but in animal cells, the template for protein synthesis persists for hours or days Therefore, increased levels of a specific protein can result from increased rates of translation of pre-existing mRNA or from stimulation of the synthesis of new mRNA. Effects of hydrocortisone and insulin on the levels of tyrosine α-ketoglutarate transaminase in cultured hepatoma cells provide examples of both mechanisms of induction (Lee et al , 1970) As seen in Figure 7.132, tyrosine transaminase activity increased approximately 10-fold following addition of hydrocortisone and approximately fourfold following addition of insulin. A lag of 1 hr is encountered before the steroid effect is evident, but the insulin effect begins immediately Addition of actinomycin D, an inhibitor

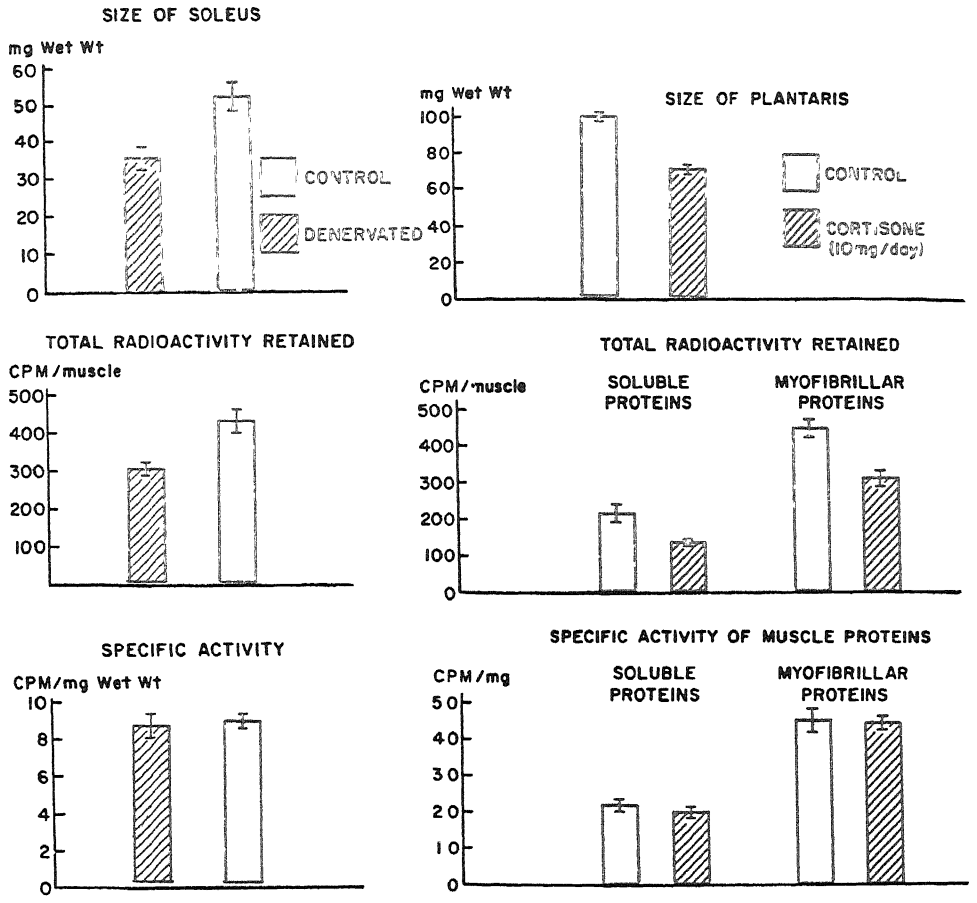

Fig 7 131 Effects of denervation and cortisone on labeled proteins in soleus and plantaris of hypophysectomized rats Animals were sacrificed 10 days after denervation Cortisone was administered for 7 days (From Goldberg 1969b)

of mRNA synthesis, along with the hormone completely blocks the effect of hydrocortisone but interfered with the insulin effect only after 2 hr of incubation These observations can be explained if hydrocortisone acts to increase enzyme levels by accelerating synthesis of mRNA within the nucleus while insulin facilitates reading of pre-existing mRNA An inhibitory effect of actinomycin in insulin-treated cells becomes apparent only when pre-existing mRNA has been degraded Half-life of tyrosine transaminase mRNA is estimated to be 2 to 3 hr In other experiments, effects of hydrocortisone and insulin were shown to be additive, strengthening the conclusion that these hormones act by different mechanisms

Cyclic-adenosine monophosphate (AMP) also functions as an inducer of tyrosine transaminase in liver cells (Wicks, 1969) This compound is proposed as the mediator of the effects of glucagon, epinephrine, and isoproterenol on tyrosine transaminase activity A comparison of the effectiveness of these inducers is presented in Table 7 20 Stimulation of enzyme synthesis by glucagon, isoproterenol, and dibutryl cyclic-AMP are inhibited by actinomycin D, suggesting that synthesis of new mRNA is involved in the effect Phosphorylation of nuclear histone by a histone kinase that is dependent upon cyclic-AMP may be involved in this induction (Langan, 1970) Activity of this kinase is increased fivefold by addition of cyclic-AMP resulting in phosphorylation of a specific serine residue in lysine-rich histone When glucagon was injected into rats, incorporation of radioactive phosphorus into liver histones was increased about 20-fold As a result of phosphorylation,

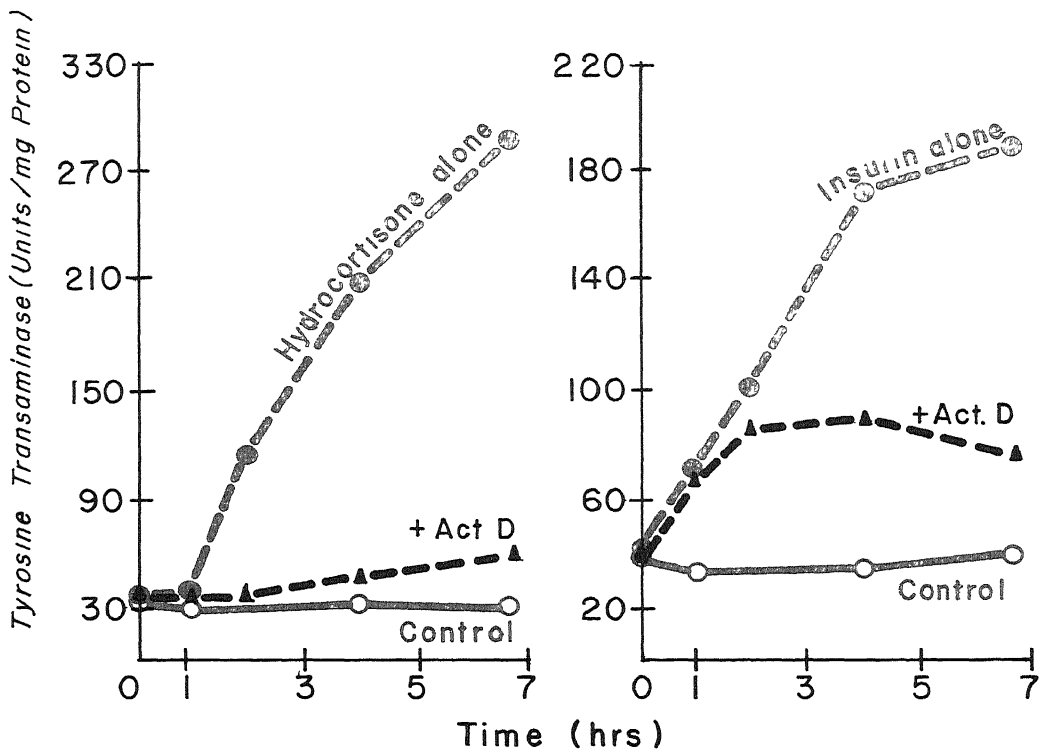

Fig 7 132 Induction of tyrosine αketoglutarate transaminase in cultured hepatoma cells by hydrocortisone and insulin Hydrocortisone concentration was 10^{-6}M and insulin concentration was 1 milliunit/ml Actinomycin D (0 2μg/ml) was added 30 min prior to addition of the hormone (From Lee et al 1970)

Table 7 20
Induction of tyrosine transaminase by hormones[a]

Additions	Final Concentration	Tyrosine Transaminase
	M	*units/mg protein*
None		7 5 ± 0 6
Hydrocortisone	1×10^{-6}	11 2 ± 0 7
Dibutyryl cyclic AMP	9×10^{-4}	18 4 ± 0 7
Glucagon	$1 1 \times 10^{-4}$	17 1 ± 1 0
Isoproterenol	$1 2 \times 10^{-4}$	15 6 ± 0 5
Insulin	$7 5 \times 10^{-5}$	9 5 ± 1 3

From Wicks, 1969

[a] An organ culture of fetal liver was used Additions were made after 42 hr in culture Two hours later the tissue was homogenized and tyrosine transaminase was assayed

histone may dissociate from specific regions of DNA, allowing for its transcription Effects of cyclic-AMP on mRNA synthesis in bacteria have also been observed (Varmus et al , 1970)

EFFECTS OF SUBSTRATE SUPPLY ON PROTEIN SYNTHESIS

A number of hormones including insulin, glucocorticoids, thyroxine, growth hormone, and estrogen increase entry of amino acids into various cells of the body Importance of these effects for the overall stimulation of protein synthesis depends upon the degree to which intracellular amino acid concentrations restrict protein synthesis in these cells In general, tissues, such as liver, that actively degrade amino acids to form glucose, fatty acids, and urea, are more dependent on a continued supply of amino acids from the plasma than are heart or skeletal muscle in which amino acid degradation is slow As seen in Figure 7 133, protein synthesis in liver varies from 60 to 200% of normal when amino acid concentrations in the perfusate range from 0 to 8 times normal plasma levels Tryptophan has been identified as an amino acid that is particularly important in maintaining normal rates of pro-

tein synthesis in this tissue (Munro, 1970) Low plasma levels of tryptophan result in low levels of tryptophan-tRNA, the activated form of the amino acid (Allen et al , 1969) On the other hand, synthesis of heart protein varies between 85 and 120% of the normal rate over this concentration range of plasma amino acids These findings indicate that a hormone-induced increase in amino acid entry into liver is of importance for the overall effect on protein synthesis, while this mechanism of action is of lesser importance for the overall effect in heart muscle

The effect of amino acid levels on protein synthesis is reflected in the aggregation of heart and liver ribosomes As shown in Figure 7 134, aggregation of liver ribosomes is restored to in vivo levels when livers are perfused with 5 times normal plasma levels of amino acids On the other hand, aggregation of heart ribosomes is only modestly responsive to variations in plasma amino acids Since these experiments are carried out in perfusion systems that lacked hormones, aggregation of liver ribosomes is more dependent upon the supply of amino acids than heart ribosomes Since incorporation of amino acids into protein increases as perfusate amino acid levels are raised, higher intracellular levels of amino acids accelerate initiation of peptide chains and results in increased numbers of polysomes and reduced levels of ribosomal subunits These findings indicate that increased amino acid supply can increase the rate of protein synthesis by raising intracellular levels of aminoacyl-tRNA and by accelerating initiation of peptide chains

REGULATION OF THE RIBOSOME CYCLE

Initiation, elongation, and termination of peptide chains make up the major groups of reactions involved in the cycling of ribosomal

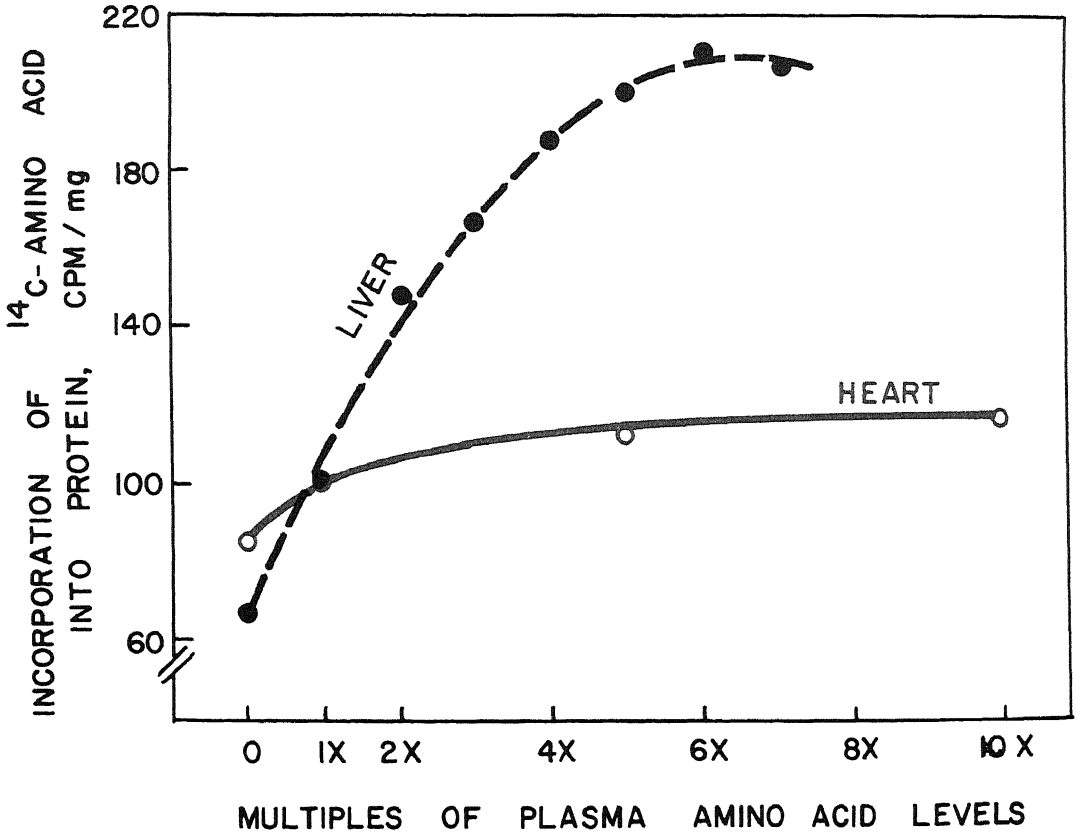

Fig 7 133 Effect or perfusate amino acid levels on incorporation of ^{14}C-amino acids into heart and liver protein Hearts and livers were perfused with buffer-containing multiples of normal plasma levels of amino acids Incorporation of ^{14}C-phenylalanine into heart protein and incorporation of ^{14}C-valine into liver protein were measured The zero point indicates that only the radioactive amino acid at normal plasma levels was added (From Jefferson and Morgan unpublished)

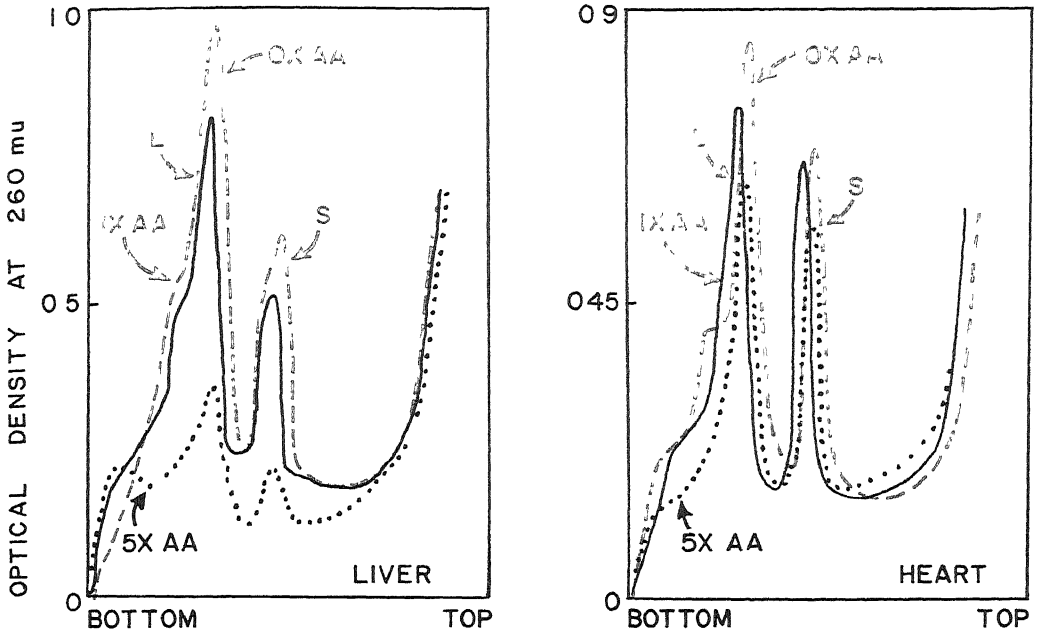

Fig 7 134 Effect of perfusate amino acid levels on aggregation of liver and heart ribosomes Hearts and livers were perfused with buffer-containing multiples of normal plasma levels of amino acids Aliquots of supernatants of homogenized liver and heart were layered on sucrose gradients and centrifuged Gradients were analyzed by pumping the contents of the tube through the flow cell of a recording spectrophotometer L indicates the large ribosomal subunit S the small subunit and 0 1 and 5 XAA the perfusate amino acid concentration in multiples of the normal plasma levels Aggregation of ribosomes in unperfused liver is similar to patterns of livers perfused with 5 times normal plasma levels of amino acids Aggregation of ribosomes in unperfused hearts is shown in Figure 7 135 (From Jefferson unpublished and Morgan et al 1971)

subunits into polysomes, down the length of messenger RNA, and back into the subunit pool If initiation of peptide chains is slow relative to elongation, ribosomal subunits accumulate and the rate of protein synthesis is slow On the other hand, inhibition of the elongation or termination groups of reactions results in decreased numbers of ribosomal subunits in association with a reduced rate of protein synthesis (Morgan et al , 1971) As indicated in Figure 7 134, a block in initiation of peptide chains develops in both heart and liver when these organs are perfused, in vitro, with normal plasma levels of amino acids In heart, this block persists even when high levels of amino acids are added.

Initiation of peptide chains in heart muscle is accelerated by addition of either insulin or fatty acids As shown in Figure 7 135, hearts that are perfused for 1 hr with buffer containing normal plasma levels of amino acids and glucose have fewer polysomes and more ribosomal subunits than unperfused hearts Addition of either insulin or fatty acid increases the number of polysomes and decreases subunits Faster rates of protein synthesis are also found These changes indicate that both of these factors accelerate initiation of peptide chains Since these effects are also demonstrable when 5 times normal plasma levels of amino acids are present, increased intracellular amino acid levels cannot account for the effect The mechanisms of the hormone and fatty acid effects on initiation are unknown, but may involve changes in intracellular levels of regulators of reactions involved in initiation The role of other hormones such as growth hormone, glucagon, and epinephrine in controlling steps in the ribosome cycle is not decided, but regulation at this level appears to be likely

Protein synthesis in skeletal muscle is controlled by insulin, growth hormone, glucocorticoids, and testosterone as well as the nutritional state of the animal As shown in Figure 7 136, aggregation of psoas muscle ribosomes is decreased when rats are fasted for 48 hr Perfusion of skeletal muscle with buffers containing

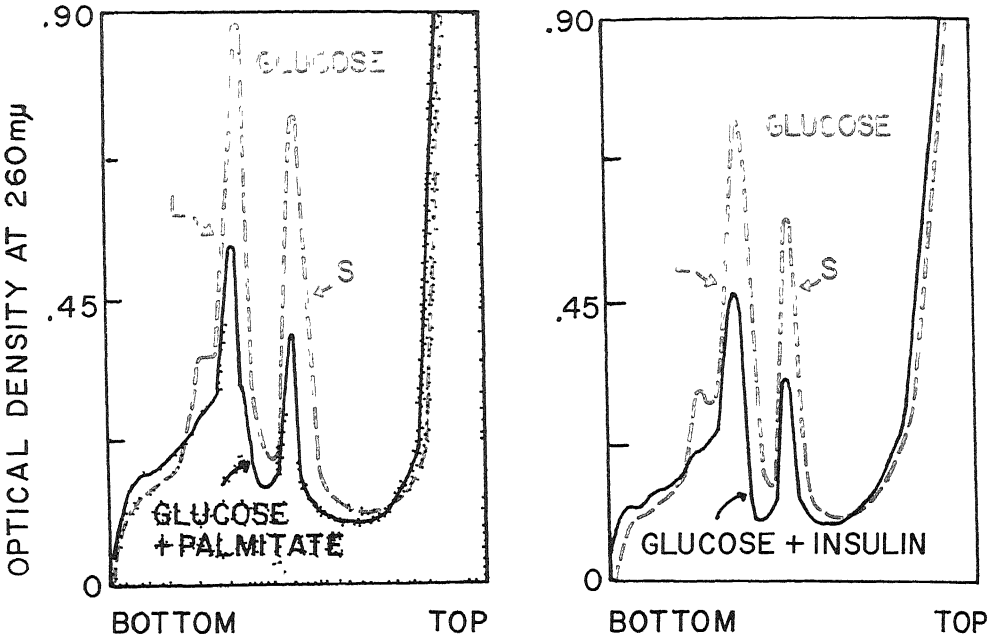

Fig 7 135 Effects of palmitate and insulin on aggregation of heart ribosomes Hearts were removed from rats fasted overight and perfused with buffer-containing glucose 3% serum albumin and normal plasma levels of all amino acids Insulin (25 mμ/ml) or palmitate (1 5m)) was added as indicated Aggregation of ribosomes was analyzed on sucrose density gradients as described in Figure 7 134 L indicates the large ribosome subunit S the small subunit and the shaded area the distribution of ribosomes in unperfused hearts Incorporation of ^{14}C-phenylalanine into heart protein was 94 c p m /mg when only glucose was present and 120 c p m /mg when either fatty acid or insulin was added (From Rannels et al 1970)

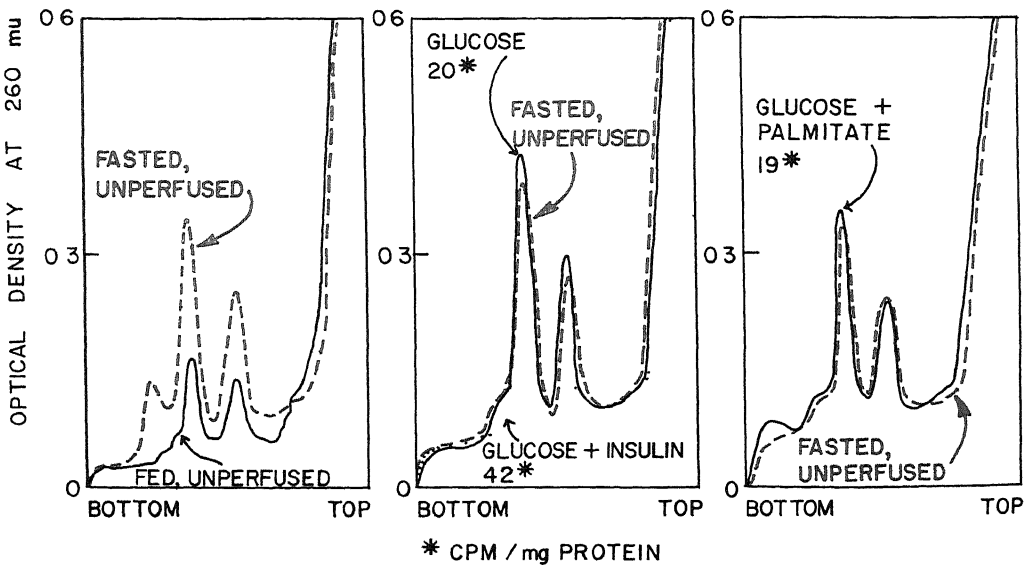

Fig 7 136 Effects of fasting, insulin and fatty acid on aggregation of psoas muscle ribosomes and on phenylalanine incorporation Psoas muscles were removed from fed or 48-hr fasted rats or from an isolated hemicorpus preparation following 90 min of perfusion with buffer-containing glucose glucose plus insulin or glucose plus palmitate Aggregation of ribosomes was analyzed on sucrose density gradients as described in Figure 7 134 The ^{14}C-phenylalanine incorporated into psoas muscle protein is shown for each of the muscles that were perfused (From Jefferson and Morgan unpublished)

insulin restores aggregation of ribosomes in muscle of starved animals, but fatty acids have no effect These changes are associated with increased rates of protein synthesis following insulin treatment, but no change in synthesis with fatty acid In comparison to heart muscle, control of the ribosome cycle in skeletal muscle by insulin is operative, but control by fatty acid is absent This situation provides for preservation of normal heart size during starvation and diabetes when insulin levels are low and fatty acid levels are high Utilization of skeletal muscle provides amino acids for glucose production through gluconeogenesis which is needed to support the metabolic needs of the brain

As indicated throughout this chapter, knowledge of hormonal control of growth and protein and nucleic acid metabolism is fragmentary Control of liver regeneration, cardiac hypertrophy, and atrophy and hypertrophy of skeletal muscle remains to be explained in terms of the control of protein synthesis and degradation Similarly, effects of hormones on the turnover of cell protein is only partially understood
